Percentage of arachis ...	100	60	50	40	30	20	10	5

For a more accurate determination of the arachis oil, the liquid is allowed to rest at 15° or 20° for three hours, the crystals are collected on a filter, washed three times with 10 c.c. of 90 per cent. alcohol, then with 70 per cent., and dissolved in boiling absolute spirit. The solvent is distilled off, the residue mixed with 100 c.c. of 90 per cent. alcohol, heated to 60° with a drop of very weak HCl, and crystallized once more. (This recrystallization is only necessary in the presence of cotton-oil, which also contains a solid fatty acid but slightly soluble in cold 90 per cent. spirit; nevertheless, as the process is not much trouble, it is safer always to employ it, in order to ensure the absolute purity of the arachis acids.) After three hours the crystals are filtered, washed three times with 10 c.c. of 90 per cent., then completely with 70 per cent. alcohol, dissolved in absolute alcohol, evaporated in a tared basin, dried at 100° C. for one hour, weighed, and their melting-point observed. As the solubility of the two acids is different, and depends on the temperature of the liquid, the amount given in the annexed table must be added to the actual weights; and then, on multiplying by $\frac{5}{0{\cdot}048}$, the percentage of earthnut-oil in the 20 grammes of olive-oil originally taken will be obtained :

Weight of Mixed Arachis Acids.	Ten perature of 90 per cent. Alcohol. 15°.	17·5°.	20°.
Between 2·70 and 0·50 gramme ...	0·070	0·080	0·090
,, 0·47 and 0·17 ,, ...	0·050	0·060	0·070
Less than 0·11 ,, ...	0·033	0·040	0·045

In the concluding portion of their article, the authors discuss the figures quoted by previous investigators (especially Renard) regarding the solubility of "arachidic acid" in 90 per cent. alcohol; they confirm Kreiling's statement that the crystals deposited from spirit of this strength really consist of two acids of the series $C_nH_{2n}O_2$ —true arachidic acid, $C_{20}H_{40}O_2$, and lignoceric acid, $C_{24}H_{48}O_2$; and they append a table giving the melting-points and solubilities of the mixed acids at various temperatures. As the result of a number of tests on arachis-oil coming from different localities, they find that the proportion of these acids always ranges between 4·30 and 5·40 (mean 4·80) per cent., and the melting-point of the mixture lies between 74° and 75° C. They also record the effect of their process when applied to olive-oil containing sesamé, rape, cotton, and maize oils, as well as the different proportions of arachis mentioned in the first table reproduced above, proving that the latter may be determined to within 2 per cent. of the amount actually present. F. H. L.

Estimation of Arachis in Oil-Mixtures. F. Jean. (*Rev. Chim. Ind.*, 1898, ix., 162; *Les Corps Gras*, 1898, xxiv., 353; through *Chem. Zeit. Rep.*, 1898, 179.)—Ten grammes of the sample are heated to 110° C. in an enamelled iron dish, 3 grammes of caustic potash dissolved in 3 or 4 c.c. of water and 5 c.c. of alcohol (36%) are added, and the mixture is stirred with a metal spatula till the soap is dry. After cooling, it is mixed in a flask with 100 c.c. of alcohol which has previously been saturated at 11° or 12° C. with the potassium salt of arachidic acid. The mass is heated under an inverted condenser, then cooled and set aside at 15° for twelve hours. The insoluble matter is filtered off, dried by pressure in paper, placed in the flask again, and once more treated with saturated alcohol of 36% exactly as before. When it has stood for another twelve hours, the potassium arachidate is filtered, pressed in paper till dry, and decomposed with 50 c.c. of boiling weak hydrochloric acid. The liberated arachidic acid is dissolved in about 10 c.c. of petroleum spirit, washed with warm water, evaporated at 100°, and weighed. Edible arachis-oil contains as an average 4·55 per cent. of arachidic acid, and its melting-point should be at least 72° C.

(See also preceding abstract.) F. H. L.

A Method of analysing Oxidized Oils. W. Fahrion. (*Zeit. angew. Chem.*, 1898, 781-785.)—From 2 to 3 grammes of the oxidized oil are saponified with 10 c.c. of 8 per cent. alcoholic potash on a boiling water-bath. The alcohol is evaporated, the soap dissolved in hot water, and the solution decomposed with hydrochloric acid in a separatory funnel, shaken with 25 c.c. of petroleum spirit, and allowed to stand overnight. As the non-volatile acids are all contained in the petroleum layer, it is unnecessary to shake out again the aqueous layer with petroleum spirit. After running off the lower liquid the petroleum layer is withdrawn, leaving the oxy-fatty acids in the funnel. If their quantity is considerable, they may enclose unoxidized fatty acids, and it is therefore advisable to dissolve them in a dilute solution of soda or ammonia, and repeat the treatment with petroleum spirit after acidifying with hydrochloric acid.

The united petroleum spirit extracts are evaporated, and the residue, consisting of the unoxidized fatty acids and unsaponifiable matter, dried to constant weight (1). It is then dissolved in 25 c.c. of 90 per cent. alcohol, and titrated with seminormal alkali, the milligrammes of KOH being calculated on the original oil. The number thus obtained, which the author terms the "inner saponification value," furnishes a measure of the non-volatile and unoxidized fatty acids.

The neutral alcoholic solution is extracted with petroleum spirit, the extracts washed with alcohol, the petroleum spirit evaporated, and the residue of unsaponifiable matter dried and weighed (2).

The difference between (1) and (2) gives the quantity of non-volatile fatty acids, whose molecular weight can be calculated from the inner saponification value.

The oxy-fatty acids left in the separatory funnel are dissolved in hot alcohol, the solvent evaporated, the residue dried to constant weight, ignited, the ash deducted, and the difference taken as the oxy-fatty acids (3).

The sum of 1+3 gives the Hehner value.

The following results were thus obtained with cottonseed-oil and three oxidation products, which were prepared by exposing the oil on wash-leather for eight and twelve days respectively. The leather was cut into fragments, and extracted with cold petroleum spirit, furnishing products A and B. The second leather still contained a considerable amount of products insoluble in petroleum spirit, which were subsequently extracted from it with cold ether (B_1). This was a thick yellow oil, soluble in alcohol.

	Cottonseed.	A.	B.	B_1.
Iodine value	108·8	55·4	46·3	29·1
Acid value	2·2	13·3	13·8	33·4
Saponification value	190·4	223·1	227·5	271·3
Inner saponification value ...	186·9	128·8	128·9	74·4
Hehner value	94·22	85·34	83·62	74·20
Unsaponifiable matter, per cent.	1.10	1·11	1·28	0·72
Oxy-fatty acids, per cent. ...	0·27	20·70	19·43	37·72
Non-volatile fatty, acids per cent.	92·85	62·53	62·91	35·76
Molecular weight of fatty acids	278·1	276·2	273·2	269·1
Melting-point of fatty acids ...	35-36°	45-46°	46°	51°

With regard to these results, the author points out that the fact that volatile acids are produced during the oxidation process is shown by the decrease in the Hehner and inner saponification values. The increase in the amount of unsaponifiable matter in B is only apparent since B and B_1 are both fractions of the same oxidation products, and the greater proportion of unsaponifiable matter was removed by the preliminary treatment with petroleum spirit which gave B.

The general conclusion arrived at on this point is that during the oxidation of fats and oils the unsaponifiable matter remains intact, and new substances are not formed from it.

Unlike the oxy-fatty acids of liver-oils (*Zeit. angew. Chem.*, 1891, 643), those of cottonseed-oil are completely soluble in ether.

The foregoing method of analysis affords a means of examining the course of oxidation during the drying of linseed-oil, and is also applicable to the examination of unoxidized fats and oils, as is seen in the following examples:

	Ox-tallow.	Olive-oil.	Butter-fat.
Saponification value ...	193·9	188·4	225·9
Inner saponification value ...	193·8	188·1	185·2
Hehner value	95·58	95·25	87·60
Unsaponifiable matter ...	0·11	0·98	0·24
Oxy-fatty acids	0·13	0·18	0·14
Non-volatile fatty acids ...	95·34	94·07	87·22
Molecular weight of fatty acids	275·0	280·1	263·7

From these results, it is manifest that when, as in the case of tallow and olive-oil, the total saponification and inner saponification values are nearly identical, the amount of volatile or of oxy-fatty acids must be insignificant.

Butter-fat, on the other hand, by reason of its volatile acids, shows a considerable difference (40·7) between the two values, and the Reichert-Meissl value (36·3 for

5 grammes) can be calculated from this difference. This calculated value is higher than the normal, owing to the fact that the Reichert value only represents a portion of the total volatile acids.

In the case of wool-fat, a modification of this method is said to have given very satisfactory results, with regard to which the author promises a future communication.

C. A. M.

INORGANIC ANALYSIS.

The Accuracy of Gold Assay. J. Loevy. (*Chem. Zeit.*, 1898, xxii., 609.)—It was recently stated before the Chemical and Metallurgical Society of South Africa that the fusion and cupellation method of determining gold is only accurate provided the whole of the metal exists in the sample in the free state; but that if some of the gold is present as a soluble salt, the results are 30 or 40 per cent. too low. To investigate this point, infusorial earth was moistened with about 0·2 per cent. of gold chloride or the double chloride of gold and sodium, dried at 110° C., mixed with the flux (sodium carbonate, litharge, borax, and Rochelle salt), and submitted to the combined fusion and cupellation process in the usual manner. Employing about 0·1 gramme of gold, the figures varied from 95·8 to 98·3 per cent. of the theoretical yield; and the author considers the deficit to be due simply to the fineness of the kieselguhr, which caused loss of gold by formation of dust. He believes that the process always gives 98 per cent., more frequently 99 or 100 per cent. of the gold actually present; and as the test can be carried out on 300 or 500 grammes of material, it cannot be advantageously replaced by wet analysis.

F. H. L.

Detection and Estimation of Calcium Hydroxide in Set Portland Cement. N. N. Ljamin. (*Zap. Imp. Russk. Techn. Obschtsch.*, 1898, xxxii., 75; through *Chem. Zeit. Rep.*, 1898, 178.)—In thin sections of set Portland cement examined by transmitted light, glittering crystals are often to be seen, which appear dark under the polariscope with crossed Nicols, and which, dissolving in hydrochloric acid without effervescence, and also in 10 per cent. sugar solution, must be either calcium hydroxide or a strongly basic silicate. The author has succeeded in isolating some of this material from cement seven years old; it formed hexagonal and rhombic crystals, and agreed goniometrically with crystals of slaked lime. On analysis it gave H_2O, 25·4 per cent.; CaO, 73·4 per cent.; insoluble in HCl, 0·5 per cent.; its specific gravity was 2·18 to 2·20, or a little higher than the normal (2·07 to 2·08).

To estimate the calcium hydrate, the set cement is ground until its particles are smaller than these crystals. It is then passed through a sieve into a Hauenschild's apparatus, and treated with a mixture of benzene and methylene iodide having the specific gravity 3·34; the vessel being placed under the receiver of an air-pump to remove air-bubbles, which would prevent the heavier portions from sinking. The calcium hydrate that rises to the surface is collected on a filter, further quantities of the same liquid mixture are added to the residual cement till all the floating matter is recovered; and finally the lime is washed with benzene and ether, dried

at 120° C., brushed off the paper into a tared watch-glass, and weighed. As the product may be contaminated with fragments of coke, etc., it can be treated again in the Hauenschild apparatus with a mixture of benzene and methylene iodide having a specific gravity lying between 1·0 and 2·0; but the amount of carbon rarely exceeds 1 per cent. of the total mass. The lime usually contains a little more (25 or 26 per cent.) volatile matter than corresponds to the formula CaH_2O_2; and about 1·5 per cent. of alumina is present, but no silica; in fact, the foreign ingredients only cause the yield of calcium hydrate to be roughly 0·5 per cent. too high.

Another method of arriving at the same result depends on the fact that calcium hydroxide only loses its water of constitution at 450° or 480° C., whereas the other substances in set Portland cement part with their water of hydration at 160°. One sample is heated for two or three hours at 180° or 200°; in another the carbon dioxide is determined; and in a third the total volatile matter. Deducting the CO_2 and the loss on heating to 200° from the latter, the amount of water in the calcium hydroxide is left; and by employing the coefficient $\frac{CaH_2O_2}{H_2O} = 4{\cdot}1$, the proportion of free lime is given. The two processes yield closely concordant figures. F. H. L.

The Determination of Potash without the previous removal of Iron, Calcium, etc. C. C. Moore. (*Jour. Amer. Chem. Soc.*, 1898, xx., 340-343.)—This is based on the fact that it is possible to dissolve ferric, aluminic, and other chlorides in acidulated alcohol after previous conversion of the potassium into the ordinary compound with platinic chloride.

The substance is dissolved by the usual digestion with acid, the excess of the latter removed, and the residue and insoluble matter filtered off. Platinic chloride solution is added to the filtrate, which is then evaporated nearly to dryness on the water-bath as in the usual determination. From 15 to 20 c.c. of the acidulated alcohol are added, and the whole allowed to stand for two or three minutes with occasional stirring. The crystalline platinum potassium salt, and part of the neutral sulphates, sodium chloride, etc., remain undissolved, while the excess of platinic chloride, and the chlorides of iron, aluminium, etc., pass into solution. The insoluble residue is washed, first, with the acidulated alcohol, and then with the Lindo ammonium chloride solution, until the sulphates, sodium chloride, etc., are washed out. The ammonium chloride is then removed by washing with 85 per cent. alcohol, and the pure potassium chlorplatinate salt left on the filter is dried and weighed as usual.

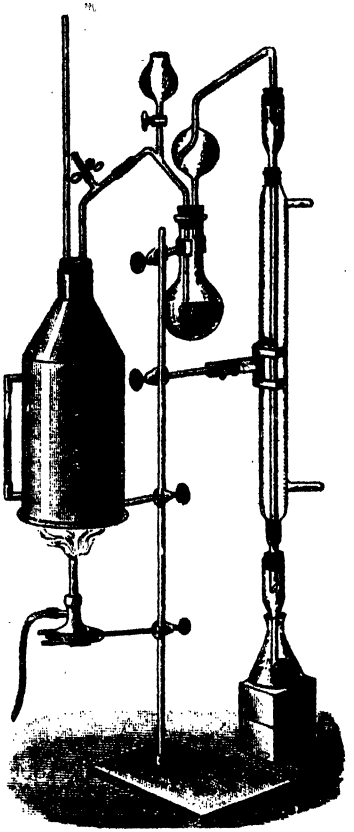
The acidulated alcohol is prepared by passing dry hydrochloric acid gas into cool 90 per cent. alcohol until 1 c.c. of the latter neutralizes about 2½ c.c. of normal potash. Some ethyl chloride is formed, but most of the gas remains in solution in an uncombined state. The solubility of potassium platinic chloride in this liquid is about 1 in 60,000 at 80° C. The results obtained by this method in experiments on the ash sample used by the Association of Official Agricultural Chemists in 1897 varied on the average 0·01 per cent. from the result found by the association.

C. A. M.

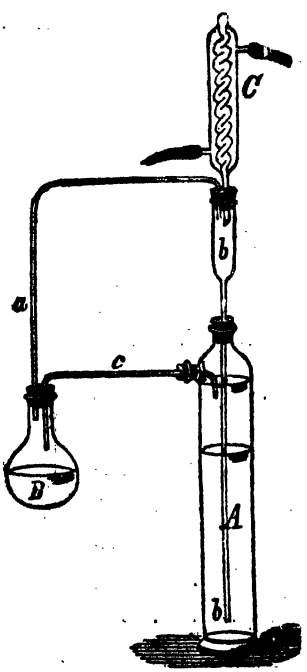
Colorimetric Estimation of the Density of Chimney Smoke. P. Fritzsche. (*Zeit. anal. Chem.*, 1898, xxxvii., 92-94.)—A small glass filter tube similar to those used in gravimetric determinations of sugar is loosely packed with 2 grammes of cellulose, and is connected by means of indiarubber tubing with another glass tube sufficiently long to project a little way into the interior of the chimney when introduced through a hole in the wall. By means of an aspirator attached to the other end of the filter-tube, from 10 to 20 litres of the gases are drawn through the cellulose. The tube is then wiped out with a clean portion of the cellulose, and the whole of the latter shaken in a stoppered flask with 200 c.c. of water, until it becomes a uniformly coloured grey pulp. This is transferred to a round-bottomed test-tube (40 to 50 mm. in diameter), and the amount of soot estimated by comparing the colour with those of a standard colour scale.

This colour scale is prepared by shaking 2 grammes of cellulose mixed with different proportions of soot (from 5 to 30 milligrammes) in 200 c.c. of water, and comparing the colour of the pulp in the manner described above with that of discs tinted to various shades with Indian ink. Once standardized, the discs are pasted on to cardboard, and a note made of the amount of soot to which they correspond.

C. A. M.



APPARATUS.



Pipette with Automatic Adjustment. H. Bremer. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 318.)—The pipette consists of two parts—the measuring tube, or pipette proper, and the stopcock attachment. The measuring tube has the usual two tubulures, which are of equal dimensions, and terminate in very small orifices; it is so constructed that it shall hold exactly the required quantity of fluid when quite full from end to end; by means of a caoutchouc stopper it is attached to the other part of the apparatus, as shown in the figure. To fill the pipette, the point is dipped into the fluid, the stopcock opened, and the fluid sucked up until it overflows at the upper orifice of the measuring tube, when the stopcock is shut off. The liquid will, of course, continue to overflow until equilibrium is re-established between the inner and the outer pressure. The pipette is discharged by turning on the stopcock. Fluids can be measured much more exactly by this pipette than by the ordinary form, since the measurement is quite independent of errors of reading off. The pipette can be made of any size or to suit any specific purpose. For measuring corrosive liquids, it is recommended that the apparatus be blown in one piece.

H. H. B. S.

New Apparatus for the Determination of Nitrogen by Kjeldahl's Method. H. Bremer. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 316.)—In this apparatus, the same flask is used for the digestion in hot sulphuric acid as for the distillation, thus obviating the necessity of transferring from one vessel to another. The flask is of about 250 c.c. capacity, and has a long neck 35 mm. wide. The digestion in this flask is said to occupy scarcely any longer time than in the flask usually employed for the purpose. As soon as the digestion is completed, the flask is cooled and 100 c.c. of water added cautiously, a little at a time, to prevent boiling. The flask is then again cooled and attached to the rest of the apparatus as shown in the figure. The soda solution is introduced through the funnel and the distillation carried out by means of a current of steam. The apparatus can also be used for the determination of ammonia by distillation with magnesia or barium carbonate. H. H. B. S.

Apparatus for the Extraction of Liquids with Immiscible Solvents. O. Foerster. (*Chem. Zeit.*, 1898, xxi., 421.)—This apparatus, which is sufficiently explained by the accomapnying diagram, is primarily intended for the extraction of unsaponified matter from soap solutions, and it is capable of recovering 99·97 per cent. of a neutral substance (cholesterin) present in a stearin soap within a period of four hours. A small quantity of aqueous liquid gradually collects in B, which must be removed at intervals, while the ethereal solution finally requires four or five washings with water. The syphon *c* should not extend into the liquid in B.

APPOINTMENT.

Mr. W. Lincolne Sutton has been appointed Public Analyst for East and West Suffolk, Ipswich, and Bury St. Edmunds, in succession to the late Mr. James Napier.

THE ANALYST.

NOVEMBER, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

NOTE ON THE EXAMINATION OF LINIMENT OF CAMPHOR.

By Norman Leonard, B.Sc., F.I.C., and H. Metcalfe Smith, F.I.C.

Liniment of Camphor has long been commonly known as "Camphorated Oil," but this synonym has only been made official in the *British Pharmacopœia* of 1898. The latter, as also the editions of 1867 and 1885, directs 1 ounce of camphor to be dissolved in 4 fluid ounces of olive oil, but no characters or tests for the finished preparation are given. Taking the specific gravity of olive oil as 0·9165, this being the mean of the limits (0·914—0·919) allowed for this oil by the *Pharmacopœia*, it is easy to calculate that the liniment should contain 21·45 per cent. by weight of camphor. We have recently met with several specimens which were deficient in camphor, one sample containing only 3 per cent. of this substance, and in two cases a mineral oil was found to have been substituted for olive oil.

The amount of camphor present is most simply and accurately found by determining the loss in weight experienced by the sample on heating. For this purpose 3 to 5 grammes of the camphorated oil are heated for two hours at 120° C. in a flat-bottomed dish or flask. Olive oil under the same conditions suffers a *gain* in weight of 0·15 per cent., and hence this figure should be *added* to the loss in weight on heating the sample, in order to obtain the true amount of camphor present. The results obtained by this method are very satisfactory, as will be seen from the following table, in which are given analyses of four solutions prepared by dissolving known weights of camphor in olive oil of 0·9164 specific gravity:—

	Camphor taken, Grammes.	Olive Oil taken, Grammes.	Camphor calculated, per Cent.	Loss on Heating, per Cent.	Corrected Loss = Camphor, per Cent.	Specific Gravity at 60° F. (H_2O at 60° = 1).
1 ...	2·361	75·918	3·01	2·93	3·08	0·9178
2 ...	5·346	70·578	7·04	6·78	6·93	0·9195
3 ...	14·530	69·912	17·21	17·10	17·25	0·9241
4 ...	15·856	54·146	22·65	22·38	22·53	0·9266

An approximation to the amount of camphor may be made by determining the specific gravity of the sample, each per cent. of camphor, as may be seen from the results given above, raising the specific gravity by about 0·00045. The following formula may be used, it being remembered that the results obtained will be of little

value if oil having a specific gravity much differing from 0·9165 has been used in the preparation of the sample :—

$$\text{Camphor per cent.} = \frac{\text{specific gravity of sample} - 0{\cdot}9165}{0{\cdot}00045}.$$

Below are given the figures obtained from four specimens of "Liniment of Camphor," No. 1 being prepared by ourselves, and the remaining three procured from chemists and druggists. As already observed, the directions given by the *Pharmacopœia* correspond to the presence of 21·45 per cent. of camphor :

	Specific Gravity at 60°.	Camphor from Loss on Heating (corrected).	Camphor calculated from Specific Gravity.
1 ...	0·9264	21·35	22·2
2 ...	0·9255	20·65	20·0
3 ...	0·9257	20·46	20·4
4 ...	0·9264	20·37	22·2

As regards the presence of mineral oil, this is usually indicated by the marked bluish fluorescence of the sample. It may be further identified, and separated from any vegetable oil which may also be present, by heating for some time with alcoholic potash, the liquid being afterwards diluted with water and filtered. The mineral oil remaining on the filter is washed with water, dried, and transferred to a weighed flask by means of a little ether, which is subsequently removed by evaporation.

We are indebted to Dr. Thomas Stevenson for permission to make use of results obtained in his laboratory.

THE RELATION BETWEEN THE SPECIFIC GRAVITY AND THE INSOLUBLE FATTY ACIDS OF BUTTER AND OTHER FATS.

By Norman Leonard, B.Sc., F.I.C.

The existence of a general correspondence between the specific gravity and the percentage of insoluble fatty acids yielded by butter and margarine is well known, a low specific gravity being, as a rule, associated with a high percentage of insoluble fatty acids, and *vice versâ*. Occasionally, abnormal results are obtained, more especially the conjunction of a high percentage of fatty acids with a comparatively high gravity. It is obvious that no natural or necessary connection exists between the two analytical data, since the fats used to adulterate butter vary in character, and the rough correspondence actually observed is due to the fact that the usual adulterants (beef and mutton fat, etc.) have approximately equal densities and yield the same proportion of insoluble fatty acids. The presence of a vegetable oil, such as cotton-seed, cocoanut, or sesamé oil, having a higher density than animal fats, but yielding nearly the same proportion of fatty acids, would be indicated by a departure from the usual relation. The investigation of the latter may, therefore, be of some value to the analyst.

Four years ago I found, on examination of the analyses of thirty-three samples of butter, that the results might be very well represented by the formula $y = k(1 - x)$, where y is the percentage of insoluble fatty acids, x the specific gravity at 100° F.

(water at 60° F. = 1), and k a constant, the mean value of which was found to be 951±1·6. I have recently examined the results obtained from thirty samples analysed during the year 1897, and found k to have the mean value 951±1·8. This close agreement with the previous result is interesting as showing the constancy of the general character of the adulterants employed. The following table is calculated from the formula $y = 951(1 - x)$:

Specific Gravity at 100° F. (H_2O at 60° F. = 1).	Insoluble Fatty Acids.	Specific Gravity at 100° F. (H_2O at 60° F. = 1).	Insoluble Fatty Acids.
·8990	96·1	·9040	91·3
·8995	95·6	·9045	90·8
·9000	95·1	·9050	90·3
·9005	94·6	·9055	89·9
·9010	94·1	·9060	89·4
·9015	93·7	·9065	88·9
·9020	93·2	·9070	88·4
·9025	92·7	·9075	88·0
·9030	92·2	·9080	87·5
·9035	91·8	·9085	87·0

Of the sixty-three samples examined, the percentage of insoluble fatty acids found by experiment differed from that calculated from the formula,

By not more than 0·5 per cent. in thirty-five cases, or 56 per cent.

By not more than 1·0 per cent. in fifty-four cases, or 86 per cent.

There were only three cases in which a difference of more than 1·4 per cent. was observed, and in each of these the insoluble fatty acids were abnormally high.

The results discussed above were obtained in the laboratory of Dr. Thomas Stevenson, to whom I am indebted for permission to make use of them.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Detection of Cotton-Seed Oil in Lard by Means of Phytosterin. A. Bömer. (*Zeit. der Untersuch. der Nahr. und Genussmittel*, 1898, 544.)—In two previous papers (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 21, *Analyst*, xxiii., 42; *Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 81, *Analyst*, xxiii., 132) the author published a method for the extraction of phytosterin and cholesterin, and showed that the phytosterin of vegetable fats, particularly that of cotton-seed oil, possesses sufficient characteristic differences from the cholesterin of animal fats to enable small quantities of the former to be detected in the presence of the latter. He now applies this principle to the detection of cotton-seed oil in lard.

The proof of the presence of phytosterin in cholesterin rests upon the melting-point and the crystalline structure of each body. The crystalline structure is, however, of itself sufficient evidence, should the quantity of phytosterin be too small to decidedly affect the melting-point of the mixture. The crystals of such mixtures

consist of short, apparently rounded needles, in part attached to one another in telescope fashion. Experiments made by slow crystallization upon larger quantities, however, yielded crystals in the form of three-sided prisms with flat ends. The results of the author's study of the melting-points of the two bodies have already been published (*cf. Analyst*, xxiii., 132). He now gives the results of a large number of observations of the melting-points and crystalline form of various mixtures of lard and cotton-seed-oil, which show that admixtures of 3 to 4 per cent., and, under favourable conditions, even 1 to 2 per cent., of cotton-seed oil in lard can be detected in this way.

The author claims that this mode of detection is easier and quicker of execution than the determination of the iodine number of the liquid fatty acids.

H. H. B. S.

Estimation of Glycogen in Meat Extracts. Lebbin. (*Pharm. Zeit.*, 1898, xliii., 519; through *Chem. Zeit. Rep.*, 1898, 214.)—Twenty-five grammes of the sample are dissolved in 100 c.c. of water, mixed with 100 or 150 c.c. of a 4 per cent. solution of caustic potash in 90 per cent. alcohol, and allowed to rest for one or two hours. The precipitate is filtered off, washed with 90 per cent. spirit, dissolved off the paper with 50 c.c. of water, and the solution faintly acidified with weak hydrochloric acid. It is next precipitated with about 10 c.c. of a solution of potassium mercuric iodide, filtered after half an hour, and the insoluble matter washed with hot water. From the filtrate the glycogen is thrown down on the addition of an equal volume of 95 per cent. alcohol, collected on a tared filter, washed with alcohol and ether, dried and weighed. The double mercuric iodide is prepared by dissolving 20 grammes of mercuric chloride in 300 c.c. of water, mixing with 20 grammes of potassium iodide also dissolved in 100 c.c., and adding more mercuric chloride as long as the precipitate continues to disappear.

F. H. L.

ORGANIC ANALYSIS.

The Characteristics of Olive-Kernel Oil. O. Klein. (*Zeit. angew. Chem.*, 1898, 847-850.)—According to Benedikt and other authorities, this oil differs from olive oil in having a sharp and bitter taste and a dark green colour, and in being readily soluble in glacial acetic acid and alcohol on account of the large percentage of free acids which it contains.

The author finds that this curious difference between the oils extracted from different parts of the same fruit is largely to be attributed to the manner in which the oil is obtained. After crushing the fruit so as to leave the stones intact, the mass is subjected to more or less complete expression in bags of esparto grass. The residual mass (*bagasses*) is left aside for a considerable time, often weeks, and is subsequently ground again and expressed or extracted. Under these circumstances, it is not surprising that considerable oxidation takes place in the moist mass, and that the oil frequently contains as much as 50 to 60 per cent. of free fatty acid, and is of a dark colour from the oxidation of the chlorophyll of the fruit.

A specimen of "kernel" oil thus obtained gave the following results on analysis:

Specific gravity, 0·9277; iodine value, 71·57; saponification value, 190·5; free fatty acid, 71·12 per cent.

The author prepared specimens of the pure kernel oil by hot and cold expression, and obtained the following analytical results with them: Specific gravity, 0·9186 to 0·9191; iodine value, 86·99 to 87·78; saponification value, 182·3 to 183·8; free acids, 1·00 to 1·78; refractive index, 1·4682 to 1·4688.

From these results it appears that the specific gravity and iodine value of pure olive-kernel oil are somewhat higher than is usually the case with olive oil. Only in exceptional instances and with oil obtained from such varieties as Seville, Cordova, and Manzanilla olives, is so high an iodine value given by olive oil. The saponification value is rather lower and the percentage of free acid higher than in olive oil. The percentage of free acids in the oil obtained from sound fresh fruit varied from 0·4 to 0·8 per cent., and the author attributed the difference to oxidation during the time which elapsed between the removal of the endocarp and expression of the oil.

In order to determine whether the presence of kernel oil in olive oil caused any depreciation in the latter, experimental mixtures were prepared in 1891 and 1892, and preserved in well-stoppered bottles in the dark until 1898. The samples showed scarcely any change in colour, taste, or smell, and the amount of free acids had only increased by about 0·2 per cent.

The author examined a specimen of olive-kernel oil by Hazura's method, and found it to contain 9·7 per cent. of solid fatty acids (consisting of 40 per cent. of stearic acid and 60 per cent. of palmitic acid). The liquid fatty acids were found to consist of oleic and linolic acids. Arachidic acid was not detected in the solid fatty acids.

The general conclusions arrived at from the research were:

1. The characteristics hitherto assigned to olive-kernel oil are really those of *bagasses* oil.

2. The physical and chemical characters of pure olive-kernel oil are very similar to those of olive oil.

3. Olive-kernel oil is as stable as olive oil, if proper precautions are taken.

4. It can be mixed with olive oil without ill effects, and there is no reason why the stone and the fruit should not be crushed and pressed together. C. A. M.

Separation of Unsaturated from Saturated Fatty Acids. K. Farnsteiner. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 390.)—The author's method is founded upon the fact that warm benzene dissolves the lead salts of the solid as well as the liquid fatty acids, but that on cooling, the salts of the solid fatty acids crystallize out almost completely, leaving the salts of the liquid fatty acids in solution. 0·6 to 1 gramme of fat is saponified with alcoholic alkali in an Erlenmeyer flask, the solution neutralized with acetic acid, using phenolphthalein as indicator, the alcohol almost completely expelled by evaporation, the soap dissolved in about 100 c.c. of boiling water, and precipitated with about 30 c.c. of a boiling solution of lead acetate containing about 1 gramme of the salt. By agitating the flask in cold water in the usual way, most of the lead salts are separated from the fluid in a compact mass.

After complete cooling, the filtrate is removed by decantation through a moistened filter, leaving the bulk of the lead salts in the flask. This, as well as the small quantity on the filter, is then washed with cold water, after which that upon the filter is washed back into the flask. The flask is now placed upon a bath of boiling water, when in a short time the lead salts will be found to melt together into a compact mass. By agitating the flask as it cools, any remaining crystals of the lead salts can be made to adhere to the sides of the flask, and the liquid can then be poured off clear. The salts are now as far as possible dried by means of a roll of filter-paper, and are then dissolved in 50 c.c. of moderately warm benzene. The solution is allowed to stand for about fifteen minutes at the temperature of the laboratory, in order to obtain a coarse crystalline separation, and is then kept for two hours at 8° to 12° C.

The filtration is conducted in the following manner: The flask is closed by a tight-fitting cork, through which two glass tubes pass, one a straight piece about 10 cm. long, reaching about 1 cm. into the flask, and the other bent in the form of a syphon. Into the open end of the bent tube inside the flask is fixed a moderately thick wad of cotton-wool, free from fat, extending a few millimetres outside the orifice. The short vertical tube is connected with a caoutchouc ball. By compressing the air within the flask by means of the ball, the liquid is forced through the plug of cotton-wool up the bent tube, and can be collected in a flask placed to receive it. When the liquid has been thus removed, the cork is lifted, and about 10 c.c. of benzene, at a temperature of about 10° C., is run into the flask. This is agitated with the precipitate, and then removed by compressing the caoutchouc ball as before. Twenty-five c.c. of benzene are then added, the bent tube lifted out of the liquid, the benzene heated to boiling to dissolve the precipitate, then cooled for one hour at 8° to 12° C., and removed by filtration through the plug as before. This operation is repeated yet again with 25 c.c. of benzene, altogether from 120 to 130 c.c. of benzene filtrate and washings being obtained.

For the separation of the liquid fatty acids, the filtrates are shaken in the usual way with an equal volume of 10 per cent. hydrochloric acid, until the salts are completely decomposed, and after two washes with water, the solution of the fatty acids is filtered through wadding and distilled in a current of hydrogen.

For the separation of the solid fatty acids, 25 to 30 c.c. of benzene are added to the lead salts in the flask, the bent tube lifted above the level of the fluid, and the benzene heated for a short time to the boiling-point. The flask is then removed from the water-bath, and the pressure-tube closed with the finger, causing air to enter through the cotton-wool plug owing to the condensation of the benzene vapour. Most of the liquid in the tube and plug is thus sucked back into the flask. The plug is then withdrawn and thoroughly extracted by boiling in a test-tube several times with a few c.c. of benzene. Finally, the lead-salts are decomposed by heating the benzene solution for fifteen minutes with a 10 per cent. hydrochloric acid solution, and the same treatment pursued as in the case of the liquid fatty acids, except that the use of hydrogen in the distillation of the benzene is omitted.

In the case of the separation of free fatty acids, the author converts them into the lead salts by means of hydrated lead oxide, prepared by precipitating lead acetate

with sodium hydrate, washing with water, alcohol and ether, drying at a gentle heat, and reducing to a fine powder. For 1 part by weight of the solid fatty acids, about 0·4 part of the hydrated lead oxide are required, and for 1 part of the liquid fatty acids about 0·2 part. An excess of the hydrated lead oxide is without influence upon the results.

The following results show the degree of accuracy obtainable :

No.	Quantity in Grammes taken for the Analysis.	C.c. of Benzene used.	Number of Precipitations.	Liquid Acids.		Solid Acids.		Remarks.
				Taken, per cent.	Found, per cent.	Taken, per cent.	Found, per cent.	
1.	0·7260	120	4	19·1	17·45	80·9	82·4	Old oleic acid.
2.	0·6646	120	4	21·35	22·4	78·65	77·5	Ditto.
3.	0·9155	100	4	33·75	30·8	66·25	67·9	Ditto, first filtrate allowed to stand overnight.
4.	0·9104	150	3	44·0	42·5	56·0	—	Ditto.
5.	0·6456	100	3	47·1	45·05	52·9	54·7	Liquid acid from olive oil.
6.	0·6190	90	3	51·2	48·8	48·8	48·7	Ditto, first filtrate allowed to stand overnight.
	0·4960	100	3	56·8	55·8	43·2	43·3	Old oleic acid.
	0·6333	125	3	59·5	—	40·5	39·4	Liquid acid from cotton oil.
9.	0·5799	110	3	60·6	61·0	39·4	39·4	Freshly prepared, almost pure oleic acid.
10.	0·7834	90	2	91·0	89·4	9·0	10·8	

The author then developes the following argument, that the percentage of unsaturated fatty acids in a mixture of fatty acids or in a fat can also be ascertained by calculation from the iodine number of the mixture and the iodine number of the liquid portion of the fatty acids, without it being necessary, as stated by Twitchell (ANALYST, 1895, 165) to determine approximately the quantity of the latter.

Let J be the iodine number of the substance, and J_1 the iodine number of the liquid portion of the fatty acids.

Then, since J_1 parts by weight of iodine correspond to 100 parts by weight of the liquid fatty acids, it follows that 1 part by weight of iodine corresponds to $\frac{100}{J_1}$ parts by weight of the liquid fatty acids. The quantity of iodine (J) absorbed by 100 parts by weight of substance consequently corresponds to $\frac{100J}{J_1}$ parts by weight of the liquid fatty acids. The formula $\frac{100J}{J_1}$ therefore gives the percentage of liquid fatty acids in the substance.

The iodine number of a sample of lard, for example, is 54, and the iodine

number of the liquid portion of the fatty acids is 90. The sample will contain $\frac{100 \times 54}{90} = 60$ per cent. of liquid—*i.e.*, unsaturated fatty acids.

The accuracy of this method is influenced first by the accurate determination of the two iodine numbers; secondly, by the amount of loss in iodine-absorbing power suffered by the unsaturated fatty acids through oxidation, etc., during their preparation; and thirdly, by the question as to whether, in the case of the incomplete separation of the lead salts, the unsaturated acids remaining in the insoluble lead salts are sufficient to influence the iodine number of the principal quantity.

H. H. B. S.

Use of Benzene in the Determination of the Iodine Numbers of Fats and of the Liquid Portion of Fatty Acids. K. Farnsteiner. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 529.)—In a recently published paper (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 390, *Analyst*, preceding Abstract) the author proposes a method for the separation of unsaturated from saturated fatty acids by means of benzene. In the present communication he shows that the iodine numbers of fats and of liquid fatty acids may be determined in the presence of benzene, if the latter be free from thiophen. Ordinary benzene, owing to the presence of this impurity, absorbs an appreciable quantity of iodine, and therefore vitiates the results. The following comparative results were obtained:

Description of Fat.	Iodine Number found in Presence of		Difference by use of Benzene.
	Chloroform.	Benzene.	
1. Lard I., prepared by author ...	49·0	48·7	−0·3
2. ,, II., from local slaughter-house	49·7	49·5	−0·2
3. Cooking fat (fabricated)	76·1	75·2	−0·9
4. Tallow I.	40·2	39·7	−0·5
5. ,, II., Australian	44·3	44·0	−0·3
6. ,, III., ,, ...	44·7	44·1	−0·6
7. Goose-fat I., pure ...	69·8	69·0	−0·8
8. ,, II.,	77·7	77·9	+0·2
9. ,, III., with lard admixture ...	72·9	72·2	−0·7
10. Sesame oil	103·9	103·1	−0·8
11. Cotton-seed oil	101·1	100·8	−0·3
12. Linseed oil	178·9	177·0	−1·9

For the determination of the iodine number of the liquid fatty acids, the author takes a portion of the mixed fatty acids corresponding to about 1 gramme of the liquid fatty acids—that is to say, about 2 grammes for lards, etc., and about 1·2 to 1·5 grammes for oils. The lead salts are produced in the usual way, and then dissolved in 100 c.c. of warm benzene, the solution allowed to stand for 10 to 15 minutes, kept for 2 hours at 8° to 12° C., and filtered without subsequent washing. The liquid fatty acids are obtained in the free state by shaking the filtrate with about 100 c.c. of a 10 per cent. hydrochloric acid solution until the layer of benzene becomes

nearly clear. After washing twice with 100 c.c. of water, the benzene solution is filtered through paper or cotton-wool without washing. From the filtrate three 25 c.c. portions are taken; two of these are used for the determination of the iodine number in the usual way; the third is used to ascertain the weight of the fatty acids taken for the determination, by distilling off the benzene in a current of hydrogen. The iodine number can also be determined in the residue from the distillation.

In the following table the results by the benzene method are compared with the results by the ether method. The two experiments in which benzene only was used are intended to show that the absorptive power of the fatty acids is not affected by the distillation in hydrogen.

No.	Description of Fat.	Iodine Number of the Liquid Portion of the Fatty Acids. Separation effected by means of					Remarks.

H. H. B. S.

The Separation of Bi-basic Fatty Acids resulting from the Oxidation of Fats. L. Bouveault. (*Bull. Soc. Chim.*, 1898, xix., 562-565.)—In the course of experiments on adipic acid, the author had occasion to separate the various fatty acids in a mixture derived from the oxidation of a fat, and consisting principally of succinic, adipic, glutaric, and pimelic acids. The following is an outline of the method which he adopted:

By distilling the mixture under ordinary pressure until the temperature reached

290° C., the whole of the succinic acid was converted into succinic anhydride, which could then be separated from the other acids by continuing the distillations under a pressure of 20 mm., when it passed over at 135° C.

The residual mixture of bibasic acids (boiling at 210° to 225° C. under 20 mm. pressure) was treated with cold ether, which dissolved about one-third of the total quantity.

The insoluble portion (M.P. 135° to 140° C.) consisted chiefly of pimelic and adipic acids, and deposited the latter on crystallization from boiling water. The adipic acid thus obtained melted at 140° C., and, though insoluble in water, was found to be extremely deliquescent.

The glutaric and pimelic acids dissolved in the ether and in the mother-liquid of the aqueous crystallization were separated by being converted into calcium salts and treated with water, in which calcium pimelate is but slightly soluble in the cold and insoluble on boiling, whilst calcium glutarate is exceedingly soluble.

The author states that Arppes' statement that pimelic acid is not present in products of the oxidation of fats with nitric acid is incorrect; in fact, in such oxidations he has found all the usual acids present in varying quantity from succinic up to sebacic acid. C. A. M

The Fractional Saponification of Oils and Fats—II. R. Henriques. (*Zeit. angew. Chem.*, 1898, 697-702.)—This paper contains some supplementary notes to the author's former communication on this subject (ANALYST, this volume, 181-183). It is stated that the conclusions arrived at as to the formation of ethyl esters of the fatty acids with liberation of the glycerin during the saponification of tri-glycerides with alcoholic potash were forestalled by Bouisin in 1857, who drew the same deductions from a similar series of experiments (*Comptes Rend.*, xlv., 35; *J. prak. Chem.*, 1857, lii., 308).

Recently Geitel (*J. prak. Chem.*, 1897, 429; 1898, 113) has come to the conclusion from mathematical and physical considerations that in the saponification of all partially decomposed tri-glycerides, mono- and di-glycerides are produced. Without attempting to refute this view on theoretical grounds, the author points out that Geitel has brought forward no experimental evidence in favour of his theory, with the exception of certain results which in his (the author's) opinion lend more support to the theory of the production of ethyl esters.

Moreover, since in his former paper the author suggested the possibility of di-glycerides being present in the residue left on saponifying linseed oil with a smaller amount of alcoholic potash than was requisite to liberate all the glycerin, he has made further experiments on this point with almond oil, and finds that only unaltered tri-glycerides are left. Even on treating almond oil for eight hours with steam at 250° to 270° C., so as to cause a disruption of the molecule and distillation of about 10 per cent. of the substance, the residual portion when washed from liberated fatty acids and glycerin was found to contain only unaltered tri-glycerides.

C. A. M.

The Determination of the Lubricating Power of Oils. E. Weiss. (*Dingler's Polyt. Journ.*, 1898, cccix., 76-80.)—The viscosity of an oil is often regarded as the

most important factor in determining the suitability of an oil for lubricating purposes, but in the author's opinion it should not be regarded as the sole criterion. By means of an apparatus which he has devised it is possible to determine the consistency of an oil, and from the result to calculate the "mobility" (*Beweglichkeit*) which furnishes a means of judging which of two oils with the same viscosity is the better lubricator.

This apparatus consists essentially of a small metal disc about 10 cm. in diameter which is made to revolve in the oil by means of clockwork actuated by a weight, the number of revolutions in a given time being dependent on the consistency of the oil. The weight is chosen so that the disc makes 150 revolutions in water at 15° C. in half a minute. Usually about 1,147 grammes are required.

On charging the vessel with a thick liquid and varying the driving weight, the resistance of the liquid is proportional to the rapidity with which the disc revolves, or $P = mu$, where P = the driving force, u = the number of revolutions in thirty seconds, and m = a constant of the oil under examination. In the case of rape oil this constant was found to be 64·27. For more mobile liquids it was determined experimentally that up to a weight of 2,500 grammes the following formula was applicable, $P = a + bu^{\frac{3}{2}}$, in which $a = 43{\cdot}5$ and $b = 0{\cdot}60853$.

For liquids whose consistency lies between that of water and rape oil, the relation between the driving weight and rapidity of revolution is more complex; but here, too, the author demonstrates that there is such a constant relation, and arrives at the formula $P = A\mu v_0 (1 - \alpha)$, in which A is a constant depending on the dimensions of the consistency apparatus, v_0 = the rapidity of revolution of the oil near the disc, μ = the coefficient of friction of the liquid, and α denotes what fraction the rapidity of revolution near the surface is of the rapidity of revolution near the disc.

For Engler's viscosimeter, which the author employs, the law of Poiseuille holds good, $T = B\mu$, in which T = the time of efflux of the liquid, and B = a constant of the particular apparatus used.

Incorporating this formula into his previous equation, the author arrives at the formula,

$$Tv_0 = \frac{P.B}{A} \cdot \frac{1}{1-\alpha}.$$

If, then, in the examination of a number of oils the same viscosimeter and consistency apparatus, and in the latter the same driving weight, are invariably used, $\frac{PB}{A}$ has always the same value, and the product of the number of revolutions and of the time of efflux in the viscosimeter must be proportional to the constant $\frac{1}{1-\alpha}$, which varies with the value of α. Thus, α and Tv_0 furnish a measure of the mobility of a fluid, since the more mobile a liquid, the less the difference between the rapidity of its revolution in different parts of the vessel. Hence the product Tv_0 is termed by the author the "mobility."

If the "mobility" were solely dependent on the coefficient of internal friction, all liquids with the same viscosity would have the same "mobility," which is not the case. The "mobility" steadily decreases as the temperature rises, and when the consistency exceeds thirty revolutions fatty oils lose their oily character.

In the case of rape oil the relation between the consistency value (U) and the viscosity value (V) can be expressed with approximate accuracy by the formula

$$(V+1{\cdot}92)\,(U-0{\cdot}08)=387{\cdot}54\,;$$

and this formula was used to calculate the figures in the fourth row of the subjoined table, which gives the comparative results obtained with that oil at varying temperatures:

No. of revolutions	17	20	24	28	30	36	40	50	56
Minutes (viscosimeter)	21	17·3	14·2	12·0	11·15	9·0	7·9	5·8	4·5
Tv_0	357	346·0	340·8	336·0	334·5	324·0	316·0	290·0	252·0
Minutes (calculated)	20·98	17·53	14·28	11·96	11·03	8·87	7·78	5·84	5·01

The curves of the changes in the viscosity and consistency caused by dilution are parallel to the curves of those brought about by heat.

The following tables give in an abridged form some of the determinations made by the author in illustration of the foregoing points:

(*c*)	59·6	6·4	453·4
Soluble glass	35·5	5·6	198·8

A comparison of these results shows that as regards "mobility" the substances in the tables stand in the following ascending order: Soluble glass, glycerin, soap solutions, gum solutions, oils. The latter, compared with one another, have the following classification: Rape oil, rape oil with colophony, melted lard, mineral oil II., liquid paraffin, castor oil, liver oil, mineral oil I. A characteristic property of castor oil is that its "mobility" increases as it becomes more fluid. C. A. M.

Some Properties of Pure and Adulterated Wax. K. Dieterich. (*Chem. Zeit.*, 1898, xxii., 729.)—The author finds that the iodine number of pure yellow beeswax, as determined by the ordinary Hübl process, varies between 8·8 and 10·7; employing the Waller method, the figures are 8·4 and 10·5 respectively. As the absorption is small, it is better to use 0·5 or 0·75 gramme for analysis, dissolving it in 40 c.c. of chloroform, and allowing the mixture to rest overnight before adding the iodine solution. Yellow wax, whether filtered or not, is completely soluble in chloroform; but white wax is not entirely dissolved. The iodine number of white wax is 4·2 to 4·4 (Hübl), 4·0 to 4·2 (Waller). A wax-like residue obtained in the manufacture of wool-grease has recently appeared on the market; and as it is much cheaper than beeswax, it may possibly be used as an adulterant. Its iodine number is 7·8 to 14·2 (Hübl), 3·1 to 3·7 (Waller); chloroform does not dissolve it wholly.

A genuine sample of yellow wax was mixed with 10 and also 20 per cent. of various foreign substances of similar nature (*cf.* table), the final iodine number of the product being determined in each case. Most of the bodies selected for trial affect the absorption one way or the other; but Carnauba and Japan wax make practically no difference. The former, however, forms a mixture which is only partly soluble in chloroform; while beeswax sophisticated with Japan wax is entirely soluble. The addition of ceresin or paraffin also causes imperfect solubility. On the whole, it would seem that the iodine absorption of true wax is subject to such wide variations that by itself it cannot always be relied upon to indicate the presence of impurity; that the degree of solubility in chloroform is a most important factor; and that to

ensure even reasonable accuracy in the valuation of any particular sample, it is necessary also to deduce the acid, ester, and saponification numbers of the material. The annexed table shows the general result produced on the constants of genuine wax by the several adulterants quoted:

	Specific Gravity.	Acid No.	Ester No.	Saponification No.,	Iodine No.

F. H. L.

Extraction of Cholesterin and Phytosterin. H. Kreis and O. Wolf. (*Chem. Zeit.*, 1898, xxii., 805.)—Although the process described by Bömer (ANALYST, xxiii., 42) affords most valuable information as to the derivation of a fat, it is lengthy, complicated, and, in hot weather, unpleasant owing to the large volumes of ether consumed. If only 10 grammes of the sample are taken for analysis, as Bömer has more recently suggested, the product is almost too small for proper examination; and Raumer's idea of evaporating the soap solution and extracting the dry residue with ether is not so easy to carry out as it sounds. The authors hope that the following modification will prove more simple and acceptable: 50 grammes of fat are saponified with alcoholic caustic soda. The solution is evaporated in a porcelain basin till it becomes syrupy, poured into 500 c.c. of boiling water in a 2-litre flask, and mixed with hydrochloric acid (sp. gr. 1·124) until phenolphthalein shows that the liquid is only just alkaline. 100 c.c. of a 10 per cent. aqueous solution of calcium chloride are then added, and the whole is shaken till the lime soaps cohere into lumps. (Absence of frothing shows that sufficient of the reagent has been employed.) It is next cooled to the ordinary temperature, filtered through cloth, and the precipitate squeezed dry in paper. Thus prepared the soaps form a friable mass and contain the whole of the cholesterin and phytosterin. The product is powdered, boiled for an hour with 100 c.c. of 95 per cent. alcohol, cooled and filtered. The filtrate is treated with 3 c.c. of 40 per cent. soda to attack any saponifiable matter left behind on the first occasion, and evaporated slowly to dryness. The residue is broken up and shaken for an hour with 50 c.c. of ether, filtered and evaporated once more. This final product is readily soluble in hot spirit; and on cooling, the cholesterin and phytosterin separate out pure and white.

Bömer has remarked (ANALYST, xxiii., 132) that the cholesterin of butter is difficult to obtain pure; the present process is available in this case also. Hitherto it has been tested on butter, lard, and cotton oil; details will follow in a subsequent communication. F. H. L.

Reaction of Lecithin with Alloxan. N. Orlow. (*Farmaz. J.*, 1898, xx., 283; through *Chem. Zeit. Rep.*, 1898, 233.)—If alcoholic solutions of lecithin and alloxan

(which must be free from nitric acid) are mixed together, the liquid turns pink, red, and dark, a voluminous red precipitate being formed. The reaction proceeds almost instantaneously on warming. The precipitate is readily soluble in water, decomposing on evaporation even in the desiccator into a brown powder resembling murexide. Ammonia does not affect the colour. The aqueous solution of the precipitate yields a violet or blue deposit with lead acetate and ammonia. Cholesterin and fats give the reaction only on heating and in a far less marked degree. Pure cholesterin does not change in colour more quickly than the alcoholic solution of alloxan alone.

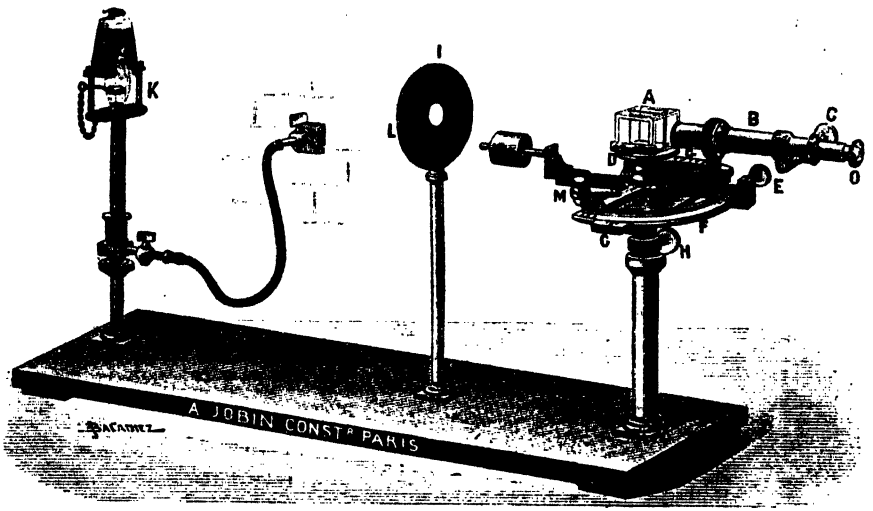
The Tornoe Spectro-areometric Method for Estimating Alcohol and Dry Extract in Beer. **M. Buisson.** (*Rev. Chim. Analyt. Appl.*, vol. vi. [10], pp. 157-164.)—The apparatus (Fig. 1) consists of a special refractometer fitted with a graduated circle and vernier for reading off the refraction in degrees, minutes, and seconds, and employing a Hallwachs' prism (A) illuminated by a monochromatic (sodium)



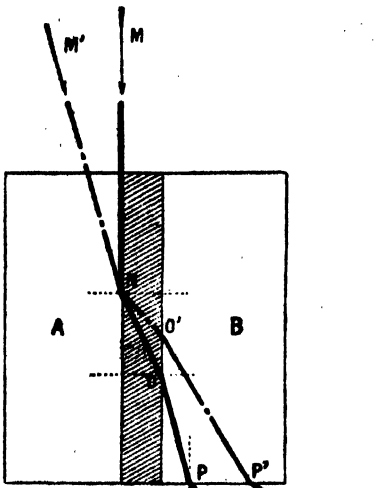


FIG. 1.

flame (K). The prism consists of a rectangular vessel divided by a partition into two compartments, one of which is filled with distilled water, and the other with the beer under examination previously freed from carbon dioxide. Equalization of temperature in the contents of the prism is ensured by agitating the whole before each reading. Of the light thrown on the prism (Fig. 2) in the direction of the partition, the rays falling on the partition are deflected by the latter and refracted through the beer, their course being indicated by M N O P R, whilst the other rays follow the direction M' N' O' P' R', the field to the right of M N being thus illuminated, whilst that to the left of the partition remains dark. The line of demarcation (M N, Fig. 3) is well defined, and its direction can be accurately determined by the aid of the cross wires in the apparatus.

In working the apparatus the prism is first carefully cleaned, filled, and put in position on the stand, the base of the eye-tube B (Fig. 1) being placed in contact with the tip of the adjusting screw E, which is then turned until the zero of the vernier coincides with the 180° mark on the scale. The eye-tube is then trained on to the lamp-flame, and the prism adjusted so that the partition is in line with the mark I on the condenser L, the part filled with water being on the left hand. The eye-piece is focussed on the cross wires, and the eye-tube—still in contact with the screw E—is turned so as to bring its extremity opposite to the compartment containing the beer, the scale also being rotated at the same time. This procedure brings into the field of vision the line of demarcation, M N (Fig. 3), the ill-defined section at the extreme right being, if necessary, placed out of view by simply turning the scale and attached apparatus in the proper direction. The platform carrying the prism is rotated so as to bring the line M N in line with the intersection of the cross wires, whereupon the position of the prism in relation to the 180° mark on the scale is noted. The prism is then rotated 180°, and the position of the line M N—now to the left of the central partition—is ascertained as before, the angle of deviation indicated by the position of the zero mark of the vernier being then read off and referred to the table which gives the corresponding quantity of dry extract.

Fig. 2.

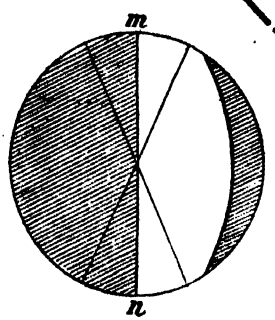

Fig. 3.

The standard temperature for the operation being fixed at 17·5° C., the following corrections must be made for other temperatures, viz., for deviations of 15°, 20° and 30° an addition of 0·7, 1·0, and 1·2 respectively for each degree C. above 17·5° C., and a corresponding deduction in cases where the temperature is below that standard, as determined, at the moment of reading off, by a thermometer inserted in the contents of the prism.

Specific gravity is estimated by the usual instrument at 17·5° C., with a correction of ±0·0002 for each degree C. above or below that limit.

Tables of estimations made with the Tornoë instrument and by the direct method, by Fernbach, Kjeldahl, and Prior, show that the differences between the two fall within the limits of experimental error. C. S.

Sugar Estimation by the Kjeldahl Process. Bruhns. (*Centralbl. Zuckerind.*, 1898, vi., 817 and 895; through *Chem. Zeit. Rep.*, 1898, 229.)—When Kjeldahl's method of estimating sugar is adopted for mixtures containing cane sugar, the copper thrown out of solution by the cane sugar is so much more copious that, other things being equal, 200 milligrammes of metal are only about equivalent to 44 milligrammes in the Soxhlet process. This depends on the longer boiling and the greater alkalinity of the modified Fehling's solution—two factors which Kjeldahl has completely overlooked. It therefore leads to quite erroneous results in the analysis of raw sugar and articles of food, etc.; and before it could be made serviceable, would require thorough investigation. It is certainly precluded from ranking as an official method. (See also ANALYST, xxiii., 271.) F. H. L.

Determination of Methoxyl. G. Gregor. (*Monatshefte für Chemie*, xix., 116.)—The author introduces sundry modifications in Zeisel's method for the determination of methoxyl (*Monatshefte für Chemie*, 1885, 989; ANALYST, xi., 119), with the object of rendering it easier and quicker of execution and more suited to technical purposes. In the first place he abolishes the direct gravimetric determination of the silver iodide, substituting for it the equally exact but quicker volumetric method of Volhard. Next he replaces the neutral silver nitrate solution of Zeisel's original method by a solution acidified with nitric acid. As Zeisel himself observed, not only does the precipitated silver iodide carry down a certain quantity of silver nitrate, but the silver nitrate solution contains traces of silver iodide. As a consequence, the precipitate and solution, according to Zeisel's procedure, require to be separately treated, the former by agitation with water to extract the silver nitrate, and the latter by evaporation to expel the alcohol, after diluting with water and acidifying with dilute nitric acid. By the use of a silver nitrate solution acidified with nitric acid the necessity for such separate treatment is avoided, for although the silver iodide carries down with it a little silver nitrate, this is easily washed out with water.

Lastly, the author prevents the reduction of silver nitrate which takes place in the tube, which dips into the alcoholic silver nitrate solution of the first flask, by employing a solution of potassium carbonate and arsenious acid instead of amorphous phosphorus. To suit the volumetric method of Volhard, the author uses an alcoholic $\frac{N}{10}$ silver nitrate solution standardized with a $\frac{N}{10}$ potassium thiocyanate solution. For the determination, 50 c.c. of this solution (acidified with a few drops of nitric acid free from nitrous) are placed in the first flask and 25 c.c. in the second. When the reaction is complete, the clear fluid is decanted from the silver iodide into a 250 c.c. measuring-flask, the precipitate washed, the washings added to the flask, and finally the silver nitrate in the second flask added also. The whole is then made up to 250 c.c. with water, mixed, filtered through a dry filter, and 50 c.c. or 100 c.c. acidified with nitric acid free from nitrous acid, and titrated with potassium thiocyanate with ferric sulphate as indicator. The following comparative results are given:

H. H. B. S.

Analysis of Lysol, Creolin, and Similar Preparations. H. Ditz and R. Clauser. (*Chem. Zeit.*, 1898, xxii., 732.)—An analysis of such products as lysol and carbolic soap involves the separation of phenols, hydrocarbons, and fatty acids one from another; and the present process depends on the fact that barium oleate is quite insoluble in hot and cold water, and only slightly soluble in 50 per cent. alcohol, whereas barium phenolate dissolves in 40 per cent. of its weight of water at 100° C., the orthocresylate in 150 per cent., the paracresylate in 320 per cent., while the rare metacresylate is very soluble. Barium oleate, however, being somewhat uncertain in composition, cannot be weighed as such: it is necessary again to liberate the oleic acid. Moreover, the fatty acids in lysol, etc., are not pure oleic, but contain stearic and palmitic as well, the barium salts of which are partly decomposed by water. Nevertheless, preliminary experiments have shown that working on lysol, which usually contains about 40 per cent. of fatty acids and 40 per cent. of phenols, the amount of the former recovered is only 0·5 per cent. too low, and this is a deficiency of no importance in the present investigation.

To carry out the analysis, 5 grammes of lysol are dissolved in 100 c.c. of warm water, 20 or 30 c.c. of 10 per cent. caustic soda added, and the mixture extracted two or three times with ether to remove the hydrocarbons. The ethereal solution is washed with very weak soda, and the latter combined with the bulk of the aqueous liquid; the ether is dried with solid potash, cautiously evaporated, and the residue dried over sulphuric acid to constant weight. The aqueous solution is carefully freed from ether on the water-bath, neutralized with hydrochloric acid, cooled completely (this is most important), treated with excess of barium chloride and a quantity of baryta-water roughly equivalent to the phenols present. The mixture is

filtered quickly, avoiding unnecessary exposure to the air, the precipitate washed with baryta-water, then cold and finally hot water, rinsed back into the original beaker, decomposed with 1 : 1 hydrochloric acid, and thrown on to the first filter again. The oleic acid is washed with hot weak acid till free from barium, with water till free from acid, dissolved in absolute alcohol and ether, and evaporated to constant weight at 100° C.

The filtrate from the barium precipitate may be acidified, extracted with ether, and the phenols recovered by evaporation; but it is better to operate as follows: In a convenient fraction of the acidified liquid the mixed phenols are determined by the Koppeschaar method (calling the bromine absorption calculated on the whole bulk A grammes). Another portion is extracted with ether, the solvent evaporated, and the residue dried for two or three hours at 100° to 110° C. (loss by volatilization is of no consequence in this test). It is then dissolved in caustic soda or baryta and titrated as before, calling the weight of the whole residue *a* grammes, and its bromine absorption B. The weight of the lysol originally taken for analysis being C grammes, the percentage of phenols is given by the formula:

$$\frac{100 \times A \times a}{B \times C}$$

F. H. L.

Volumetric Determination of Nitrophenol Derivatives. L. Schwarz. (*Monatshefte für Chemie*, xix., 139.)—The author has carried out experiments upon the determination of the nitrophenol derivatives by taking advantage of the liberation of free iodine resulting from the action of potassium iodide and iodate. The iodine was determined volumetrically by a $\frac{N}{10}$ sodium thiosulphate solution freshly standardized before each series of experiments was commenced. The starch emulsion was prepared as recommended by Zulkowski and Topf (*Zeit. für analyt. Chemie*, xxvi., 138) by diluting a glycerin emulsion with solution of common salt. The results show that tri- and tetra-nitro derivatives can be determined in this way without particular regard being paid to the length of time allowed for the action; but that in the case of dinitro-derivatives substitution of iodine takes place if the heating is too long continued, and for the same reason mononitro-derivatives cannot be determined in this way at all. Experiments with tribromophenol and with tetrabromfluorescin (eosin) led to the conclusion that these substances are not adapted to this method of determination.

H. H. B. S.

The Composition of the Ash of some Raw Tanning Materials. W. K. Alsop and J. H. Yokum. (*Jour. Amer. Chem. Soc.*, 1898, xx., 338-340.)—With the object of obtaining fuller information on the composition of some of the common sources of tannin, the authors have made complete analyses of a large number of samples, the average results of which are given in the subjoined table.

The method by which the tannin was determined was that of the Association of Official Agricultural Chemists, 1897. The total extract was obtained by extracting the bark with boiling water and evaporating the solution, the residue in the extractor, returned as cellulose and insoluble matter, being determined by difference. The soluble solids were the solids of the extract soluble at 18° C., and the red colouring

matter the difference between the total and the soluble solids. The non-tannins (mainly glucosides of unknown composition) consisted of the soluble solids not absorbed by hide.

The very much larger amount of ash in the oak than in the hemlock bark was due to the fact that the latter does not grow on a limestone soil.

C. A. M.

INORGANIC ANALYSIS.

Estimation of Lead in its Ores. L. Schneider. (*Oesterr. Zeits. Berg. u. Hüttenw.*, 1898, xlvi., 431; through *Chem. Zeit. Rep.*, 1898, 212.)—The author has investigated the influence of several substances upon the degree of insolubility of lead sulphate. He finds that tartaric, and more particularly nitric, acids raise its solubility in water; and that, although the presence of sulphuric acid, tartaric acid, or ammonium sulphate diminishes the solvent action of the nitric acid, yet lead cannot be completely precipitated unless the latter forms less than 1 per cent. of the liquid. He suggests the following process for the analysis of lead ores: 1 gramme is boiled for ten or fifteen minutes with 5 c.c. of strong hydrochloric acid, when 5 c.c. of strong nitric acid are added, and the mixture heated till the brown vapours

disappear. The lead salt is dissolved in 10 grammes of tartaric acid and 25 c.c. of water, and treated with 25 c.c. of strong ammonia. The insoluble residue consists only of quartz and barium sulphate. The filtrate, diluted to 300 c.c., is warmed with 50 c.c. of 1 : 1 sulphuric acid, the precipitate washed with 1 per cent. acid, dried and weighed. If all these conditions are adhered to, there is no necessity to drive off the nitric acid, because in the final filtrate and washings, which amount to about 500 c.c., 0·003 gramme of lead sulphate always remains in solution, and the obvious correction can easily be made. F. H. L.

Volumetric Estimation of Lead Peroxide by Means of Arsenious Acid. C. Reichard. (*Chem. Zeit.*, 1898, xxii., 774.)—Although lead peroxide is not attacked by an aqueous or ammoniacal solution of arsenious acid, in strong caustic soda solution at the boiling-point it is quantitatively reduced to monoxide: $2PbO_2 + As_2O_3 = 2PbO + As_2O_5$. Since the substance is largely used as an oxidizer in the manufacture of dyes, the percentage of available oxygen it contains is often the most important factor, and to save calculation, therefore, the analysis may be conducted exactly as follows: The peroxide is brought to a fine powder, being preferably passed through a cloth; 0·1 gramme is weighed out, and introduced into a known excess of a solution of arsenious acid in concentrated caustic soda containing 0·0099 gramme of As_2O_3 (= 0·0016 gramme of oxygen) per c.c. The whole is boiled with further additions of highly concentrated alkali till the liquid is colourless or but faintly yellow. It is then diluted, acidified with sulphuric acid, and the amount of arsenious acid remaining estimated by titration with permanganate. If preferred, the neutral solution may be filtered, treated with sodium bicarbonate, cooled, and similarly titrated with iodine and starch. F. H. L.

Examination of Alloys containing Lead and Antimony. A. Fraenkel. *Mittheil. techn. Gew. Mus. Vienna*, 1898, viii., 334; through *Chem. Zeit. Rep.*, 1898, 229.)—Alloys which contain lead, copper, and phosphorus as well as tin and antimony are attacked with nitric acid, the residue fused with caustic soda in a silver crucible, the melt extracted with water, diluted with one-third its volume of alcohol, and filtered after standing for twenty-four hours. The filtrate (F) contains sodium stannate and phosphate, and the whole of the lead undissolved by the nitric acid at first; the residue (R) contains the antimony and copper. In (F) the lead is precipitated with sulphuretted hydrogen and determined as usual; the filtrate is treated with sulphuric or acetic acid to throw down tin sulphide, which is converted into oxide and weighed as such. The filtrate from the tin is evaporated and the phosphoric acid estimated. (R) is dissolved in hydrochloric and tartaric acids, and precipitated with sulphuretted hydrogen; the antimony sulphide is dissolved by digestion with ammonium sulphide, filtered from the copper, thrown down together with some sulphur by means of acid, collected on a tared filter, and the antimony determined in a portion by ignition in a current of carbon dioxide. The original nitric acid solution is investigated in the ordinary fashion. F. H. L.

The Determination of Lead in Alloys. W. E. Garrigues. (*Journ. Amer. Chem. Soc.*, 1898, xx., 508-510.)—The following method is based on the fact that lead chromate is insoluble in ammonia, whilst copper chromate is readily soluble. Where applicable, it is much more rapid than precipitation of the lead as sulphate.

The solution of the lead and copper in nitric acid is mixed with potassium bichromate in excess, followed by a large excess of ammonia. The liquid is heated until the supernatant liquid becomes clear, and the precipitate of lead chromate collected in a Gooch crucible containing a single disc of filter-paper as the filtering medium, washed with dilute ammonia, hot water, and alcohol, and dried in the water-oven.

This method is essentially a separation of lead from copper and zinc; but when antimony, bismuth, or iron are present, the sulphate method must be employed. In determining lead in the presence of antimony, it is possible to prevent the small quantity left in the filtrate from the tin from being precipitated with the lead sulphate by adding a large amount of sulphuric acid, diluting sparingly, and filtering as rapidly as possible.

A rapid modification of the sulphate process, in which the lead is obtained without previous removal of tin, is described in the form of an account of an experiment:

Half a gramme of solder, containing, according to the sulphate and chromate determinations, 58·83 and 58·80 per cent. of lead respectively, was oxidized with nitric acid, 20 c.c. of strong sulphuric acid added, and the liquid evaporated until dense fumes appeared. The metastannic acid was completely dissolved. After adding 80 c.c. of cold water, the solution was well stirred and the lead sulphate collected on a Gooch's filter. The quantity of lead thus found was 59 per cent.

The filtrate was made alkaline with ammonia, and sulphuric acid added until the liquid turned methyl orange decidedly red. The liquid was boiled, and the voluminous white precipitate collected on a filter, ignited in a strong blast, and weighed as stannic oxide. The amount of tin calculated from the result was 41·1 per cent.

If more than 80 c.c. of water were used for the dilution, or if the solution was left on the water-bath for an hour or two, the tin began to precipitate slowly.

C. A. M.

Estimation of Nickel in the Presence of Iron. B. Neumann. (*Chem. Zeit.*, 1898, xxii., 731.)—Five grammes of steel borings are dissolved in dilute sulphuric acid, and the carbon and iron oxidized with bromine, nitric acid, or preferably hydrogen peroxide. The solution is brought into a 500 c.c. flask, ammonium sulphate added, the iron precipitated with ammonia, the liquid boiled, excess of ammonia introduced, and after cooling diluted to the mark. One hundred c.c. (= 1 gramme) are filtered off, diluted slightly, warmed and treated with a current of 1 or 2 ampères at 3·4 to 3·8 volts for one-and-a-half to two hours. The space occupied by freshly-precipitated ferric hydrate is not known, but in ordinary steels the error thus caused will not exceed 0·5 per cent. of the nickel obtained. In steels rich in nickel, where only 0·5 gramme is taken for electrolysis, it will be about 0·2 per cent.; and in nickel

ores, etc., containing 50 or 60 per cent. of iron, not more than 0·2 or 0·3 per cent. Nickel ores are attacked first with hydrochloric acid, then with nitric, and evaporated with sulphuric acid till white fumes appear. The heavy metals are thrown down with sulphuretted hydrogen, excess of the reagent removed by heat, the liquid oxidized with bromine or hydrogen peroxide, and 100 c.c. of the solution (= 1 gramme of material) treated as before. Cobalt remains in the liquid, and is deposited with the nickel.

One sample of nickel-steel which gave 4·12 per cent. of Ni when the iron was removed by fourfold precipitation gave 4·02 per cent. of Ni by the author's process; electrolysed in presence of the ferric hydrate, the yield was 4·00 per cent. (corrected). A specimen of nickel ore examined by the author's method gave 6·02 per cent. of Ni + Co; four precipitations of the iron gave 6·15 per cent. of Ni + Co; electrolysis without removal of the iron gave 5·98 per cent. of Ni + Co (corrected); Rothe's process (extraction of the hydrochloric acid solution with ether, to dissolve iron and cobalt) gave 5·60 per cent. of Ni. The proportion of cobalt, specially estimated with nitroso-β-naphthol, was 0·50 per cent. F. H. L.

The Use of Hydrofluoric Acid in the Determination of Manganese in Iron and Ores. A. P. Ford and I. M. Bregowsky. (*Journ. Amer. Chem. Soc.*, 1898, xx., 504-506.)—In order to avoid the evaporation which is necessary when hydrofluoric acid is used in the determination of manganese in high silicon pig-irons, the authors have made experiments on the direct use of the acid with eventually successful results. The iron is dissolved, and the manganese precipitated with potassium chlorate. As soon as the precipitation is complete a few drops of hydrofluoric acid (the quantity depending on the amount of silicon present) are added, and the liquid boiled until the hydrofluoric acid is expelled. A little more potassium chlorate is then added (about 1 gramme), and the liquid concentrated as much as desired. The solution filters rapidly, and the graphitic carbon will be found to be almost completely oxidized owing to the removal of the enveloping silica.

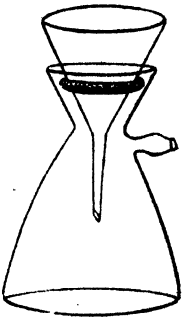
Similarly, in the case of manganese ores a few drops of hydrofluoric acid are added *after* the precipitation of the manganese with potassium chlorate, and if the first addition does not clear the solution in a minute or two, a few more drops are added. With a little practice, the amount required can be judged by the amount of floating gelatinous silica.

As to the action of the acid on the beakers, the authors state that, though they become opaque, their life is but little diminished. It is, however, advisable to keep a number of beakers apart for manganese determinations only. C. A. M.

Aluminium used as an Electrode. G. J. Hough. (*Journ. Amer. Chem. Soc.*, 1898, xx., 302, 303.)—The author states that aluminium can replace platinum as an electrode to a limited extent. It can be used as the cathode with nitric acid solutions without being affected, but cannot be used as the anode, for at that pole it is readily oxidized and dissolved. It is attacked by the free acid in sulphate or chloride

solutions, but can be employed when these are converted into the double oxalate of potassium or ammonium, as recommended by Classen. It is not attacked by cold solutions of potassium cyanide or oxalate, even under electrolytic action. Not being acted upon by hot or cold nitric acid, the metals deposited on it should readily be dissolved, but the author has not yet tested its applicability thoroughly and minutely, except in the case of copper analysis. Being so much lighter than platinum, its use reduces the chance of error in weighing the deposited metal, while its cheapness is a further advantage. C. A. M.

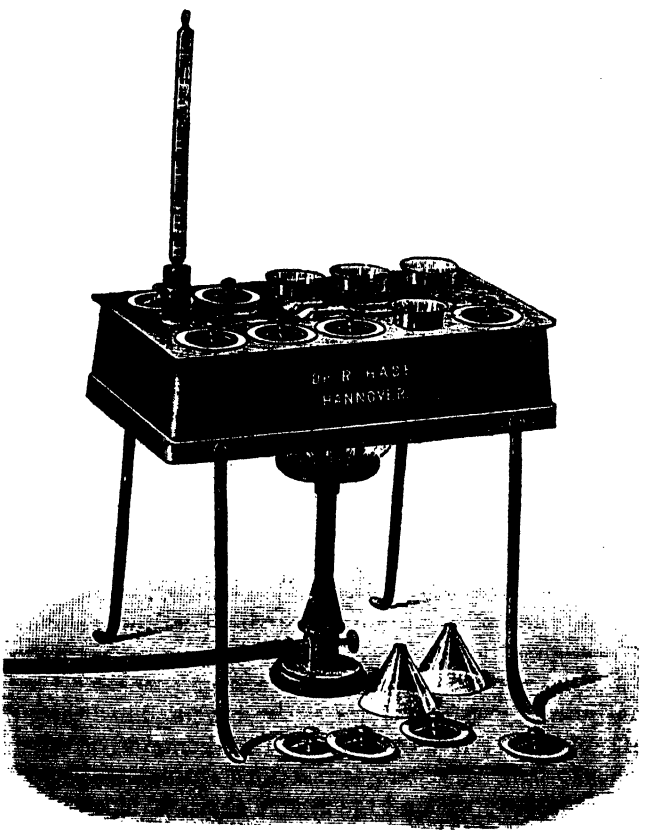
Detection of Normal Carbonate in Bicarbonate of Soda. N. Kubli. (*Arch. Pharm.*, 1898, ccxxxvi., 321; through *Chem. Zeit. Rep.*, 1898, 228.)—A 0·1 per cent. solution of quinine hydrochloride is not precipitated by sodium bicarbonate unless more than 2 per cent. of normal carbonate is present. To apply the test, 3 grammes of bicarbonate are dissolved in 50 c.c. of water at a temperature of 5° or 6° C., without agitation, in a closed vessel. On adding an equal volume of the quinine reagent, the mixture should remain clear. F. H. L.



Volumetric Estimation of Nitric Acid. W. Ackermann. (*Chem. Zeit.*, 1898, xxii., 690.)—This process depends on the reduction of nitrates to ammonia by means of ferrous hydrate. One gramme of potassium nitrate, 30 c.c. of caustic soda (specific gravity 1·33), and 40 grammes of crystallized ferrous sulphate, are placed in a 500 c.c. flask with 160 c.c. of water; a small quantity of reduced iron is added to assist the boiling, and the liquid is distilled into standard acid in the usual fashion. The operation proceeds quietly, and is generally finished in half an hour; but the complete evolution of the ammonia may easily be ascertained by removing the beaker containing the acid, washing the outside of the condensing tube, and testing the next 30 or 40 drops of distillate with litmus-paper. Should this prove to be still alkaline, more water may be added to the flask, and the distillation continued slowly; but as it is a sign that the reduction has not been successful, it is perhaps better to repeat the whole analysis. Blank experiments are necessary to estimate the amount of nitric acid in the several reagents, and in order to keep the correction as small as possible, the ferrous sulphate should be prepared from iron wire and pure acid, and good commercial caustic soda employed instead of the "pure" article. The above-mentioned proportion of water may be doubled or trebled if desired, but larger quantities tend to imperfect reduction, because on prolonged boiling and before suitable concentration is reached the ferrous hydrate loses its activity. The weight of caustic soda should be kept as specified; that is to say, it should form only a slight excess over the amount needed to decompose the ferrous sulphate.

Alkali chlorides, sulphates, and acetates do not interfere with the process; tartrates hinder the reaction; and phosphates, as existing in artificial manures, involve the following modification: The solution of the fertilizer is mixed in the distilling flask with sufficient calcium chloride solution of known strength to convert the whole of the soluble phosphorus into tribasic phosphate; the alkali is then dropped in with constant agitation, until an excess equivalent to 2 c.c. of the calcium chloride is attained; the ferrous sulphate and metallic iron are next added; the

liquid is made up to 170 c.c. (to allow for the extra viscidity caused by the calcium phosphate), and the analysis is finally conducted as before.



Figures quoted by the author show that, in working on 1 gramme of saltpetre under ordinary conditions, the variations in the end results will not exceed 1 or 2 milligrammes. F. H. L.

APPARATUS.

A New Vacuum Filter Flask. R. Walther. (*Pharm. Central. H.*, 1898, xxxix., 550; through *Chem. Zeit. Rep.*, 1898, 209.) — The construction of this apparatus is shown in the sketch, the shaded portion being a hollow (pneumatic) rubber ring filled with air, which fits any flask or funnel indifferently, and makes a tight joint by its own compression. F. H. L.

Apparatus for the Determination of the Reichert - Meissl Number of Butter. M. Siegfeld. (*Chem. Zeit.*, 1898, xxii., 738.) — In the Milchwirthschaftliche Institut at Hameln a pipette is used for measuring out the quantity of butter-fat required for this process, which, when manipulated uniformly, always delivers between 4·967 and 5·045 grammes. The maximum variation, therefore, corresponds to a difference of 0·2 or 0·3 in the Reichert - Meissl number; and this is quite insignificant in comparison with other sources of error. For the filtration of the fat and for keeping the pipettes warm a special water-bath, as illustrated herewith, is employed. The thermometer has a red mark at 50° C. to make it more conspicuous; but for ordinary purposes the temperature needs only to be maintained between 45° and 55° C. F. H. L.

REVIEWS.

A Short Course of Inorganic Qualitative Analysis for Engineering Students. By J. S. C. Wells, Ph.D., Instructor in Analytical Chemistry, Columbia University. New York: John Wiley and Sons. London: Chapman and Hall. 1898.

The object of this work is to give a "short but thorough" course in inorganic qualitative analysis for the use of students who have but a limited time to devote to the subject. There is no doubt that the student who may use Mr. Wells' book with zeal and discretion will necessarily gain a valuable knowledge of elementary qualitative analysis, but the work is no royal road to an understanding of the subject; and although excellent in many respects, is not without serious defects. To begin with some of its excellences—equations are freely used, the tables of separation are well printed, arranged, and expressed, and the tables of reactions representing skeleton schemes of separation (using formulæ only) form a valuable and somewhat original feature. For the rest, it differs but little from the innumerable works of this kind, and lacks the masterly treatment which we find in such manuals as those of Clowes and Coleman, Tilden, or Thorpe and Muir. It is admittedly based on Fresenius, who has been curtailed and improved upon in a somewhat wayward fashion. The descriptions of reactions are too lengthy and involved, and there is much unnecessary waste of space in text and tables, so as to leave an impression that the book would be equally useful if reduced to 150 pages, instead of the 300 of which it consists at present.

H. W. H.

A Laboratory Guide in Qualitative Chemical Analysis. By H. C. Wells, M.A., Professor of Analytical Chemistry and Metallurgy in the Sheffield Scientific School of Yale University. New York: John Wiley and Sons. London: Chapman and Hall. 1898.

This work is the printed presentment of a method of instruction which has been used by the author for fourteen years. Fresenius, who might, indeed, be called the primogenitor of analytical text-books, has again been largely drawn upon; but changes have been made where the author has considered them "advantageous," and a "few novelties" have also been introduced. One of these is a rearrangement of Fresenius' groups, which seems liable to render confusion worse confounded.

The work has but little to recommend it, and its sphere of usefulness might be greater if it were much condensed. The main idea seems to be an attempt to make the student evolve analytical methods out of his own inner consciousness by a series of elaborate exercises, which are by no means of a practical character. Take, for instance, the first exercise, where the pupil is directed to find by experiments which, out of twenty-seven solutions (of the common metals), yield a precipitate with hydrochloric acid. The simple reactions of this group are dealt with at inordinate length, and similarly with all the groups through fifty-six long pages. Blowpipe tests are not considered, as "they are usually studied in connection with determinative mineralogy"; but Fresenius may be consulted. Next following we have directions

for making reagents which are used in the first part. The ensuing chapter, on ionization and ions, is far too brief to be of any real value or interest; and after various chapters on the classification of salts and chemical equations, etc., we are finally, on p. 101, introduced to the reactions of the metals and acid radicles!

The most original feature of the work consists in twenty pages of chemical labels at the end, arranged so as to be torn out for use in the laboratory. H. W. H.

PRACTICAL ORGANIC CHEMISTRY: THE DETECTION AND PROPERTIES OF SOME OF THE MORE IMPORTANT ORGANIC COMPOUNDS. By S. RIDEAL, D.Sc., F.I.C. Second edition. London: H. K. Lewis. 1898.

Many students, and not a few teachers, will welcome the second edition of this useful and able little volume, which fills a special gap in analytical text-books. It deals with a definite class of compounds in a direct and succinct fashion, which is extremely refreshing in comparison with the two last-mentioned works, with which it is only fair to say it has nothing in common. The reactions of several important organic compounds have been added, and note has been taken of alterations in the new British Pharmacopœia, but the size of the book has not been unduly increased. On one point only can we bring ourselves to disagree with Dr. Rideal, and that is as regards the omission of any scheme of analysis; such a scheme is, we think, much needed. A summary of distinctive tests for each group is, however, still included, and forms a basis on which an earnest student may work out a scheme for himself. Although the work is specially adapted for the London University and other examinations, it will without doubt be appreciated by a wider circle of scientific workers.

H. W. H.

LABORATORY TEXT-BOOK FOR BREWERS. By LAWRENCE BRIANT. Second edition. (London: Fell and Briant.) Price 10s. 6d. net.

The first edition of this useful work, which was published in 1884, was for a long time the standard book on the analysis of the materials used in the brewery; but as time went on, and in the meantime this department of chemistry progressed somewhat rapidly, the work naturally fell behind the times. The new edition, which has been promised for a very long time, effectually disposes of this drawback, for it has been thoroughly brought up to date, and to do this effectually has necessitated the re-writing of the whole book. The new edition possesses all the good qualities of the old, such as simplicity and clearness of style, and the student is greatly assisted by the examples appended to the description of the various analyses. A few statements have crept in which will need correction in a future edition, of which the following are examples: P. 4, "Ungelatinized starch is not acted upon by diastase"; p. 20, "Levulose oxidizes into saccharic acid by contact with dilute nitric acid"; p. 27, "Amido-acids are formed when amides are heated with a mineral acid." However, these are trifles when compared with the otherwise excellent character of the information supplied, which will be found most useful to brewing analysts and students of brewing chemistry. W. J. S.

TECHNICAL MYCOLOGY: THE UTILIZATION OF MICRO-ORGANISMS IN THE ARTS AND MANUFACTURES. By Dr. FRANZ LAFAR, with a Preface by Dr. EMIL C. HANSEN. Translated by CHARLES T. C. SALTER. Vol. I.: Schizomycetic Fermentation. (London: Charles Griffin and Co.) Price 15s.

This is the first time that mycology in its practical application to the arts and manufactures has been treated in a thorough and exhaustive manner. Such a book as this was urgently needed, for in recent years the subject on which it treats has made enormous advances; it is only when the whole of the instances are collected together that we realize how numerous the industries are in which micro-organisms play an important part.

The introduction is divided into three parts; the first of these treats on the theory of spontaneous generation, and gives a historical résumé of the various views on this subject which have dominated the scientific world from time to time. The author is of opinion that, though abiogenesis is yet unproven, it may not be impossible. The next division contains a short and similarly historical summary of the principal views which have been advanced in explanation of the phenomena of fermentation. Dr. Lafar defines this process as "a decomposition or transformation of substances of various kinds induced by the vital activity of fungi." The third division treats of the position of the organisms of fermentation in the botanical system. We now come to the body of the book, which is divided into sections. The first of these is devoted to a description of the general morphology and physiology of the schizomycetes; Section II. to their general biology and classification; Section III. treats on the methods of sterilization and for obtaining pure cultures; the following section on the behaviour of the chromogenic, photogenic, and thermogenic bacteria. The remaining five sections are mainly devoted to the consideration of those micro-organisms which are immediately concerned in, or affect, processes carried out in manufacturing operations, such as the "retting" of flax, souring of cream, the fermentation of the liquors used in tanning, the ripening of cheese, the manufacture of vinegar, and many others. From this some idea may be gained of the comprehensive nature of the work, which is, with reference to these subjects, a perfect mine of wealth. Without doubt the book is indispensable to all who are engaged in any of those industries in which bacterial fermentations are concerned, and for the scientist it forms a valuable work of reference; so good is it that we look forward with something like impatience for the appearance of the second volume, which will treat on the Saccharomycetes and the fermentations they induce.

The book is well printed, the illustrations excellent, and, altogether, it is got up in handsome style. The translator, Mr. Salter, is to be congratulated on the excellent manner in which he has accomplished his task. W. J. S.

THE ANALYST.

DECEMBER, 1898.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, November 2, in the Rooms of the Chemical Society, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

The following gentlemen were proposed for election as members of the Society: Mr. J. F. H. Gilbard, 8, Glaskin Villas, Lea Bridge Road, London, N.E., Gas Examiner; Mr. Martin Priest, Assayer to the Imperial Mint, Nanking, China; and Mr. Lester Reed, F.I.C., 19, South Park Hill Road, Croydon, Public Analyst for the Borough of Croydon.

Mr. G. W. Slatter, A.R.C.Sc., F.I.C., was elected a member; and Mr. A. J. Bull was elected an associate.

The following papers were read and discussed: "A Curious Meat-Preservative" and "A Method for the Quantitative Separation of Acetic and Valeric Acids," by Alfred C. Chapman. "Automatic Pipettes and Burettes" and "The Effects of Recent Drought on the Quality of Milk," by A. W. Stokes. A paper entitled "Contributions to the Chemistry of Drying Oils, with a Method for the Examination of Linseed Oil," by Otto Hehner and C. A. Mitchell, B.A., was then read, but its discussion, on account of the lateness of the hour, was postponed.

A CURIOUS MEAT-PRESERVATIVE.

BY ALFRED C. CHAPMAN, F.I.C.

(Read at the Meeting, November 2, 1898.)

SOME time ago I received for analysis an antiseptic solution intended for the preservation of meat. The liquid, which was colourless, possessed a mixed odour of sulphurous and benzoic acids, and proved on examination to have a somewhat remarkable composition. The analysis, which was only qualitative, revealed the presence of the following substances: aluminium sulphate, sodium chloride, sodium nitrate, sulphurous acid, chloral hydrate, benzoic acid, and a small quantity of iodine, apparently existing as hydriodic acid. The alum was evidently intended to exert its astringent effect upon the fibre of the meat, whilst the remaining constituents (with the exception, perhaps, of the chloral) are, of course, well known to be possessed of marked preservative and antiseptic properties. Both the chloral and the benzoic acid would doubtless be volatilized during the cooking of the meat, and

this fact probably suggested the use of benzoic instead of the more active salicylic acid. In the course of my practice I had never before encountered chloral hydrate as a constituent of a food-preservative, and I thought that a short note calling attention to its use for such a purpose might not prove uninteresting to the members of this Society.

DISCUSSION.

DR. RIDEAL said that preservatives of this kind were almost invariably of French origin. He had met with several, the composition of which was similar in character to that of Mr. Chapman's sample. Chloral hydrate was present in some, but not in all. The main idea of the manufacturers of such mixtures seemed to be to use a large number of different ingredients, apparently with a view to baffling analysts.

CONTRIBUTION TO THE CHEMISTRY OF DRYING OILS; WITH A METHOD FOR THE EXAMINATION OF LINSEED OIL.

BY OTTO HEHNER AND C. A. MITCHELL, B.A.

(Read at the Meeting, November 2, 1898.)

OUR present knowledge of the composition and constitution of the fluid fatty acids occurring in natural fluid glycerides dates back no further than the year 1888, when K. Hazura, together with a number of collaborateurs, published a series of exceedingly important papers in the *Monatshefte für Chemie*. Up to that time the fluid portion of oils, drying and non-drying, was described as olein.

Hazura showed that when fluid fatty acids obtained from various oils were oxidized in alkaline solution with potassium permanganate, a number of different hydroxy-derivatives were produced. He isolated and described the characteristics of these compounds, and concluded from his investigations that the unsaturated fatty acids from fixed oils take up as many hydroxyl groups as there are free valencies, yielding saturated hydroxy-fatty acids containing the same number of carbon atoms as the original molecule. He also showed that the unsaturated fatty acids in question combined directly with bromine, as many bromine atoms being fixed as there are free valencies. He thus differentiated between acids of different degrees of non-saturation, and supplied a scientific explanation of the Hübl iodine value.

We give in a tabular form a statement of his results:

TABLE I.

Original Acid.	Bromo-compound.	M.P.	Oxidation Product.	M.P.
Oleic ($C_{18}H_{34}O_2$)	Dibrom-stearic acid $C_{18}H_{34}Br_2O_2$	Liquid	Dihydroxy-stearic acid $C_{18}H_{34}(OH)_2O_2$	137° C.
Linolic ($C_{18}H_{32}O_2$)	Tetrabrom-stearic acid $C_{18}H_{32}Br_4O_2$	114–115° C.	Sativic acid $C_{18}H_{32}(OH)_4O_2$	173° C.
Linolenic ($C_{18}H_{30}O_2$)	Hexabrom-stearic acid $C_{18}H_{30}Br_6O_2$	177° C.	Linusic acid $C_{18}H_{30}(OH)_6O_2$	203° C.
Isolinolenic ($C_{18}H_{30}O_2$)	—	—	Isolinusic $C_{18}H_{30}(OH)_6O_2$	173–175° C.

From the yields of the hydroxy-derivatives, which, as will be seen from the following tables, were very far from quantitative, Hazura and Grüssner made an approximate estimation of the composition of the unsaturated acids of a number of oils:

TABLE II.

	100 Grammes of Liquid Fatty Acids yielded:				
	Linseed.	Hemp.	Nut.	Poppy.	Cotton.
Dihydroxy-stearic acid ...	1·2	4·0	2·5	8·5	23·0
Sativic acid	6·5	24·0	25·0	18·5	31·5
Linusic + isolinusic acids ...	20·3	2·5	2·0	0·3	—
	28·0	30·5	29·5	27·3	54·5

TABLE III.

	Approximate Percentage Composition of Liquid Fatty Acids.				
	Linseed.	Hemp.	Nut.	Poppy.	Cotton.
Oleic acid	5	15	7	30	40
Linolic acid	15	70	80	65	60
Linolenic / Isolinolenic acids	15 / 65	15	13	5	0

It is obvious from the numbers given in Table II. that there must have been a considerable destruction of the first products of oxidation, especially of those derived from the least saturated acids; Hazura, in fact, obtained a number of further oxidation-products, indicating the rupture of the molecule. Nevertheless, it may be interesting to compare Hazura's estimates and the iodine values deduced therefrom, with the actual iodine numbers recorded for the fatty acids from the several oils, bearing in mind that the latter are for the total free fatty acids, while Hazura's numbers are for the unsaturated acids only.

TABLE IV.

	Linseed.	Hemp.	Nut.	Poppy.	Cotton.
Iodine number calculated from Hazura's results	251	181·5	187	158	145
Iodine value of total acids ...	160-180	141	145	139	113

The calculated iodine value of oleic acid is 90; of linolic acid, 181·4; and of linolenic and isolinolenic acid, 274·1.

With regard to isolinolenic acid, Hazura and Grüssner inferred its existence solely from the oxidation-products formed; they did not obtain a bromo-derivative, and hence did not isolate the acid.

After making allowance for the presence of saturated fatty acids, it will be seen that there is an approximate correspondence between the calculated and the actual figures in the case of all but the linseed oil, which is said to contain about 15 per cent. of solid acids.

We have repeated some of Hazura's work, and have prepared some, at least, of the derivatives discovered by him, paying particular attention to the bromine-derivatives.

On adding a sufficiency of bromine to an ethereal or acetic acid solution of linseed fatty acids, kept at a temperature of about 5° C., an abundant precipitate immediately forms. Part of this is exceedingly insoluble, while a part can be washed away with ether. The insoluble portion is the hexabrom-derivative of Hazura, although the composition of the substance does not exactly correspond with the formula, even after extraction for days with ether.

Thus, in four separate experiments we obtained compounds with the following percentages of bromine :

	Found.	Theoretical.
1.	61·38	63·31
2.	61·47	
3.	61·80	
4.	61·64	

We found the melting-point from 180° to 181° C., while Hazura gives 177° C. We determined the percentage of bromine-derivative yielded by a considerable number of samples of linseed oil fatty acids, and found them to vary from 20 to 26 per cent. Hazura obtained from 100 parts of the fluid linseed oil acids 40 of hexabromide, having a melting-point of 177° C. We believe that his precipitates must have included a considerable proportion of tetrabromide, seeing that it is difficult to entirely wash the latter out, as the above analyses of the persistently washed products show.

After the hexabromide has been filtered off, precipitates are obtainable which contain upwards of 50 per cent. of bromine, the tetrabromide formula requiring 53·32 per cent. of bromine. The part remaining in solution, when recovered by the evaporation of the solvent, consists of a semi-solid mass, evidently a mixture of dibromide and tetrabromide. This we found to contain 45 per cent. of bromine, the pure dibromide requiring 36·18 per cent. The tetrabromide of Hazura can be much more readily obtained from maize oil fatty acids than from linseed. But here, again, the actual percentage of bromine, even after numerous crystallizations from alcohol, falls somewhat short of the theoretical amount. Our product contained 51·97 per cent. of bromine, against a theoretical 53·32 per cent. The melting-point was 113·4° C. (corr.), against Hazura's 114° to 115° C.

The dibromide we have not been able to obtain in a pure condition.

On boiling the hexa- and tetra-bromine compounds with alcoholic potassium hydroxide the bromine is entirely eliminated. Theory requires for complete elimination of the bromine from the hexa-compound 51·8 per cent. of potassium hydroxide. In four separate determinations 51·33, 51·61, 51·50, and 51·5 per cent. of potassium hydroxide were consumed. On liberating the free acids from the resulting alkali salts no crystallizable substances could be obtained, the products being viscid yellow oils, which did not dry after being exposed to the air for a week, and which were, therefore, neither the hydroxyacids, which result from oxidation by permanganate, nor the less saturated products which would have resulted from an elimination of 6HBr from the molecule. At the same time, the oil absorbed iodine from Hübl's solution to the extent of 61 to 63 per cent. After the titration of the excess of iodine added, the solutions rapidly became blue again from the further liberation of iodine. On re-bromination hydrobromic acid was evolved, and the original hexabromide was not reproduced. In this particular it behaved like the acids from boiled linseed oil.

The bromine can likewise be completely removed from the dibromides and tetrabromides by boiling with alcoholic potassium hydroxide, and the acids thus obtained are also oily fluids with low iodine absorption.

Hazura, by reduction of the hexa-bromide with zinc and hydrochloric acid, prepared linolenic acid, which, however, owing to its oxidizable nature, could not be obtained pure and with the theoretical iodine value. He found 245, as compared with the theoretical 274·1. We have also made efforts in this direction, taking every precaution to keep away oxygen, yet were not more successful, since the iodine absorption of our linolenic acid only reached 241·8. The acid obtained was a nearly colourless oil of a specific gravity 0·9228 at 15·5° C. (compared with water at the same temperature) which absorbed oxygen from the air with great rapidity and quickly became dark brown. On dissolving this linolenic acid in acetic acid and adding bromine, the hexabromide was produced, but not quantitatively, only 46 to 50 per cent. of the yield being obtainable; dense fumes of hydrobromic acid were given off. With the advance of oxidation in a linseed oil the yield of hexabromide decreases with the decrease in the iodine value. A linseed oil with an original iodine value of 160·7, with a yield of hexabromide of 22·5 per cent. (probably not quite pure hexa-compound) on the fatty acids, was heated on the water-bath for a day and air blown through at intervals. The iodine value of the fatty acids was 147·3, and the yield of insoluble bromo-compound obtained under precisely the same conditions as before was 16·7 and 15·9 per cent. respectively in two determinations. A sample of boiled linseed oil, with an iodine value of 115·2, gave absolutely no precipitate on treatment with bromine, but hydrobromic acid was evolved. It appears probable to us that the amount of hydrobromic acid produced will be found to be a measure of such oxidation as occurs during the "boiling" of linseed and other oils. It will be remembered that McIlhiney (ANALYST, xix., 141) has already made experiments, from which he deduces a method for the determination of resin-acids in linseed oil, based upon the elimination of hydrobromic acid on bromination.

We have also submitted the unsaturated fatty acids obtained from maize oil to oxidation with alkaline permanganate, and are in a position to entirely confirm Hazura's statements as to the composition and properties of sativic acid, except that the melting-point of our purest substance was 174°, instead of 173° as found by him.

Acting upon the fatty acids liberated from other oils with bromine, we found that almond oil, with an iodine value of 95·68, gave no solid product of any kind. Mixtures of almond and linseed oil acids yielded amounts of insoluble bromide corresponding very approximately to the percentage of the linseed oil acids present, provided the operations were always carried out under precisely the same conditions as to amount of acids taken, temperature, solvent used, and washing. Quantities of from 0·2 to 0·3 grammes of the fatty acids were dissolved in 10 c.c. of acetic acid and the solution cooled to 5° C. in a corked flask. Bromine was then added drop by drop until a permanent bromine colour was observed. After standing for three hours the liquid was filtered through a Soxhlet tube containing asbestos, and washed with chilled acetic acid, alcohol, and ether, in successive portions of 5 c.c. each. The residue, which was white, was dried in the water-oven to constant weight. Attempts to use

larger quantities of fatty acid were unsuccessful, owing to the difficulty of filtration and washing until colourless in a Soxhlet tube.

TABLE V.

Acids used.	Linseed Oil. Per Cent.	Insoluble Bromide, Per Cent.	Linseed Oil Acid calculated from Bromide.
Linseed oil	100	21	
Almond oil	0	0	0
Linseed + almond ...	7·9	1·62	7·7
,, ,, ...	8·7	1·97	9·3
,, ,, ...	20·2	4·24	20·1
,, ,, ...	37·5	7·53	35·3
Poppy oil	0	0	0
Poppy + linseed	18·3	3·35	16
,, ,, ...	37·3	8·17	38·9
Cotton-seed oil	0	0	0
Cotton-seed + linseed ...	43·3	8·43	40·1
,, ,, ...	60·1	11·6	55·2

It need hardly be said that poppy-seed and cotton-seed oil acids also furnish the tetrabromide, which, however, comes down more slowly than the hexabromide, and is more or less completely removed by washing the deposit. The deposit from poppy-seed oil acids melted at 112° C., and that from cotton-seed oil acids at 113° C.

Although the results stated in the preceding table are fairly satisfactory, yet the method is so empirical as not to commend itself. Moreover, when larger quantities of acids are operated upon, tetrabromide is apt to come down simultaneously with the hexa-compound, and to wash this free from the former considerable quantities of solvent are necessary, in which the hexabromide is not completely insoluble.

A more reliable method is to obtain the mixture of solid compounds, washing this but slightly in order to remove readily soluble dibromide, and then to determine the percentage of bromine in the dried and weighed precipitate. From the amount of bromine found it is easy to calculate the relative proportion of the hexabromide in the mixture by means of the formula

$$\frac{63{\cdot}3\,x}{100} \times \frac{(100-x)53{\cdot}3}{100} = m$$

or $10\,x = 100(m - 53{\cdot}3)$ or $x = 10(m - 53{\cdot}3)$, in which m equals the percentage of bromine found, x the required percentage of hexabromide, and 63·3 and 53·3 the respective percentage of bromine in the pure hexa- and tetra-compounds.

To illustrate this mode of working an outline of an experiment on linseed oil acids may be described. About 2 grammes of linseed oil acids (which by the method used in the experiments given in Table V. yielded from 20 to 23 per cent. of insoluble bromides) were brominated, but the deposit was washed with a far larger amount of acetic acid and ether than previously mentioned. By this washing the amount of deposit was reduced to 13 per cent., which melted at 179° C., and was therefore practically pure hexabromide. The filtrate and washings were allowed to concentrate spontaneously, whereby a further crystalline deposit amounting to 8·16 per cent. was

obtained. This deposit contained 58·8 per cent. of bromine, which, calculated by the formula given above, corresponds to 4·48 per cent. of hexabromide. Hence, the total percentage of hexabromide equalled 17·48. The filtrate from the second precipitate did not yield any further solid deposit, but only a heavy yellow oil.

This mode of operating may afford a solution of the problem of determining the relative percentages of oleic, linolic and linolenic acids in a mixture of fluid fatty acids, provided the saturated fatty acids are first separated. Further experiments on this important point will be carried out.

The idea naturally suggests itself to obviate the separation of the acids from oils and to operate upon the glycerides instead. When an oil, the fatty acids of which give insoluble bromine-compounds, is dissolved in ether or other suitable solvent, and bromine is added, there is an immediate precipitate produced, which is much more insoluble than the acid hexabromide; and consequently can be washed readily and efficiently. The precipitate can be collected either in a Soxhlet tube, if the quantity taken is small, or on a counterpoised filter, but we recommend the method of working which we employed for the estimation of stearic acid in mixtures of fatty acids (see ANALYST, vol. xxi., p. 322); but instead of filtering through cotton we find the best filtering material to be thin flexible chamois-leather tied over the end of the small thistle-funnel, from which any adhering precipitate can afterwards readily be removed by washing.

From 1 to 2 grammes of the glycerides are dissolved in 40 c.c. of ether, to which a few c.c. of glacial acetic acid are added, the precipitate forming being more granular from such a mixture than when ether alone is employed. The solution is cooled in an ice-chest and bromine added, the flask being preferably left all night in the ice. This, however, is not essential for ordinary working. The liquid is filtered off by the suction-funnel attached to a pump, the flask washed out with four successive portions of 10 c.c. of ether at 0° C., and the residue dried in the flask to constant weight. But even when ether at ordinary temperature is used, no considerable error is introduced.

Various samples of pure linseed oil were examined by this method, with the following results:

TABLE VI.

Sample.	Oil taken.	Weight of Precipitate.	Percentage of Deposit.
A	1·3226	0·3156	23·86
A	3·1005	0·7573	24·42
B	0·6792	0·1765	25·8
C	1·0000	0·2480	24·8
C	1·0000	0·2500	25·0

A sample of walnut oil gave, in two determinations, 1·9 and 1·42 per cent. of bromo-compound. Poppy oil (four specimens) gave no deposit, nor did brazil-nut oil, maize oil, cotton-seed oil, olive oil, Japanese wood oil, or almond oil. Mixtures of linseed oil and other oils gave percentages of bromine-compound in proportion to the percentage of linseed oil, as will be seen from the following table:

Oils Used.	Linseed Oil, Per Cent.	Insoluble Bromide, Per Cent.	Linseed Oil calculated from Bromide.
Linseed A and walnut ...	69	16·6	69
,, ,, ...	38·2	9·3	38·1
Linseed A and maize oil...	52	12·4	50·8
,, ,, ...	50·5	12·2	50·0
,, ,, ...	51·7	12·6	51·6

It will be seen from the above figures that the determination of the amount of the precipitate can usefully serve for testing the purity of unoxidized linseed oil. More extended investigation as to the variation in the proportion of the precipitate-yielding substance would, of course, be necessary, although as far as we have gone the variation appears to be small.

Considerable interest is attached to the nature and composition of the insoluble bromine-compound. From its origin it cannot be identical with the acid hexabromide; this is also shown by its melting-point, which is from 143·5° to 144° C., against hexabromide (177° C., Hazura; 180° C. to 181° C., Hehner and Mitchell). If it were hexabromo-linolenic glyceride, it would contain 62·28 per cent. of bromine. It cannot be linolic tetrabromo-glyceride with 52·23 per cent. bromine, since maize oil does not furnish any insoluble compound, while the free acids readily yield large amounts of the acid tetrabromo-derivative. We have made a considerable number of bromine determinations, which gave remarkably constant results. In various preparations we found 56·38, 55·7, 56·38, 56·32, 55·55, 56·17, and 56·32 per cent. bromine. This percentage is too low for the hexabromo-glyceride and too high for the tetrabromo-compound. Dr. Streatfield, of the Finsbury Technical College, was kind enough to make carbon and hydrogen determinations of a specimen of the material. Its ultimate composition was as follows:

Carbon	32·97
Hydrogen	5·42
Bromine	56·18
Oxygen	4·44
Ash	0·99
	100·00

Calculated for the ash-free material, the composition is as follows:

Carbon	33·29
Hydrogen	5·48
Bromine	56·74
Oxygen	4·49
	100·00

We are inclined to attribute to the bromo-compound the formula $C_{57}H_{96}O_6Br_{14}$, which would require:

Carbon	34·27
Hydrogen	4·81
Bromine	56·11
Oxygen	4·81
	100·00

It must be remembered that the substance, on account of its insolubility, could not be purified by crystallization. In addition, the presence of mineral matter, probably derived from the oil itself, would tend to make deductions from the results still more uncertain. The percentage of bromine in the substance strongly points towards a mixed bromo-ester, and we suggest, very tentatively, the following formula:

$$C_3H_5\begin{cases}C_{18}H_{29}O_2Br_6\\C_{18}H_{29}O_2Br_6\\C_{18}H_{33}O_2Br_2,\end{cases}$$

which, however, cannot be definitely accepted until a perfectly pure specimen has been examined. We are the more inclined towards a mixed glyceride formula, since the existence of such mixed esters has been fairly well proved in the case of butter-fat, and also because it is impossible to separate, even by persistently carried out recrystallization, the stearin from palmitin contained in animal fats. When, on the other hand, the glycerides are broken up by saponification, the separation is readily effected, and from the fatty acids separated from linseed oil a nearly pure hexa-bromide is readily obtained.

We have also made experiments with other classes of oils. Thus the acids of rape oil, which contains rapic acid, $C_{18}H_{34}O_3$ (which, unlike ricinoleic acid, does not appear to be a hydroxy-acid), yielded with bromine 3·6 per cent. of an insoluble bromo-acid containing 58·6 per cent. of bromine, and having a melting-point of 179° C. It was, therefore, neither the hexa- nor the tetrabromo-compound of Hazura. Rape oil itself gave 0·9 per cent. of insoluble precipitate only; this was not further examined. The similar mustard-husk oil gave a fine granular precipitate amounting to 1·5 per cent.

Some of the marine animal oils approach linseed oil in many of their properties, especially in their iodine absorption. It is interesting to note that the (impure) linolenic acid which we prepared from linseed oil had a marked odour of fish oil, and that pure linseed oil, when heated in steam, often emits a similar fishy smell.

The free acids prepared from cod-liver oil gave on bromination a white precipitate, which, when dried in the water-oven, became dark brown. It amounted to 18 per cent., and contained 62·91 per cent. of bromine (theory requires for the hexa-compound 63·31 per cent.). The air-dried substance had no definite melting-point, but decomposed below 200° C. Attempts were made to determine its melting-point in a sealed tube, but these also yielded no results.

The cod-liver oil itself (the glyceride) yielded with bromine an immediate precipitate, consisting partly of a solid substance, and partly of a heavy oil, which was difficult to separate from the former. Eventually a perfectly white solid substance was prepared, which amounted to 42·9 per cent. and contained 56·32 per cent. of bromine. It had no sharp melting-point, decomposition taking place before fusion occurred. Cod oil behaved in an analogous manner, yielding 35·5 per cent. of insoluble compound, which was not further examined.

Shark oil, similarly, gave 22 per cent. of a bromine-compound, and whale oil 25 per cent.

The investigations of Hazura, both as regards the hydroxy-derivatives and the

bromine compounds of the unsaturated fatty acids, are of such great importance that it seems surprising so little has been done by other observers since the publication of his papers. We trust that our small contribution to the subject will cause others to pursue research in this direction. We have already indicated in several places starting-points for further work, and we are convinced that valuable additions to our scanty knowledge of the unsaturated fatty acids would result. If our supposition of the existence of a compound glyceride of the unsaturated fatty acids be confirmed, it would probably furnish an explanation of the different properties of oils possessing similar chemical constants.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Pumpkin-seed Oil and its Adulterants. H. Poda. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 625-628.)—This oil (*Oleum cucurbitæ*) is used in Austria and Hungary for dietetic purposes in place of olive oil, to which it comes next in price. Its usual adulterants are linseed oil, sesame oil, cotton-seed oil, and rape-seed oil. Such sophistication can be detected by comparing the iodine and refractometer numbers, the specific gravity and melting-points of the fatty acids. Two samples of the pure oil prepared by the author gave the following results:

	Description.	Iodine Number.	Saponification Number.	Refractometer Number at 25° C.
Oil I.	Cold pressed ...	124·49–123·91	189·31–189·51	70·2
	Hot pressed ...	123·69–122·85	189·24–189·37	71·4
Oil II.	Cold pressed ...	125·12–125·13	189·93–189·99	71·1
	Hot pressed ...	124·31–124·76	189·56–189·62	72·0

In the author's opinion pure samples should give results between the following limits:

Specific Gravity.	Iodine Number according to Hübl.	Saponification Number.	Melting-point of the Fatty Acids.		Refractometer Number at 25° C.
			Beginning.	Ending.	
0·923–0·925	122·76–130·68	188·36–190·17	26·5–28·5	28·4–29·8	70·0–72·5

Methoxyl Determination applied to the Examination of Resins, Balsams, and other Drugs. G. Gregor. (*Oesterreich. Chem. Zeit.*, 1898, 253, 254, and 288-290.)—The author has recently published a modification of Zeissel's method for the determination of methoxyl (*Monatshefte für Chemie*, xix., 116; ANALYST, this vol., 297). In the present paper he gives the methyl numbers of certain resins, balsams, and drugs as furnished by his method. In the first of the following tables,

Bamberger's results are given side by side with those obtained by the author for the sake of comparison :

RESINS AND BALSAMS.

No.	Description of Resin or Balsam.	Methyl Number.

TOXICOLOGICAL ANALYSIS.

Micro-Chemical Identification of Spermatic Fluid Stains. C. Kippenberger. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 602.)—The identification of traces of seminal fluid by means of the spermatozoa being not always possible, the author has investigated the method of Florence, depending upon the reaction with iodine and potassium iodide, with the view of its application to forensic work, and finds that this must be accepted with considerable reserve. The reagent is a solution of 1·65 grammes of potassium iodide and 2·54 grammes of iodine in 30 c.c. of distilled water. On mixing an aqueous extract of seminal fluid with this reagent, crystals of a dark-brown colour, varying in form from long-shaped rhombic tables to fine needles, are produced. The crystals vary somewhat in size, as well as in form, and are soluble in excess of the reagent, and in ether, alcohol, acids, and alkalies. The method of employing the test is as follows: An extract is first made by warming the stains or fluid with a little water on the water-bath. The extract is then acidified with hydrochloric acid, cooled, and dry ammonium sulphate added. which causes a separation to occur. The fluid is then filtered, a few drops of the filtrate mixed with the reagent and the mixture examined under the microscope.

The researches of Richter (*Wiener Klin. Wochenschrift*, 1897, 569) and of Lecco (*Wiener Klin. Wochenschrift*, 1897, 820) led to the supposition that the constituent giving rise to the reaction was cholin, either normally present in small quantities or produced by the decomposition of lecithin, a recognised constituent of the seminal fluid. The author's experiments do not confirm this, but lead rather to the conclusion that the reaction is due to xanthine bodies and to creatinine. Further, the author is not able to confirm the statement of Florence that the reaction is only obtained with human seminal fluid. Experiments with the seminal fluid of bulls, rams, gazelles, camels, foxes, asses, dogs, amphibious animals, and birds, all resulted in the characteristic reaction, though slight differences were observable in certain cases. Contrary to Posner's experience, the author finds that seminal fluid which has become putrid still gives the reaction, and this applies also to old stains.

With regard to other animal secretions, menstrual fluid, and, in one case, normal blood, gave a very similar reaction, which might be mistaken for the reaction with seminal fluid. Normal saliva and saliva from tuberculous persons gave negative results, as also did pus, unless mixed with blood. No reaction was obtained with urine, but, as this excretion contains small quantities of both xanthine bodies and creatinine, it is probable that the reaction would be obtained by the use of large quantities or of an extract. H. H. B. S.

ORGANIC ANALYSIS.

The Freezing-point of Glacial Acetic Acid. J. C. Umney. (*Pharm. Jour.*, 1898, 242.)—In the British Pharmacopœia of 1885 glacial acetic acid was described as containing "nearly" 99 per cent. by weight of hydrogen acetate. In the new Pharmacopœia (1898) the strength of the acid is given as 99 per cent., and it is provided that the acid shall have a specific gravity of 1·058, and that it shall remain solid until the temperature rises above 60° F. (15·5° C.).

The author points out that this solidification-temperature is not in agreement with the percentage. Rudorff (*Pharm. Jour.*, Series 3, ii., 241) states that the strength of glacial acid can be estimated with greater accuracy by determining the freezing-point than by titration with alkali, and gives the following table:

100 Parts of Mixture.			Solidifying Point. ° C.
Containing 0·0	of water	... ...	16·7
,, 0·497	,,	... ...	16·65
,, 0·99	,,	... ...	14·8
,, 1·477	,,	... ...	14·00
,, 1·961	,,	... ...	13·25

From this it is evident that glacial acetic acid containing actually 99 per cent. of hydrogen acetate does not remain solid above 14·8° C.

According to the U.S.A. Pharmacopœia, glacial acid contains 99 per cent. of absolute acid, solidifies somewhat below 15° C., and becomes liquid again at about 15° C.

The commercial importance of this apparently trivial point is shown by the fact that glacial acid is admitted into New Zealand at an *ad valorem* duty of 20 per cent.,

but if the acid falls below the British Pharmacopœia standard, 5d. per lb. duty has to be paid, or about five times as much as the proper duty. The New Zealand Customs have hitherto based their decision as to the strength of the acid on its liquefying-point after freezing, and regarding the statement of the British Pharmacopœia as absolutely accurate, they charge the 5d. per lb. duty on all acid melting below 15·5° C.

C. A. M.

Estimation of Formic Acid in Presence of Acetic Acid and Readily Oxidisable Organic Bodies. A. Leys. (*Ann. et Rev. Chim. Analyt.*, vol. iii. [8], pp. 255-260.)—The method is based on the reduction of mercuric acetate to the mercurous salt.

In the case of liquids containing acetic and formic acids, the total acidity is first determined in terms of the former. If the relative proportion of formic acid is very low, the liquid is diluted until the acidity measures 20 to 30 per cent.; but if the ratio is as 1 : 20 of acetic acid, dilution to 2 per cent. of acidity is necessary.

Ten c.c. are then taken, mixed with 20 to 30 c.c. of a 20 per cent. solution of mercuric acetate, and made up to 100 c.c. with water, the whole being heated to boiling-point within seven or eight minutes, and then immediately set aside to cool until the following day. The brilliant white crystals of mercurous acetate deposited are filtered through glass wool, brought on to the filter, then washed with 95 per cent. alcohol, acidified with 2 per cent. of glacial acetic acid (to prevent decomposition of any residual mercuric acetate), and finally with neutral 95 per cent. alcohol. After removing the alcohol by anhydrous ether, and evaporating the latter, preferably *in vacuo*, the precipitate is dissolved as rapidly as possible in nitric acid diluted with its own volume of water, and an aliquot part of the solution is precipitated with sodium chloride, the mercurous chloride being then weighed after drying at 100° C. The weight multiplied by the factor 0·0976 gives the corresponding amount of formic acid. Drying should not be prolonged more than is absolutely necessary, or a loss of weight, due to volatilization, will occur.

When the liquid under examination contains alcohol in addition to formic acid, 2 c.c. of glacial acetic acid must be added to the test sample before adding the mercuric acetate, to prevent precipitation of the latter. Should the proportion of alcohol be relatively high, the crystals of mercurous acetate formed may be granular and dense, instead of the fine scales obtained in the first-named case.

If both alcohol and acetic acid (the latter in sufficient amount) are present in the liquid, then no further addition of this acid is necessary.

The method is also applicable in presence of acetic and formic aldehyde, and is recommended by the author for the estimation of formic acid in natural spirits and commercial formaldehyde, as well as for the titration of formaldehyde after oxidation.

C. S.

A Very Sensitive Test for Bromine in Urine. A. Jolles. (*Zeit. anal. Chem.*, 1898, xxxvii., 439-440.)—This test is based on the fact observed by the author that, on treating a hot acid solution of urine with permanganate, any bromine compounds

present are decomposed with the liberation of free bromine, which can be readily identified by means of *p*-dimethyl-phenyl-diamine paper. This is prepared by dipping filter-paper into a solution (0·5 gramme in 500 c.c.) of the hydrochloride of *p*-dimethyl-phenyl-diamine, and leaving it to dry. This substance gives with bromine a red colouring matter, the probable composition of which is $NH : C_6H_4 : N(CH_3)_2Br$, and which, in the solid condition, has a metallic, green glittering appearance. The reagent-paper, when brought into contact with bromine vapour, gives a violet coloration in the centre, while the edges are blue, gradually changing into grey, and finally into brown. The reaction is extremely sensitive, and is capable of detecting 0·001 gramme of sodium bromide in 100 c.c. of urine.

The corresponding iodine reaction is much weaker, and the coloration of the paper (yellowish brown) is quite distinct, so that traces of bromine can readily be detected in the presence of large quantities of iodine. Chlorine, too, gives a very feeble reaction, which does not interfere with the bromine reaction.

The test is made in the following manner: 10 c.c. of the urine are acidified with sulphuric acid, and an excess of potassium permanganate is added. The flask is warmed on the water-bath, and a moistened strip of the reagent-paper placed in the neck of the flask.

The fluorescein-paper recommended by Baubigny (ANALYST, this volume, 23) is also very suitable for the detection of bromine liberated from urine by means of permanganate. C. A. M.

On the Coagulation of Albumin. G. Halphen. (*Jour. Pharm. Chim.*, 1898, viii., 173-175.)—In order to assist the coagulation of albumin in solutions of pepsin and in urine, the author has made experiments on the addition of ammonium salts. He finds that salts of ammonium, such as the chloride and the citrate, accelerate the coagulation of albumin. A sufficient quantity of a 10 per cent. solution are added to the albuminous solution before boiling, and the precipitate collected on a weighed filter, washed, dried, and weighed. C. A. M.

The Detection of Pyramidon (Dimethyl-amido-antipyrine) in Urine. A. Jolles. (*Zeit. anal. Chem.*, 1898, xxxvii., 441-442.)—Pyramidon is an antipyrine-derivative which has recently been prepared and recommended by Filehne (*Berlin Klin. Wochens.*, 1896, 48). It gives a characteristic bluish-violet coloration with ferric chloride, which, like the analogous red colour given by antipyrine, rapidly disappears. A fugitive violet coloration is also produced by it on treatment with a nitrite and sulphuric acid. The test which the author has worked out for its detection in urine is based on the fact that it is oxidized by halogens with the production of a violet coloration. The blue colour yielded with an alcoholic solution of bromine soon fades, but that obtained with an alcoholic solution of iodine changes after some time to red. Hydrogen peroxide gives a blue colour on warming; the action of permanganate is too energetic, and a colourless compound results which no longer reacts with halogens. Weaker oxidizing reagents, such as arsenic acid and alkaline copper solution, do not give a blue coloration. The behaviour of pyramidon towards the halogens is to be

chiefly attributed to the presence of the dimethyl-amido group, which, as has often been observed, readily reacts with oxidizing agents.

Most of these reagents give no characteristic results with pyramidon in urine. Ferric chloride produces the violet colour, but less markedly than in aqueous solution. On the other hand, alcoholic iodine is very sensitive, and by testing the urine with a very dilute solution (10 per cent. iodine solution diluted with 9 volumes of water) there is formed on the surface of the liquid a sharp violet red ring, which on standing changes to reddish-brown. The author finds that when pyramidon is taken in doses of 0·2 gramme twice a day it is readily detected in the urine by means of this test.

C. A. M.

Detection of Carbon Monoxide in Confined Air. F. Jean. (*Ann. et Rev. Chim. Analyt.*, vol. iii. [8], pp. 260, 261.)—The Marmet permanganate reagent being liable to reduction by other agencies than carbon monoxide present in samples of air, the author prefers to draw the air through a tube containing cuprous chloride solution, which, in presence of the monoxide, deposits a characteristic red precipitate.

C. S.

The precipitate thus formed is according to Berthelot (*Ann. Chem. Pharm.*, xcviii., 392) probably $Cu_2Cl_2.CO.2H_2O$.—Ed.

The Volumetric Estimation of Certain Alkaloids as Higher Periodides. A. B. Prescott and H. M. Gordin. (*Jour. Amer. Chem. Soc.*, 1898, xx., 706-724.)—By adding a solution of iodine in potassium iodide to a solution of an alkaloidal salt, the lowest periodide (in most cases a tri-iodide) is generally formed; if the iodine be kept in excess the highest periodide is formed. Of these latter some are stable and can be recrystallized, while others readily decompose in solution into free iodine and lower periodides. Atropine enneaiodide belongs to the first class; strychnine and brucine heptaiodides to the second. The only periodide of morphine which the authors could obtain was the tetraiodide already prepared by Jörgensen. Aconitine yielded (probably) a tri-iodide and a heptaiodide.

The formulæ and iodine factors of the higher periodides so far determined are:

	Ratio of Alkaloid to 1 of Iodine.	Alkaloid Factor of 1 c.c. of $\frac{N}{10}$ Iodine Solution.
Atropine, $C_{17}H_{23}NO_3.HI.I_8$ ...	0·2849 ...	0·0036048
Strychnine, $C_{21}H_{22}N_2O_2.HI.I_6$ ...	0·4390 ...	0·00555467
Brucine, $C_{23}H_{26}N_2O_4.HI.I_6$ ...	0·5179 ...	0·00655299
Morphine, $C_{17}H_{19}NO_3.HI.I_9$ ...	0·74918 ...	0·00947937
Caffeine, $C_8H_{10}N_4O_2.HI.I_4$ (Gomberg)	0·3834 ...	0·00485

The general method to be followed in estimating the strength of an aqueous solution of an alkaloidal salt is as follows: To about 10 c.c. of $\frac{N}{10}$ iodine solution, diluted with a little water, is added 1 c.c. of the acidulated alkaloidal solution, and the mixture well shaken for a few minutes. If the clear supernatant liquid does not retain a dark-red colour after the separation of the precipitate, the alkaloidal solution is too strong and must be diluted. When the right dilution has been ascertained, the acidulated alkaloid solution is made up to definite volume, and 10 to 15 c.c. of it run from a burette into a graduated vessel containing 25 to 30 c.c.

of $\frac{N}{10}$ iodine solution, diluted with a little water. The mixture is made up to definite volume and shaken, until the supernatant liquid is clear and of a dark-red colour. If not, the determination must be recommenced with a larger excess of iodine, as an addition of more of the iodine solution to the same mixture is out of the question, since the lower periodides when once formed might not take up more iodine. With morphine, which only forms one periodide, this precaution is unnecessary. When perfectly clear, an aliquot portion of the liquid is filtered off and the excess of iodine determined with standard sodium thiosulphate. Thus the quantity of iodine multiplied by the "ratio of the alkaloid to 1 of iodine" gives the quantity of the alkaloid in question.

The authors state that they have obtained satisfactory results by this method, in the determination of the total alkaloids in nux vomica and belladonna after extracting them with various solvents. They also confirm the accuracy of Gomberg's method of determining caffeine (ANALYST, vol. xxi., 193). C. A. M.

Notes on Taka Diastase. W. E. Stone and H. E. Wright. (*Jour. Amer. Chem. Soc.*, 1898, xx., 639-648.)—The authors have made a series of experiments on the action of taka diastase (ANALYST, this volume, 108) on potato-starch as compared with that of malt diastase. They found that its action at the outset was more rapid, the blue colour of the starch with iodine changing almost immediately to reddish and violet tints, while the starch paste was very rapidly liquefied. On the other hand, the complete conversion of the starch into compounds which no longer gave colour reactions with iodine was effected much earlier by the malt diastase, this final result being scarcely attained by the taka diastase after several hours. Parallel experiments, in which the solutions were examined with the polarimeter at stated intervals, showed that the products of the action of taka diastase had invariably a lower specific rotation than those from malt diastase, which the authors attributed to the more rapid conversion into maltose.

These results being unfavourable to the use of taka diastase in place of malt diastase in the quantitative determination of starch, the authors made further experiments with different materials in which a starch estimation is commonly required. One gramme each of air-dried finely-ground wheat, maize, and potato were heated to the boiling-point during thirty minutes with 50 c.c. of water. After cooling to 60° C., 10 c.c. of malt infusion were added to each, and the temperature maintained at 60° C. A second series was prepared in the same way, to each of which was added 0·05 gramme of taka diastase, and a third series in which the quantity added was 0·1 gramme, the temperature being maintained at 40° C. After four and a half hours all were tested with iodine, and it was found that in those treated with malt infusion the whole of the starch had disappeared from the potato, while the wheat and maize still showed traces under the microscope. In those treated with taka diastase all showed an abundance of unchanged starch. After seven hours the samples treated with malt infusion were quite free from starch, but the taka diastase samples still contained a large quantity, and even after an additional twelve hours' treatment the starch reaction had not disappeared.

As a further test, duplicate quantitative determinations were made of the starch contained in a specimen of air-dried wheat, the solvent in the first instance being a freshly-prepared infusion of malt, and in the second a solution containing 0·05 gramme of taka diastase. In each case the sugar was determined by titration with Fehling's solution, and the results calculated to starch. The treatment with malt extract gave 55·46 per cent. of starch, while the determination by means of taka diastase gave 52·94 per cent.

From these experiments, the authors conclude that under the usual conditions of the analysis taka diastase is unsuitable for the quantitative determination of starch.

C. A. M.

The Quantitative Estimation of Proteids. H. Schjerning. (*Zeit., anal. Chem.*, 1898, xxxvii., 413-422.)—In this paper the author sums up the results of his previous communications, and embodies them in a complete method for the estimation of proteid substances in solution (*cf. Zeit. anal. Chem.*, xxxiii., 263; xxxiv., 135; xxxv., 285; and ANALYST, 1898, 105 and 185).

The reagents required are:

1. A solution of tin chloride prepared by dissolving 50 grammes of tin in a weighed flask containing a sufficient quantity of boiling concentrated hydrochloric acid and a little platinic chloride. The solution is evaporated down to about 130 grammes, made up to a litre, and filtered.
2. A solution of normal lead acetate containing about 10 per cent. of the salt, and 10 to 12 drops of 45 per cent. acetic acid in a litre.
3. A 5 per cent. solution of mercuric chloride.
4. Pure, dry ferric acetate.
5. Dilute acetic acid containing 15 c.c. of 45 per cent. acid in a litre.
6. A solution of pure uranium acetate (about 10 per cent.), free from ammonia.
7. Pure, crystallized magnesium sulphate.
8. A solution of ordinary sodium phosphate, containing 0·4 per cent. of the crystallized salt.
9. A solution of calcium chloride (about 10 per cent.).

The solution of the proteids is first diluted so that 10 c.c. contains a quantity of total nitrogen corresponding with about 5 c.c. of decinormal acid. Under some conditions the precipitations are readily made, but when the solution contains little or no ash, it is necessary to add mineral matter (solutions 8 and 9). In order to determine whether this addition is required, the following test is made: If the number of c.c. of the proteid solution, which correspond with about 10 c.c. of $\frac{N}{10}$ acid, do on boiling not completely precipitate the iron from a solution of 0·8 grammes of ferric acetate dissolved in 40 c.c. of dilute acetic acid (reagent 5) and 50 to 100 c.c. of water, the proteid solution must be regarded as poor in ash, and the precipitations by tin, lead, and iron must be made after the addition of mineral matter (reagents 8 and 9).

The Tin Chloride Precipitation.—About 5 c.c. of the tin chloride solution (reagent 1) are added to 25 c.c. of the proteid solution. After stirring well, the

beaker is covered with a glass and left for from six to twenty hours. The precipitate is then collected on a filter and washed with cold water. If the proteid solution is poor in ash, 10 c.c. of calcium chloride solution (reagent 9) are added before the tin chloride, and the precipitate washed with a cold 1 per cent. solution of calcium chloride.

The Lead Precipitation.—To 25 c.c. of the proteid solution are added a sufficient amount of the lead acetate solution (No. 2), the amount varying with different substances. Care must be taken that the excess of lead is not too great, or part of the precipitate may be redissolved. After adding the reagent, the liquid is boiled, and the precipitate collected and washed with cold water. If the proteid solution contains little ash, sodium phosphate solution (No. 8) is added in the proportion of about three volumes to each volume of the lead acetate solution used, before boiling. Since the lead precipitate is somewhat soluble in the precipitating reagent, a correction is necessary, which the author has determined experimentally to correspond with 0·15 c.c. of $\frac{N}{10}$ acid for each 100 c.c. of filtrate and washings.

The Mercuric Chloride Precipitation.—Five c.c. of the mercuric chloride solution (No. 3) are added to 25 c.c. of the proteid solution, the liquid allowed to stand from four to twenty hours at the ordinary temperature, the precipitate filtered off and washed with a cold 0·5 per cent. solution of mercuric chloride, and the nitrogen it contains determined by Kjeldahl's method.

The Iron Precipitation.—0·8 gramme of ferric acetate is dissolved in 40 c.c. of the dilute acetic acid (reagent 5), and 50 to 100 c.c. of water in a beaker, and the solution heated to boiling, with constant stirring. 20 c.c. of the proteid solution are then added, and the liquid again brought to the boiling point. The precipitate is filtered off and washed three or four times with boiling water. The filtrate should be quite clear, and if this is not the case, an addition of from 15 to 25 c.c. of the sodium phosphate solution should be made immediately after the second boiling, the liquid being in the meantime stirred and kept boiling. With a little practice the right amount of sodium phosphate can be estimated. 20 c.c. have no injurious effect if these directions are followed, and only in exceptional cases is it necessary to add greater quantities (at most 25 c.c.).

The Uranium Precipitation.—25 c.c. of the proteid solution are mixed with 20 to 25 c.c. of the uranium acetate solution, the liquid heated to the boiling-point with constant stirring, and allowed to stand for some hours, or until the following day, in a dark place. The precipitate is washed with a cold 1 to 2 per cent. solution of uranium acetate. The correction necessary for the solubility of the precipitate corresponds with 0·10 c.c. of $\frac{N}{10}$ acid for each 100 c.c. of filtrate and washings.

The Magnesium Sulphate Precipitation.—Five or six drops of 45 per cent. acetic acid are added to 20 c.c. of the proteid solution, and the beaker placed in a water bath, which is kept at a temperature of from 33° to 36° C. From 18 to 20 grammes of finely powdered magnesium sulphate ($MgSO_4 + 7H_2O$) are added, with constant stirring, and the liquid allowed to stand for thirty minutes to one hour at the ordinary temperature, a stir being given from time to time. The precipitate is filtered off and washed with a cold saturated solution of magnesium sulphate containing 4 to 5 grammes of 45 per cent. acetic acid per litre.

The relation of the several precipitates is given in the following scheme:

Precipitate.		Contains the Proteids.	Precipitate.	Contains the Proteids.
Tin Chloride = *a*		Albumin I		Albumin I
Lead Acetate / Mercuric Chloride	= *b*	Albumin I, Albumin II, Denucleïn	Uranium Acetate = *d*	Albumin II, Denucleïn, Propeptone, Peptone
Ferric Acetate = *c*		Albumin I, Albumin II, Denucleïn, Propeptone	Magnesium Sulphate	Albumin I, Albumin II, Propeptone

The quantity of the different groups of proteids can thus be readily determined, as was shown in a former communication. The proteids precipitated by lead acetate and mercuric chloride are identical, but as the mercury usually gives more satisfactory results than the lead, the latter need only be used in exceptional cases. The author concludes his paper with tables of the results obtained with solutions of various kinds of proteids which are very similar to those given in his former paper. C. A. M.

The Analytical Methods of distinguishing the Nitrogen of Proteids from that of Amides. J. W. Mallet. (Bulletin 54, United States Department of Agriculture.)—The author has investigated various methods which have been proposed for separating these two classes of bodies, such as dialysis; interaction with nitrous acid; treatment with permanganate in presence of free alkali or acid; with sodium hypobromite; behaviour with cupric hydroxide; precipitation by alcohol; the behaviour of several new or little-used reagents, such as phenol, trichlor-acetic acid, formaldehyde, etc.; of tannin; and also that of phosphotungstic acid. This last reagent proved in most cases the most reliable one, and when applied under proper conditions afforded satisfactory results, though in certain cases tannin was found to be the preferable reagent. Some of the special facts on which the application of phosphotungstic acid depends are new, and the particular use made of these points of behaviour has not been hitherto described. The assumptions of Stutzer, that the proteids and allied substances are precipitated by phosphotungstic acid, and that the amides are not precipitated, must be qualified. Thus peptones are incompletely precipitated, while flesh-bases, such as creatine, creatinine, etc., are fully precipitated. Some substances also of an amidic nature give precipitates which are almost insoluble in water, but the solubility of which is much increased by rise of temperature. It was found that the substances experimented with might be divided into the three following classes:

(*a*) Those which, even in pretty strong solutions, give no precipitate with phosphotungstic acid.

(*b*) Those which are precipitated in strong solutions, the precipitate redissolving with more or less ease on heating the liquid (or on treating the precipitate with hot water) and reappearing on cooling.

(*c*) Those which are precipitated, the precipitate not being sensibly soluble, and

the supernatant liquid remaining clear on being heated along with the precipitate and subsequently cooled.

Under the first head fall glycocine, alanine, leucine, asparagine, aspartic acid, tyrosine, and allantoin; under the second, glutamine, creatine, creatinine, hypoxanthine, carnine, and urea. The precipitate given by peptone becomes clotted on heating, and dissolves to a considerable extent, being reprecipitated on cooling. Under the third head are included egg-albumin, fibrin, casein, legumin, globulin, vitellin, myosin, syntonin, hæmoglobin, albumose, gelatin, and chondrin.

The following amidic substances yielded precipitates with phosphotungstic acid, which were found to be soluble in hot water in the following proportions: That from betaine, 1 part in 71 parts of water at 98·2° C.; creatine, 1 : 107 parts at 98·1°; creatinine, 1 : 222 at 97·9°; hypoxanthine, 1 : 98 at 97·6°; carnine, 1 : 132 at 98·4°. It seemed possible, by precipitating with phosphotungstic acid, and washing the precipitate with hot water, to separate the amidic substances from all proteid and proteid-like bodies, except the peptones. These last are, according to most authorities, completely precipitated by tannin; hence this reagent disposes of the one case unprovided for by phosphotungstic acid.

The precipitants employed were 5 and 10 per cent. solutions of phosphoduodecitungstic acid in 2·5 per cent. hydrochloric acid, and 5 and 10 per cent. aqueous solutions of tannic acid.

The method proposed is given below nearly in the author's own words. It is stated, for the sake of simplicity, first as applied to the analysis of meat, raw or cooked, and the variations required in the examination of other classes of food materials are given afterwards.

A carefully selected and accurately weighed sample is to be ground in a glazed porcelain mortar with as much sharp-edged siliceous sand, previously heated to redness with free exposure to air, or with as much hard glass in small, sharp splinters similarly ignited, as will suffice to thoroughly subdivide the tissue and reduce it to the condition of a smooth pulp. Of this pulp, very carefully mixed, so as to insure uniformity, two aliquot parts are to be taken. In one the total nitrogen is to be determined by the well-known Gunning-Kjeldahl process, using a rather large proportion of sulphuric acid, so that no previous drying of the sample is needed. The other part is to be digested with cold water, filtered on to a nitrogen-free filter, and the residue washed on the filter with water at the same low temperature as long as it gives up soluble matter in sensible amount. Cold water is used to avoid action on and extraction of the gelatinoids. Creatinine is quite easily dissolved, as is also sarcosine; creatine with tolerable facility. Xanthine, hypoxanthine (1 : 300), and carnine (1 : 312), are less soluble.

The filtrate is then to be slightly acidified with acetic acid, heated to about 90° C., and again filtered from any coagulum. A little more sand or pulverized glass may with advantage be stirred in before bringing it on to the filter the second time.

To this second filtrate is to be added an acidified solution of phosphotungstic acid as long as a precipitate continues to form, avoiding any very large excess of the reagent. With a moderate amount of sand or pulverized glass added, to prevent the formation of a dense clot, the liquid and precipitate are to be heated to about 90° C.,

filtered, and the precipitate washed thoroughly on the filter with water at about the same temperature.

Assuming now that nitrogen is present in the sample under examination only in the two forms of proteids and simpler amidic compounds, the three filters used and their contents are to be submitted to the Gunning-Kjeldahl process. By subtraction of the nitrogen found from the total nitrogen previously determined, the amount of this element present in the simpler amidic compounds will be obtained.

In cases involving the presence of ammonia or its salts, nitrates, or alkaloids, the nitrogen occurring in these forms must be deducted from the total nitrogen before recording the residue as nitrogen of the simpler amides and amido-acids. In like manner a separation of lecithin, when present, may be effected by the use of ether as a solvent, followed by a mixture of ether and alcohol, in order to secure a complete extraction. A determination of phosphorus is made the basis of a calculation of lecithin-nitrogen, and this is in turn subtracted from the total nitrogen found.

When peptones are present, these are to be precipitated by tannic acid from the solution which has been acidified with acetic acid and heated. After this has completely cooled down, and before adding phosphotungstic acid, the filter on which the tannic acid precipitate is collected and washed with cold water is, with its contents, to be submitted to the modified Kjeldahl process, and the nitrogen obtained reckoned as part of the proteid nitrogen.

The several filters and precipitates from which the proteid nitrogen is obtained may either be treated separately by the Kjeldahl process, or, preferably, may all be brought together and submitted to this process in a single operation. If the latter course be pursued, it will be well to introduce each filter with its contents as soon as washed into the strong sulphuric acid, so as to avoid any possible decomposition and loss of nitrogen as ammonia until all the filters have been brought together and the moist combustion process can be proceeded with.

When proteoses are present, it may be well to make a check determination of their amount by saturation of the aqueous solution (after acidification with acetic acid, heating and subsequent cooling) with zinc sulphate, determining nitrogen in the precipitate so formed by means of the Kjeldahl process.

When gelatinoids are present, as may be the case with soups, stews, and meat extracts, hot water may be used at once for solution or washing the original material, and this with the advantage of facilitating the extraction of the less soluble simpler amides and amido-acids. These are, as a rule, more easily dissolved in the presence of a little free acid; hence acidification at an early stage of the treatment is advantageous. In a case in which tyrosine might be present, as in some vegetable materials, and possibly among unabsorbed residua of food, the use of hot water and the presence of free acid would greatly increase the solubility of this substance.

In food of vegetable origin where much starch is present it will be better to avoid the use of hot water at first, so that the solution may not be loaded with viscid material, rendering filtration difficult.

In all cases in which the food material to be examined is already fluid from the presence of water—as, for instance, soup, milk, and the like—filtration will of course at once be resorted to, being almost always much facilitated by the addition of sand

or pulverized glass, and only such further quantity of water will be used as is required for washing the undissolved matter left upon the filter.

In the presence of fat in large quantity it may be well first to remove this, or most of it, by extraction with ether. The simpler amidic substances are, as a rule, insoluble in ether, but by way of precaution the ethereal solution of fats might be shaken up two or three times with acidified water, and the watery fluid evaporated and tested for nitrogen.

In regard to the method of reporting results, the most important point is the separate statement of the amount of nitrogen present in the form of proteids and their congeners, and in the form of the simpler amides and amidc-acids. But in attempting to calculate from the nitrogen found under these heads the actual amount of the proximate nitrogenous constituents of the food material examined, the difficulty arises as to what factor should be used for multiplying the nitrogen found in each case.

The author suggests the following factors :

For proteids and allied substances, multiply nitrogen found by the ordinary factor 6·25.

For flesh-bases and simpler amides of animal origin in food-materials, multiply by 3·05.

For simpler amides and amido-acids of vegetable origin in food materials, multiply by 5·15.

For mixed amidic constituents of unabsorbed solid residua in digestion experiments, multiply by 9·45.

As a matter of general practice, it is recommended that in all statements of the results the actual amounts of nitrogen obtained should be given, so that if, with further knowledge of the nature of the proximate nitrogenous constituents present, the factor used in calculation be subsequently changed, the original experimental work will still retain its value. W. J. S.

Quantitative Estimation of the Bitter Principles in Hops. C. J. Lintner. (*Zeits. für d. ges. Brauwesen*, vol. xxi. [31], pp. 407-410.) In order to overcome the inconveniences arising in the ordinary gravimetric method for the extraction and drying of the bitter constituents, the author recommends titration of the extract with decinormal alkali, using phenol-phthalein as indicator.

Ten grammes of hops are placed in a half litre flask, and extracted by means of 300 c.c. of petroleum spirit (B. P. 30° to 50° C.) for eight hours, under an efficient reflux condenser, the flask being immersed to a depth of 2 to 3 c.m. in water kept at about 50° C. When the operation is completed, the contents of the flask are cooled to 17·5° C., made up to 505 c.c. (=500 c.c. of liquid) with petroleum spirit, and filtered into a stoppered flask. This should be performed as quickly as possible, to prevent the extraction of γ-resin, which would falsify the results.

One hundred c.c. of the filtered extract are titrated with alcoholic (96 per cent. by volume alcohol) decinormal potassium hydroxide. To facilitate the admixture of the liquid with the reagent, 80 c.c. of 96 per cent. by volume alcohol are added, and

10 drops of phenol-phthalein (1 : 100) solution are used as indicator. The reagent is added until the yellow colour of the liquid shows a decided red tinge, the end point being easily distinguishable after a little practice. A blank titration must be made to ascertain the volume of alkali consumed in neutralizing the petroleum spirit and alcohol.

The resulting values multiplied by 0·4 express the content of bitter principle in terms of lupulinic acid. C. S.

INORGANIC ANALYSIS.

The Determination of Technically Available Molybdenum in Molybdenum Glance. H. Bornträger. (*Zeit. anal. Chem.*, 1898, xxxvii., 438.)—Most of the methods employed for the determination of molybdenum give the total amount of the metal, and not that available for technical purposes, which, however, is most frequently required in a valuation of an ore. In the following method described by the author only the readily available molybdenum is estimated:

About 1 gramme of the molybdenum glance is digested in an Erlenmeyer flask for about two hours with 25 c.c. of strong nitric acid, until all the molybdenum has been converted into molybdic acid. Ammonia is then added to dissolve the molybdic acid and the liquid filtered. The residue is again digested with nitric acid and treated with ammonia, and the combined filtrates mixed with nitric acid and evaporated to dryness. The residue, consisting of molybdic acid and ammonium nitrate, is digested with dilute alcohol (50 per cent.), in which the ammonium nitrate is soluble. The molybdic acid left behind is collected on a weighed filter, washed with 50 per cent. alcohol, dried, and weighed; or preferably it is dissolved in 50 c.c. of normal ammonia, and the solution titrated with normal sulphuric acid, the difference being calculated into molybdic acid. C. A. M.

A New Volumetric Method for the Determination of Copper. R. K. Meade. (*Journ. Amer. Chem. Soc.*, 1898, xx., 610-613.)—The following method is claimed to be superior to the iodine and cyanide methods, both in rapidity and accuracy. The copper is brought into solution as sulphate, the greater part of the free acid neutralized with ammonia, the solution warmed, an excess of sulphurous acid added, followed by an excess of ammonium or potassium thiocyanate. The solution is filtered through asbestos with the aid of a filter pump, and the precipitate and filter, after being well washed, are heated in a beaker with a solution of caustic potash or soda. The reaction which takes place is shown in the equation

$$2CuSCN + 2KOH = Cu_2O + H_2O + 2KSCN.$$

The oxide is filtered off on asbestos, and washed with hot water. The precipitate and filter are again placed in the same beaker, and an excess of ferric chloride or ferric sulphate (free from nitric acid, free chlorine, or ferrous salts) added, together with a little dilute sulphuric acid.

The solution is then titrated with standard permanganate, and the iron equivalent

of the permanganate used, multiplied by 1·125 gives the weight of copper in the sample.

Instead of sulphurous acid, acid ammonium or sodium sulphite may be used to reduce the copper. Since copper is the only metal precipitated as thiocyanate from an acid solution, the presence of arsenic, antimony, bismuth, or zinc will not affect the results. The caustic alkali solution used to convert the cuprous thiocyanate into cuprous oxide must not be too strong, or some of the copper will go into solution. The author recommends a solution of about semi-normal strength.

The results obtained by this method in the analysis of a sample of pure copper were in close agreement with those of an electrolytic determination. The comparative figures given by the two methods with specimens of copper ore are shown in the subjoined table :

Sample.	Grammes.	Per Cent. Copper by Thiocyanate-permanganate Method.	Per Cent. Copper by Electrolytic Method.
1. Chalcopyrite I. ...	1·0	19·85	19·95
2. ,, ...	1·0	19·70	19·86
3. Chalcopyrite II. ...	2·0	6·16	6·37
4. ,, ...	2·0	6·21	6·30
5. Malachite	1·0	36·19	36·10
6. ,, ...	1·0	36·19	36·15
7. Tetrahedrite	1·0	21·05	21·06
8. ,, ...	1·0	20·90	21·18

The author states that after the ore has been brought into solution duplicate analyses can easily be made in from half to three-quarters of an hour. C. A. M.

The Determination of Uranium. **H. Borntträger.** (*Zeit. anal. Chem.*, 1898, xxxvii., 436, 437.)—A. Patera described a method of determining uranium which consisted in dissolving the ore in nitric acid, diluting with water, saturating the solution with sodium carbonate, boiling and filtering off, and washing the precipitate. The filtrate, which besides uranium contained only traces of other metals, was mixed with sodium hydroxide, and the precipitate washed, ignited, and weighed as $Na_2O.2UO_3$, corresponding with 88·3 per cent. of UO_3.

While this method gives good results with rich ores, it is otherwise with ores containing only 33 to 65 per cent. of UO_3, and especially with uranium sand, which contains only from 8 to 18 per cent. In such cases considerable quantities of silica are dissolved, and are weighed with the uranium. To obviate this the author recommends dissolving the ignited precipitate in hydrochloric acid, filtering off the silica, and again precipitating the uranium with sodium hydroxide or ammonia, and weighing it as $Na_2O.2UO_3$, or UO_3. The method is illustrated by the following results :

	I.	II.	III.	IV.	V.
Uranium ore taken, grammes	1·606	1·198	1·123	1·430	2·180
Crude sodium uranate, grammes ...	1·190	0·920	0·750	1·155	1·800
Containing SiO_2, grammes	0·026	0·040	0·025	0·037	0·040
UO_3 precipitated with NH_3, grammes	1·010	0·780	0·622	0·857	1·325
Per cent. of UO_3	62·90	65·70	55·40	59·90	61·00

C. A. M.

Determination of very small Quantities of Phosphoric Acid. A. Jolles and F. Neurath. (*Monatshefte für Chemie*, 1898, xix., 5.)—A solution of potassium molybdate is first prepared by dissolving 8 grammes in 50 c.c. of water, and adding 50 c.c. of pure nitric acid of 1·2 specific gravity. One hundred c.c. of this solution are required for 0·1 gramme P_2O_5, so that for any quantity below 0·001 gramme 1 c.c. is sufficient. Twenty c.c. of the solution to be tested, which must be clear and colourless, are placed in a test-glass, 1 c.c. of the molybdate solution added, and the whole warmed to about 80° C. The colour is then compared with that produced under exactly similar conditions by known quantities of sodium phosphate—*e.g.*, 0·001, 0·00075, 0·0005, etc. The following results show the degree of accuracy obtainable:

P_2O_5 taken, Gramme.	P_2O_5 found, Gramme.	Difference, Gramme.
0·001	0·001	0
0·00085	Between 0·001 and 0·00075 nearer to 0·00075 0·000812	0·000038
0·00061	Between 0·00075 and 0·0005 midway 0·000625	0·000015
0·0005	0·0005	0
0·0004	Between 0·0005 and 0·00025 nearer to 0·0005 0·000437	0·000037
0·0003	Between 0·0005 and 0·00025 nearer to 0·00025 0·000312	0·000012
0·00022	0·00025	0·00003
0·00016	Between 0·00025 and 0·0001 nearer to 0·0001 0·000138	0·000022
0·0001	0·0001	
0·00006	Between 0·000075 and 0·00005 0·0000625	0·0000025

Small quantities of inorganic salts, such as are found, for instance, in natural waters, have no influence upon the results. H. H. B. S.

Titration of Phosphoric Acid with Uranium. N. Orlow. (*Farmaz. J.*, 1898, xx., 283; through *Chem. Zeit. Rep.*, 1898, 233.)—As the standardization of

uranium solutions on pure sodium phosphate is troublesome, the author recommends the use of the double acetate of uranium and sodium—$Na(C_2H_3O_2).2UO_2(C_2H_3O_2)_2$—which forms anhydrous crystals, and can easily be obtained pure. F. H. L.

APPARATUS.

Lubricants for Glass Stopcocks. F. C. Phillips. (*Jour. Amer. Chem. Soc.*, 1898, xx., 678-681.)—With the object of producing a more suitable lubricant for glass stopcocks, the author has made a series of experiments with various substances. A mixture which gave very satisfactory results was: Pure unvulcanized rubber, 70 parts; spermaceti, 25 parts; and vaseline, 5 parts. The materials were thoroughly mixed while hot, the rubber being melted first and the others stirred in. Another preparation, which gave still better results, was made by mixing 70 parts of pure rubber with 30 parts of yellow unbleached beeswax. Old rubber does not answer well, as the mixture may become more or less granular and opaque. It is stated that this lubricant prevents glass taps from sticking, even when concentrated solutions of alkali are used, and is quite translucent in thin layers. C. A. M.

REVIEW.

COMMERCIAL ORGANIC ANALYSIS. By ALFRED H. ALLEN. Second edition. Vol. IV. London: J. and A. Churchill. Price 18s.

With Vol. iv. the second edition of Mr. Allen's treatise, the production of which has extended over a period of fourteen years, is brought to its long-hoped-for conclusion. We need say nothing as to the merits of the earlier portions of the work, since these have already been criticised in these pages and have stood the test of time and use. The concluding volume is worthy of its predecessors—*finis coronat opus*—and analysts are now placed in full possession of the greatest treatise on organic analysis which has ever appeared in England, or, indeed, in any country—a treatise which has become as indispensable in the laboratory as the classical work of Fresenius. Mr. Allen is to be congratulated on the completion of the work to which, as he himself tells us, he has devoted the best years of his life.

The volume under review commences with an account of the classification and the general properties and reactions of proteids or albuminous principles; a detailed description is then given of the proteids of the egg, blood-plasma, urine, and plants. The last section treats more especially of the composition of wheat, barley, and malt. We note that the author restricts the terms "proteid" and "albuminous" to the substances of which albumin is the type, whilst gelatin and kindred substances are classed under the head of proteoïds or albuminoïds. The word "album*en*" is also limited to its original signification—namely, white of egg—the term "album*in*" being applied to the most characteristic constituent of this and similar substances. These are welcome endeavours to secure uniformity in a nomenclature which is at present somewhat confused.

The succeeding 178 pages are devoted to the consideration of milk and milk-products; and this is, perhaps, that portion of the volume which will appeal more

especially to the public analyst. The average composition of milk, the methods for its analysis, the detection of adulteration, the question of standards and limits, the use of preservatives, etc., are discussed with ample detail, and the results of the most recent experiments are recorded. Cheese, cream, condensed milk, and other preparations of milk, are then dealt with in an equally comprehensive and satisfactory manner; butter has already been considered in vol. ii. We are glad to find that, through the courtesy of Dr. T. E. Thorpe, Mr. Allen has been enabled to include a description, taken verbatim from an as yet unpublished report to the Local Government Board, of the method now adopted in the Government laboratory for the analysis of altered milk. With the general principles of the method analysts are already acquainted, and it is now to be hoped that its value will be tested experimentally by independent observers. The analyses recorded in the report of samples of milk which have been kept for various periods—in some cases more than a year—certainly speak well for the process, which has, moreover, a scientific basis.

Meat and meat-products are next considered, and the composition and analysis of meat-extracts receives full attention. A bibliography of this latter subject, which has been so much in evidence of late years, adds to the value of this portion of the work.

Much of the following section, which deals with the proteids of digestion, has little to do with "commercial" analysis; but the author has judged it well—and rightly, as we think—to record all facts which he has found to be of practical or analytical interest. The most recent views of modern authorities on this difficult subject are here to be found, and an account of the ingenious speculations of Latham and others as to the constitution of albumin affords a relief to the more practical parts of the volume.

A chapter on hæmoglobin and allied substances concludes the discussion of the true proteids, and an excellent account of the chemico-legal examination of blood-stains is here given. We may remark that the author differs from most British authorities on this subject in attaching considerable value to the measurement of the *average* size of the blood corpuscles in the differentiation of the blood of man and other animals, even in the case of old and dried stains.

The remaining portion of the work treats of the proteoïds or albuminoïds, which are classed under the four heads of Collagenes or Gelatoïds, Fibroïds, Chitinoïds, and Keratoïds. Among other matters of practical or commercial importance here dealt with may be mentioned the analysis of gelatin, the valuation of glue, and the examination of silk, wool, hair, and other fibres.

A long list of addenda comprises notes on original publications which appeared too late to admit of being incorporated in the work. The recent alleged synthesis of albumin or peptone finds a place here, and it is pertinently pointed out that a process not involving the use of sulphur in any form cannot possibly result in the formation of a true proteid.

Those analysts who have been unable to procure the earlier volumes of Mr. Allen's treatise, which have long been out of print, will be glad to learn that they are being revised by Dr. Henry Leffmann, of Philadelphia. Vol. i. has already been issued, and Vol. ii. will follow shortly. T. S. & N. L.

THE ANALYST.

JANUARY, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, December 7, in the Chemical Society's Rooms, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the previous meeting were read and confirmed.

The following gentlemen were proposed for election as members of the Society: Mr. Harry Broadbent, F.I.C., Analytical Chemist to Messrs. Goodall, Backhouse and Co., Leeds; Mr. William Thomas Burgess, F.I.C., chemist in charge of the laboratory of Sir Edward Frankland, K.C.B., F.R.S., Reigate; and Professor Thomas S. Goodwin, the Veterinary College, Glasgow.

The President read the following list of officers and members of Council for the ensuing year, as nominated by the existing Council for election at the annual meeting:

President.—W. W. Fisher, M.A.

Vice-Presidents (who have filled the office of President).—M. A. Adams, F.R.C.S.; A. H. Allen; Sir Charles A. Cameron, M.D., F.R.C.S.; A. Dupré, Ph.D., F.R.S.; Bernard Dyer, D.Sc.; Otto Hehner; Alfred Hill, M.D., F.R.S.E.; J. Muter, M.A., Ph.D., F.R.S.E.; Thomas Stevenson, M.D., F.R.C.P.

Vice-Presidents (who have not filled the office of President).—Charles E. Cassal; E. W. T. Jones; S. Rideal, D.Sc.

Hon. Treasurer.—E. W. Voelcker.

Hon. Secretaries.—E. J. Bevan, A. C. Chapman.

Other Members of Council.—Arthur R. Ling; C. A. Mitchell, B.A.; James Nimmo; Thomas A. Pooley, B.Sc.; R. T. Thomson; Rowland Williams.

The names of those members of the Council who do not retire this year are Bertram Blount; Sidney Harvey; C. G. Moor, M.A.; F. Wallis Stoddart; John White; and W. C. Young.

Mr. J. F. H. Gilbard and Mr. Martin Priest were elected members of the Society.

An illustrated lecture was delivered by Mr. A. H. ALLEN on "The Use of the Micro-Spectroscope, and the Methods of detecting Blood in Chemico-Legal Investigations."

AN AUTOMATIC BURETTE.

By H. Droop Richmond.

(*Read at the Meeting, June* 1, 1898.)

Some years ago it was the custom in my laboratory to measure off the sulphuric acid for the Leffmann-Beam process by means of a 100 c.c. burette, which was filled by means of a siphon with a tap to it; the acid ran in at the top of the burette, and the operator had to stand by the burette till the acid reached the zero mark, and then to turn off the tap.

To prevent the possibility of accidental overflow of the acid, it occurred to me to fill the burette from the bottom, using a three-way tap, and to cork up the top with a cork carrying a tube of diameter so small that the volume of the acid in the tube could be neglected (Fig. 1). A trial convinced me that the method was slow, owing to the time that sulphuric acid took to run out of the narrow tube, and a little consideration revealed the fact that the error was much larger than was at first glance apparent.

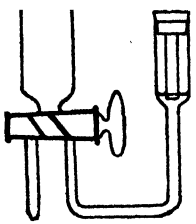

Fig. 1.

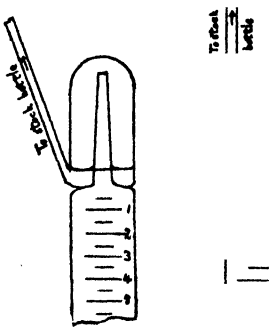

Fig. 2.

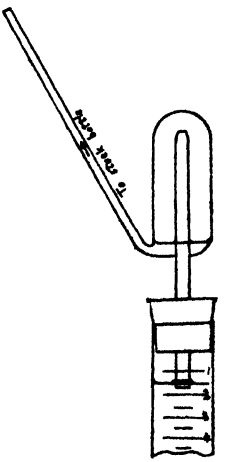
Fig. 3.



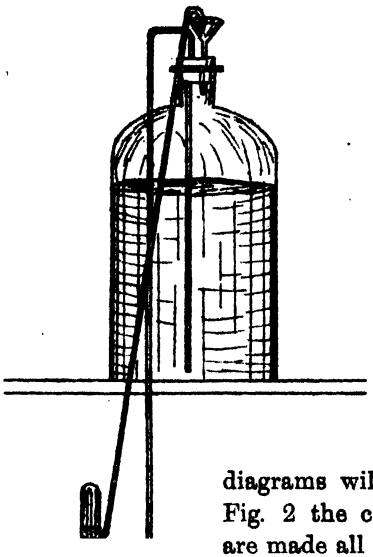


Fig. 4.

The following demonstration will show the nature of the errors introduced. The level of the acid a depends not only upon the level of the end of the tube, but on the pressure on the air in the space above; if h and h_1 represent the heights to which the acid rises when the stock-bottle is full and empty respectively, the volume of air in the space will vary in the proportion of

$$x \times \frac{760}{760 + ah \times \frac{d}{13{\cdot}6}} \quad \text{to } x \times \frac{760}{760 + a_1 h_1 \times \frac{d}{13{\cdot}6}}$$

where x = volume of air at 760 mm. pressure, d = density of liquid filling tube; taking x as 10 c.c., the distance from h to h_1 as 250 mm., and d as 1·82, which were the approximate values of the trial apparatus, a variation of nearly 0·5 c.c between the volume delivered when the stock-bottle is full and nearly empty is found; this variation is much greater than that due to the actual volume of acid in the tube, which was less than 0·2 c.c.; both variations go in the same direction, and the combined error quite unfits this apparatus for anything more than rough work.

A fairly obvious modification was to place the air-chamber above, instead of below, the effective zero point; this was accomplished by drawing out the end of the burette to a narrow tube, and enclosing this in an air-chamber. The following diagrams will show two forms of accomplishing this end. In Fig. 2 the chamber and an exit-tube for the excess of liquid are made all in one piece (*A* form); in Fig. 3 the exit-tube passes through a cork (*B* form). A further modification, which was not so accurate, but was convenient where great accuracy was not desired (*e.g.*, the measurement of sulphuric acid for the Leffmann-Beam process, for which I have used it for the last four years), is shown at Fig. 4 (*C* form). This enables an ordinary burette to be used, and, provided that the lower air-space is kept as small as possible, is quite accurate enough, and has the advantage that the zero point can be altered if desired, though it must be borne in mind that an alteration of the zero point will cause an alteration in the extent of the error. Of these forms *B* is preferable, and is capable of greater accuracy than *C*, and is not so liable to break as *A*.

In the case of corrosive liquids the connection between the stock-bottle and the burette is made by a siphon and the well-known air-trap, which enables an indiarubber connection to be used, and diminishes the risk of breakage.

Fig. 5.

The diagram (Fig. 5) shows a burette (*C* form) with all connections; after a measurement has been performed the tap is turned half round, and the burette is automatically filled to the zero point ready for use when required.

The liquid siphons over from the stock-bottle, fills the burette to the top, and then runs over into the air-chamber; from this it is forced up by the pressure of the incoming liquid up the ascending tube till

the level is equal to that in the stock-bottle; the zero is quite automatically adjusted and requires no attention.

When the liquid is run out, air enters through the ascending tube and bubbles through the liquid in the air-chamber. When the burette is again filled the liquid in the air-chamber is forced back into the bottle.

AUTOMATIC BURETTES.

By A. W. Stokes, F.I.C.

(*Read at the Meeting, November* 2, 1898.)

During the last few years I have interested myself in devising automatic apparatus for the purpose of rapidly, accurately, and safely measuring liquids, especially such liquids as strong ammonia and sulphuric acid.

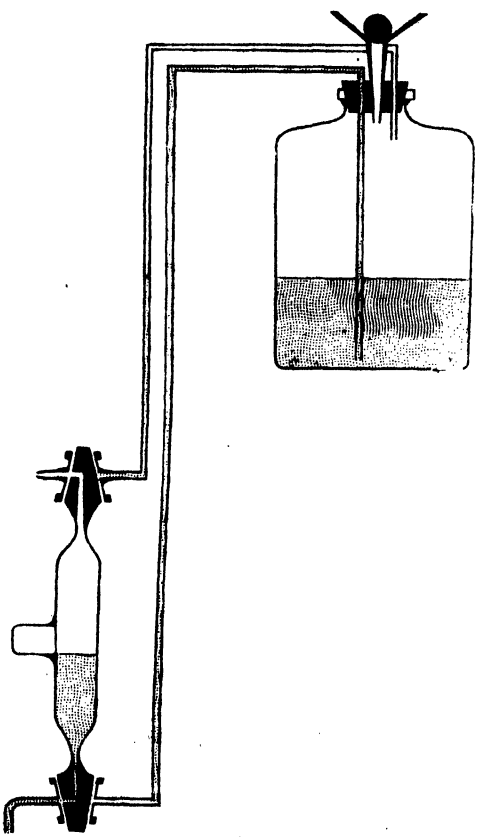

Fig. 1.

To be truly automatic, the apparatus should *without watching*—

1. Fill itself.
2. Empty itself.
3. Refill itself at the same time that it is emptying.
4. Be incapable of letting the whole of the supply run from the reservoir.
5. Need only one motion of the hand for all these operations.
6. Be adjustable to deliver any required quantity.

Only one of the apparatus I show you to-night fulfils all these requirements.

Fig. 1 is a plan I contrived that for exactitude excels all the apparatus hitherto introduced for this purpose. In this the measuring vessel, having a lateral opening at the top and another at the bottom, itself revolves. The lower end connected with the supply revolves in a sleeve, and the upper end, in communication with the overflow, revolves in another sleeve. The instant the measuring vessel is revolved all connection with the reservoir is cut off, so that an absolutely exact quantity is contained in the measure. Half a revolution brings its lower opening to the exit-tube, and its upper opening to an air-inlet. This form takes up its own supply of air, so

that the reservoir may be a closed vessel, if necessary. It, however, does not at the same time refill itself, nor can the quantity it delivers be varied without changing the measuring vessel.

Fig. 2 involves a new principle—that is, the introduction of a capillary tube into the measuring vessel so as to vary its capacity at will, and to avoid connecting the reservoir with any over-flow pipe. The capillary tube really forms an over-flow pipe, but as it is carried straight up above the level of the reservoir there can be no actual over-flow. By forcing this tube down into the measuring-vessel, the capacity of this latter is lessened, so that it will deliver a smaller quantity than before. The capillary tube also protects the cork through which it passes from being acted upon by any corrosive liquid that one may be measuring. But when the level of the liquid in the reservoir varies, it would apparently result that a varying quantity of liquid would be delivered, due to the greater or lesser height of the over-flow in the capillary tube. But a capillary tube may be used whose whole length would be filled by a single drop. Evidently, then, the variation of a few inches in the level of the reservoir will not vary the quantity delivered by more than some fraction of a drop.

Time, however, is lost with this apparatus, because it does not refill itself at the same time that it is emptying.

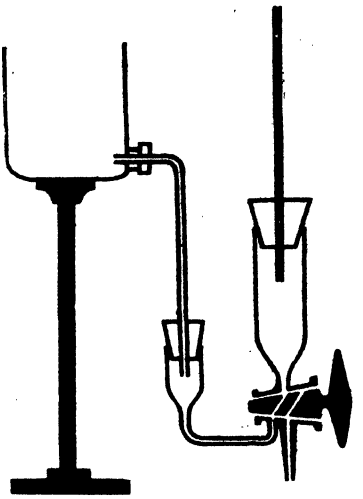

FIG. 2.

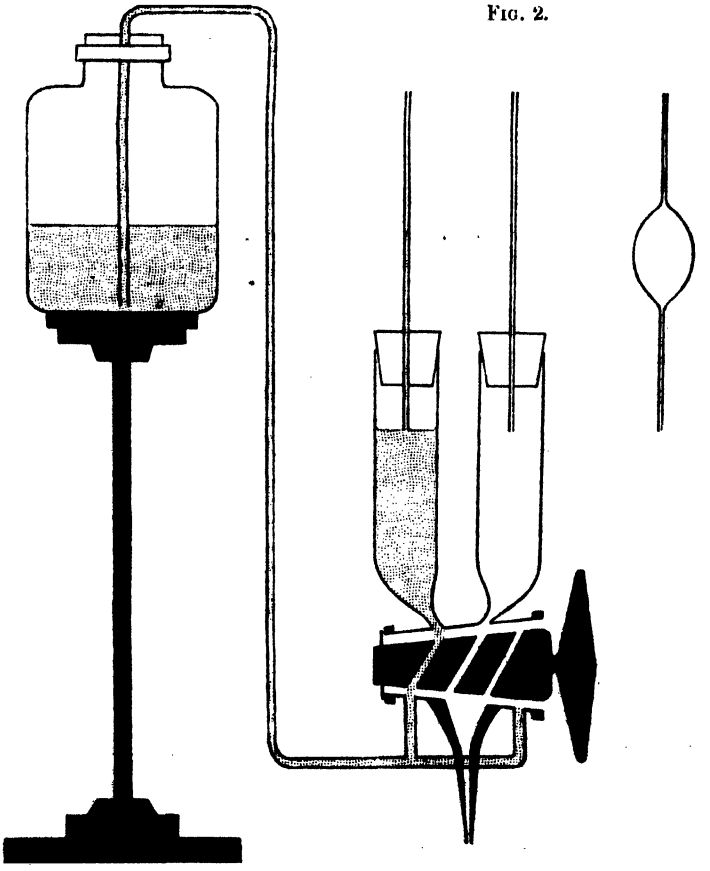

FIG. 3.

In Fig. 3 I duplicated the measuring-vessel, and used a capillary tube in each. By the kindness of Messrs. Lister, of Dursley, who have patented this and some other of my measuring devices, I am able to show you specimens to-night.

It fulfils all six of the conditions I noted at the beginning of this paper, as required of a truly automatic measure, and needs only a half-turn of the tap to repeat the measuring indefinitely. Its supply-pipe, acting as a syphon, can be dipped into any ordinary reagent-bottle without removing this from its shelf, and it will then deliver any required quantity.

When different quantities are required alternately, one capillary tube can be pushed down further than the other, so that one measuring-tube will, for instance, give 5 c.c., the other 10 c.c. at every half-turn of the tap. By using a capillary tube with a bulb blown on it accurate quantities far larger than the capacity of the measuring vessel can be delivered. The measuring vessel in such case serves only as a regulator, the bulb holding most of the quantity to be delivered.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Alteration in the Character of Butter Produced by Feeding with Fat. G. Baumert and F. Falke. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 665-678.)—The authors give the results of a series of experiments undertaken with the view of testing the effect produced upon butter by feeding cows upon fats. The experiments were made upon two cows, Swiss and Dutch. The fats used—sesame oil, cocoanut oil, and almond oil—were selected on account of their dissimilarity from each other, as well as from butter itself. They were administered in the form of emulsions. The following plan of feeding, embracing five periods of twenty days each, was carried out: (1) Hay and rape meal only. (2) Hay and rape meal with sesame oil. (3) Hay and rape meal with cocoanut oil. (4) Hay and rape meal with almond oil. (5) Hay and rape meal only. The milk was passed through a separator and the cream churned to butter. The butter obtained was then at once melted at 40° to 50° C., allowed to stand for some time at the same temperature, and the fat clarified by filtration. Its examination included the determination of the Köttstorfer and Reichert-Meissl numbers, the Hübl and iodine numbers, the melting-points and refractions. The results showed that the butter fat was not only greatly changed in character through the feeding with the fats, but that the alteration, as indicated by the numbers obtained, was always in the direction of the numbers characterizing the three fats used in the experiments. In other words, the butter fats produced by feeding with sesame oil, cocoanut oil, and almond oil, exhibited the same characteristics as would be found in artificial mixtures of butter fat with the three oils in question. This is clearly shown in the following table of average results:

Description of the Periods.	Refraction.			Köttstorfer Number.			Reichert-Meissl Number.			Hübl Number.		
	Swiss Cow.	Fat administered.	Dutch Cow.	Swiss Cow.	Fat administered.	Dutch Cow.	Swiss Cow.	Fat administered.	Dutch Cow.	Swiss Cow.	Fat administered.	Dutch Cow.
Period I.	+1·7	—	+2·4	224	—	223	31·0	—	29·5	44·3	—	45·0
Sesame oil		+17·6			190			0·4			116	
Period II.	+5·6		+5·4	204		206	16·9		15·7	53·9		52·9
Cocoanut oil		−9·2			255			8			9	
Period III.	−0·5		−0·6	237		230	20·0		18·6	37·1		35·2
Almond oil		+13·6			195			0			98	
Period IV.	+3·6		+4·3	210		207	19·7		15·3	50·9		53·9
Period V....	+3·0	—	+3·6	218	—	216	22·0	—	24·4	41·2	—	44·5

The attempt to detect sesame oil in the butter produced in feeding with this oil by means of the furfurol and hydrochloric acid test was, however, not successful.

As regards the melting-point determinations, these yielded the following averages:

Period.	I.	II.	III.	IV.	V.
Swiss cow ...	34·16°	37·00°	33·58°	34·28°	34·50°
Dutch cow ...	33·96°	36·76°	34·76°	34·50°	35·15°

Compared with the melting-point of pure butter-fat, these results are all very high, the highest being in the case of the sesame oil feeding (II.), which agrees with the results of previous observers (*cf.* Reprint, vol. xxiii., p. 255). H. H. B. S.

On the Volatile and Insoluble Fatty Acids in Butter. R. Henriques. (*Chem. Rev. Fett u. Harz-Ind.*, vol. v. [9], pp. 169-172.)—The author investigated several samples of pure butter exhibiting unusually low Reichert-Meissl values, with the idea of devising a method for distinguishing these butters from mixed butters. It is based on the differences in the actual quantity of and the average molecular weight of the volatile and non-volatile fatty acids. The results, however, showed that butters with a normal R.-M. number contained 5 to 6 per cent., those with an abnormal 4 to 5 per cent. of volatile fatty acids, the average molecular weight of which varied from 93·3 to 99·8; hence the results have but a negative value for analytical practice.

With regard to the insoluble fatty acids, in these the Hehner number ranged between 86·5 and 89·1 for normal and 88·96 to 90·68 for abnormal butters; but a difficulty arose in the estimation of the average molecular weight, in that the values found on drying at 105° to 110° C. (viz., 267 to 270) differed from those (256·3 to 263) obtained when the drying was effected at the ordinary temperature in a vacuum desiccator.

The author, however, considers that, assuming butter to contain a large proportion of oleic acid, the above figures indicate that a considerable amount of an acid of lower molecular weight than palmitic acid is present; and that by isolating this acid and separating the unsaturated from the saturated acids it is not improbable, provided the assumption of a low average molecular weight for this undetected acid be found correct, that the presence of extraneous fats in butter may be discovered by the relatively higher molecular weight of the saturated acids they contain. C. S.

The Action of Formaldehyde on Flesh. E. Ehrlich. (*Zeit. Fleisch u. Milch. Hyg.*, 1898, viii., 232.)—The author has made experiments on the preservation of flesh by means of an 8 per cent. solution of formaldehyde. He finds that beef is preserved without the production of any unpleasant odour, but that the meat is only eatable for a short time after the treatment with the antiseptic. Horseflesh, on the other hand, invariably develops a characteristic intense smell within forty-eight hours, resembling that of roast goose-flesh. Only in one instance was a faint suspicion of this odour met with in the case of beef, and the author suggests that this difference may give a further means of distinguishing between the two kinds of flesh. C. A. M.

The Amount of Zinc contained in German Dried Fruit. P. Kulisch. (*Zeit. angew. Chem.*, 1898, 1015-1016.)—The author states that the zinc so frequently met with in American dried fruit is derived not from any addition of zinc salts, but from the action of the acid juices of the fruit on the zinc trays of the drying apparatus. On continued use, these become coated with a hard crust of dried juice, which largely prevents the fruit from coming in contact with the metal, and in such dried fruit the amount of zinc is naturally less. Since all modern German drying apparatus is constructed on the American plan, with zinc-wire trays, the author has examined different kinds of dried German fruit in order to determine to what extent they were contaminated with the metal. The quantities found in 100 grammes of fruit containing the usual commercial percentage of water were :

	Gramme.
Apple rings *a*	0·031
,, ,, *b*	0·021
Apple chips *a*	0·023
,, ,, *b*	0·027
Pear slices *a*	0·020
,, ,, *b*	0·026

All the samples thus contained an amount of zinc not much less than the mean quantity found in American apple rings (*cf.* ANALYST, xx., 251). C. A. M.

A Volumetric Assay of Opium. A. B. Prescott and H. M. Gordin. (*Jour. Amer. Chem. Soc.*, 1898, xx., 724-728.)—This is an application of the authors' general method for the estimation of alkaloids (*cf.* ANALYST, xxiii., 324). The opium alkaloids are liberated by the action of ammonia in the presence of certain solvents. The free narcotine, papaverine, codeine, and thebaine are removed by percolation with benzene, after which the morphine is extracted by percolation with acetone. The acetone is evaporated, and the residue taken up with lime-water, which completely dissolves and purifies the morphine. The solution is filtered, acidulated with hydrochloric acid, and the alkaloid estimated as periodide by titration with Wagner's reagent.

The details of the assay are as follows: 1 gramme of the finely-powdered opium is triturated in a mortar with 2 or 3 c.c. of a mixture of 5 c.c. of ammonia, 5 c.c. of alcohol, 20 c.c. of ether, and 10 c.c. of chloroform. The covered mortar is left for about three hours, with an occasional gentle shake, after which about 15 grammes of dry finely-powdered common salt are stirred into the pasty mass. It is then left in a warm place (30° to 35° C.) for two or three hours, and afterwards placed in a

desiccator containing sulphuric acid and a dish of paraffin wax until perfectly dry. The contents are next transferred to a small glass percolator (22 cm. by 1·3 cm.), and percolated with benzene until the percolate is colourless and gives no turbidity with Wagner's reagent. The dish beneath the percolator is replaced, and the percolation continued to complete exhaustion with acetone, as much as 200 c.c. of the solvent being usually required. The acetone extract is evaporated to dryness at a temperature not exceeding 45° C., the residue triturated with fresh lime-water, the solution poured without filtering into a stoppered cylinder of 100 c.c., the dish washed out with lime-water, and the liquid in the cylinder made up to 100 c.c. with lime-water. The cylinder is well shaken for half an hour, and filtered into a second cylinder until the filtrate amounts to 50 c.c. This liquid is rendered just acid with 10 per cent. hydrochloric acid and 25 c.c. of the $\frac{N}{10}$ iodine solution run in from a burette with constant shaking of the cylinder. After the addition of water to any convenient mark in the cylinder, the latter is shaken for about twenty minutes, until on standing the supernatant liquid (in which there should be an excess of iodine) is perfectly clear. An aliquot portion (one half) is then filtered off and the excess of iodine titrated with standard thiosulphate. The amount of iodine consumed by the alkaloid multiplied by the factor 0·0094793 gives the percentage of morphine in 0·5 gramme of the opium.

The precautions most essential are: (1) That the opium residue be thoroughly dry before percolation; (2) that the acetone should not contain anything distilling below 54° C. or above 58° C.; and (3) that after the excess of iodine has been added the cylinder be continuously shaken until the supernatant liquid is quite clear.

The following were the results obtained by this method in the assay of three samples of commercial opium:

		Opium Taken. Grammes.		Iodine Consumed by 0·5 gramme.		Morphine Per cent.
A	1	1·0036		0·116644		17·41
	2	1·008		0·116732		17·37
	3	1·0022		0·116642		17·44
B	1	1·0033		0·08872		13·25
	2	1·0023		0·08872		13·20
	3	1·0026		0·08872		13·21
C	1	0·9969		0·096319		14·48
	2	1·0016		0·097219		14·55
	3	0·9988		0·094552		14·19

C. A. M.

Estimation of Hydrastine in "Extractum Hydrastis Fluidum." **N. Rusting.** (*Pharm. C. H.*, 1898, xxxix., 787; through *Chem. Zeit. Rep.*, 1898, 289.)—Ten grammes of the extract are weighed into a large flask, diluted with 20 c.c. of water, and boiled and agitated till the total weight is reduced below 20 grammes. After cooling, water is added to make the weight exactly 20 grammes, a little infusorial earth introduced, and the whole filtered. Ten grammes of the filtrate are shaken with 25 c.c. of spirit and 3 c.c. of 10 per cent. ammonia; after a few minutes 25 c.c. of petroleum ether are run in, the liquid is again agitated, and 2 grammes of tragacanth are added. Forty c.c. of the clear ethereal liquid (equal to 4 grammes of the extract) are evaporated down to about 15 c.c. over warm water, and the vessel is put

aside for several hours in a cool place. The supernatant liquor is then cautiously poured off, and the hydrastine crystals dried in the water-oven and weighed.

F. H. L.

Notes on Estimating Eucalyptol. L. F. Kebler. (*Amer. Journ. Pharm.*, 1898, lxx., 492-494.)—Each species of the eucalyptus genus (about 120) apparently yields a distinctively characteristic oil, of which the United States Pharmacopœia recognises that distilled from the fresh leaves of *E. globulus*, *E. oleosa*, and some other species.

With regard to the differentiation of the official oils from the others the author points out that the specific gravity and rotatory power may be valuable criteria, but that the oil can be so mixed as to make these factors of little service. The phellandrene test is also serviceable, but the chief desideratum is to know the amount of eucalyptol in the oil.

In 1894 L. R. Scammell took out a patent for the preparation of eucalyptol on a large scale (*Eng. Pat.* 14,138), which was based on the fact that on adding concentrated phosphoric acid (specific gravity 1·75 to 1·78) to the oil at the ordinary temperature (not exceeding 60° F.), a crystalline compound of eucalyptol phosphate separated out, which, after being purified by pressure, or centrifugal force, was decomposed with hot water.

Faulding (*Chemist and Druggist*, 1895, 310) examined this process as applied to the quantitative estimation of eucalyptol and found that it gave excellent results. Helbing (*Pharm. Record*, xxxiii., 26), however, came to the conclusion that it was valueless for quantitative work, and the author's results confirm this.

By a modification of the process he has succeeded in obtaining closely approximate results in the following manner: Eight grammes of the oil are weighed into a beaker, which is cooled in ice-water. Four c.c. of phosphoric acid (1·75) are added, the beaker again placed in ice-water, and, after cooling, the contents thoroughly mixed by means of a glass rod. The eucalyptol phosphate is removed, purified by heavy pressure in folds of filter-paper, and weighed. It is then decomposed with hot water, the liberated phosphoric acid titrated with standard alkali, and the eucalyptol obtained by difference. In some cases it is necessary to add more phosphoric acid, especially with pure eucalyptol.

The results obtained by this method with pure eucalyptol and a number of oils are given in the subjoined table, in which the direct percentage of eucalyptol was obtained by Scammell's process.

No.	Specific Gravity at 15° C.	Grammes of Solid Eucalyptol Phosphate.	Per cent. of Eucalyptol, by difference.	Per cent. of Eucalyptol, direct.
1	0·9350	14·78	103·75	62·14
2	0·9153	10·70	73·62	31·20
3	0·9116	8·10	54·75	23·17
4	0·8912	7·13	43·62	24·29
5	0·8955	3·50	23·37	—
6	0·8876	did not congeal	—	—
7	0·9081	,,	—	—
8	0·9424	9·9	73·84	49·23

Of these samples No. 1 was pure eucalyptol, 2 and 8 were special oils at a high price, and the remainder such as are commonly met with in the wholesale trade.

C. A. M.

TOXICOLOGICAL ANALYSIS.

Piutti's Reagent for Alkaloids (Iodine-derivative of Para-ethoxyphenylsuccinimide). G. Simoncelli and N. Scarpitti. (*Gazz. chim. Ital.*, 1898, xxviii. [2], 171; through *Chem. Zeit. Rep.*, 1898, 279.)—The authors have investigated several iodine reagents for alkaloids, including those of Bouchardat and Selmi, and they find the most delicate to be one of the substances recommended by Piutti—viz., the iodine derivative of *p*-ethoxyphenylsuccinimide. This is prepared by treating the imide with a solution of iodine and potassium iodide in acetic acid. F. H. L.

Detection of Acetylene in Cases of Poisoning therewith. D. Vitali. (*Boll. chim. farm.*, 1898, xxxvii., 449; through *Chem. Zeit. Rep.*, 1898, 247.)—The suspected blood is mixed with 5 or 8 per cent. of pure acetone, placed in a retort, and distilled into an empty condenser and a set of absorbing bulbs containing more acetone. The retort is heated on a water-bath, the condenser and bulbs kept cold in ice. The acetone passes over, carrying the acetylene with it, and the latter may be identified by its characteristic reactions. Hydrogen sulphide and phosphide, which often occur in the crude gas, also dissolve in the acetone, and can be sought for therein. F. H. L.

Detection of Free Nitric Acid in Toxicological Work. D. Vitali. (*Oesterreich. Chem. Zeit.*, 1898, 333.)—The organs to be examined are warmed on a water-bath, water being added if needful, and freshly precipitated barium carbonate is introduced, a little at a time, as long as it dissolves. The mixture is then evaporated to dryness, and the residue boiled three or four times with an equal volume of absolute alcohol. By this procedure the calcium and magnesium nitrates are brought into solution, whilst sodium nitrate, the calcium nitrate naturally present in the organism, and the barium nitrate formed by the action of the free nitric acid upon the barium carbonate, remain in the residue. The alcoholic solutions are then evaporated to dryness, the residue taken up with water and neutralized very carefully with solution of barium hydrate. The fluid is then again evaporated to dryness, and treated with absolute alcohol. The undissolved residue is taken up with water, the solution treated with a little lead acetate, to precipitate organic matter, and filtered. The filtrate is then treated with hydrogen sulphide, to remove the lead, filtered, and the clear filtrate concentrated by evaporation, and dried in an exsiccator. The residue is examined for crystals of barium nitrate, which can be recognised by their crystalline form and by the usual tests. In this way it is possible to determine those nitric acid

compounds with albuminous bodies (acidalbumins) which are soluble in alcohol. The insoluble residue from the first treatment with alcohol contains, as already mentioned, the sodium nitrate, the barium nitrate resulting from the treatment with barium carbonate, and the calcium nitrate which must be regarded as a normal constituent of the body. It is made slightly alkaline with sodium carbonate, by which the nitric acid of the acidalbumins insoluble in absolute alcohol is neutralized, and the barium nitrate resulting from the free nitric acid is converted into sodium nitrate, whilst the calcium and sodium nitrates remain unchanged. The solution is filtered, the filtrate evaporated to dryness, and the residue treated with boiling absolute alcohol, which takes up the calcium nitrate, whilst leaving the sodium nitrate undissolved. The insoluble portion is dissolved in water, treated with a slight excess of lead acetate, the solution filtered, and the lead separated by hydrogen sulphide. The clear colourless fluid which is thus obtained is concentrated by evaporation, and dried in an exsiccator. Crystals of sodium nitrate in this residue can then be detected by the usual tests.

Another method which the author has used successfully is as follows: The intestines are cut into small pieces, and treated with freshly precipitated strychnine. As strychnine nitrate has an acid reaction, the neutralization cannot be controlled by means of litmus paper. The mixture is dialyzed, the residue twice extracted with warm water, the filtered fluids evaporated to dryness, and the residue treated with boiling alcohol. The alcoholic solution is then filtered, evaporated to dryness, the residue taken up with water, decolorized by treatment with lead acetate, followed by hydrogen sulphide, and the filtrate concentrated. Strychnine nitrate, formed by the union of the strychnine with free nitric acid, if present, would here crystallize out, and be determinable in the usual way. H. H. B. S.

Destruction of Organic Substances in Chemico-Forensic Work. C. Kippenberger. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 683-687.)—Villiers a short time since (*Compt. Rend.*, 1897, 1457) advised the use of a mixture of nitric and hydrochloric acids, with the addition of a solution of a manganese salt, for the destruction of organic substances. He stated that with this mixture the liver, spleen, and lungs could be oxidized in a few minutes, and the muscles within an hour—much more quickly, in fact, than by the use of potassium chlorate and hydrochloric acid, as recommended by Fresenius and Von Babo. The author is unable to confirm this, but found, on the contrary, that in order to complete the action it became necessary to add potassium chlorate from time to time with continued heating. The experiments made with Villiers' method, however, led to the trial of a manganese salt in conjunction with potassium chlorate and hydrochloric acid, and in this case the author found a decided acceleration of oxidation to result from the use of manganese. The most suitable manganese compounds for the purpose are manganic dioxide and manganous chloride, of which the former has the advantage of being a stock reagent in every laboratory. The sulphate is less suitable, on account of the possibility of metals in the case of metallic poisoning (*e.g.*, lead, mercury, or silver) becoming

converted into insoluble sulphates, and so causing difficulties in the subsequent analysis. It is sufficient to add a little manganic dioxide to the substance mixed with hydrochloric acid, and then to follow up with potassium chlorate in the usual way.

H. H. B. S.

ORGANIC ANALYSIS.

Detection and Estimation of Methyl Alcohol in Ethyl Alcohol. Trillat. (*Ann. et Rev. Chim. Analyt.*, vol. iii. [9], pp. 294-300.) — The author finds that ethylal and methylal are constantly formed amongst the products of the oxidation of ethyl alcohol, and that these furnish, when combined with dimethylaniline, bases differing in properties.

The base obtained from ethyl alcohol corresponds to the formula $C_2H_4 : 2[C_6H_4N : (CH_3)_2]$, and when dissolved in dilute acetic acid and treated with lead dioxide yields a blue solution, changing immediately to green, afterwards to yellow, and becoming completely colourless when boiled.

On the other hand, the base from methyl alcohol ($CH_2 . [C_6H_4N : (CH_3)_2]$) gives a persistent blue coloration, which is rendered more intense by boiling, and enables 1 part of the base to be detected in 200,000 parts of solution.

The same phenomenon is developed when the two alcohols are mixed, but in order to secure oxidation when the proportion of methyl alcohol is small, it is necessary to dilute the mixture with 10 volumes of water calculated to absolute alcohol, and it is advisable to employ 1·5 part of potassium dichromate to each part of absolute alcohol present. Another essential preliminary to the reaction is the careful rectification of the dimethylaniline to remove impurities.

In applying the test, 20 c.c. of the sample of alcohol are added to 300 c.c. of water and 30 grammes of powdered potassium dichromate, then cooled and mixed with 100 grammes of 20 per cent. sulphuric acid. After the reaction has proceeded for one hour the liquid is distilled, the first 50 c.c. (rich in acetaldehyde) being rejected. The distillate is neutralized with sodium carbonate and made up to 400 c.c. One-fourth of this is heated on a water-bath for five hours at 65° to 70° C. in a small closed flask, with 2 c.c. of rectified dimethylaniline and 1 c.c. of 10 per cent. sulphuric acid, with occasional agitation.

After neutralizing with alkali and distilling off the excess of dimethylaniline, a portion of the liquid is acidified with acetic acid, then treated with a few drops of water containing lead dioxide in suspension, and boiled in order to develop the blue coloration indicative of methyl alcohol.

The coloration is compared in the usual manner with typical samples prepared beforehand, and is sufficiently decisive to detect 1 per cent. of methyl alcohol. When the latter exceeds 5 per cent., the base may be weighed direct. C. S.

The Estimation of Caramel. Fradiss. (*Bull. Ass. Chim.*, 1898, xvi., 280.)— The substance under examination is mixed with methylic alcohol, which is evaporated on the water bath. The residue is dried first *in vacuo*, and then thoroughly in a

current of dry air. It is then extracted for two hours under a reflux condenser with methylic alcohol (95 per cent.), which dissolves all the caramel. The filtered extract is mixed with an excess of amylic alcohol which precipitates the caramel, and the precipitate, after being dissolved and reprecipitated two or three times, is finally dried on a weighed filter at 90° C. Various samples of molasses examined by this method were found to contain from 1·10 to 2·50 per cent. of caramel. C. A. M.

The Characteristics of Curcas Oil. O. Klein. (*Zeit. angew. Chem.*, 1898, 1012-1015.)—The *Jatropha Curcas*, from the seeds of which this oil is obtained, grows to a height of 3 or 4 metres, and is cultivated in all the Portuguese colonies, but especially in the Cape Verde Islands, which supply about three-fourths of the total quantity shipped to Portugal. There are two factories where the oil is extracted in Lisbon, the finely-divided seeds being subjected to hot pressure. The oil is used for lubricating and lighting, and in the soap and candle manufactures, and the pressed residue fetches a high price for manure.

The physical and chemical constants of the oil extracted in different ways by the author and of a commercial specimen were :

	Cold Pressed.	Hot Pressed.	Cold Pressed.	Extracted with Ether.	Commercial. Hot Pressed.
Specific gravity	0·9210	0·9240	0·9199	0·9207	0·9208
Refractive index at 25° C. ...	1·4686	1·4689	1·4687	1·4687	1·4681
Iodine value	109·8	109·1	110·4	109·1	107·9
Saponification value ...	203·5	203·6	197·5	197·0	198·1
Free acids	4·96	4·65	0·83	0·57	0·68
Volatile acids	7·10	5·5	—		

The oil is of a yellowish-red colour, which varies in shade according to the degree of pressure and heat to which the seeds were subjected. It has a characteristic odour, which cannot be readily mistaken. The acetyl values of the hot-pressed and extracted oil were 34·7 and 51·7 respectively by Benedikt and Ulzer's original process. By Lewkowitsch's method (*Journ. Soc. Chem. Ind.*), the corresponding figures were 17·6 and 25·3. The melting-point of the fatty acids determined in a capillary tube was 29·5° to 30·5° C., and the solidifying point 25·75° to 26·5°. The oil is soluble in alcohol to the extent of 24·12 per cent. It is insoluble in cold glacial acetic acid, but readily dissolves in the hot acid. The viscosity in Engler's apparatus at 20° C. was 9·45, so that in this respect curcas oil comes between crude rape-seed oil and olive oil, the latter having a viscosity of 9·03 to 10·3 (Künkler). The phytosterin determined by Bömer's method was 0·58 per cent.

According to Hiepe (*Rep. d. anal. Chem.*, v., 226), curcas oil is frequently used to adulterate olive oil in Portugal, but the author states that he has never yet met with any instance of such adulteration, although he has examined hundreds of suspicious samples of olive oil. Moreover, he considers such an admixture extremely improbable, taking into account the facts that 10 drops of curcas oil have a greater purgative effect than a tablespoonful of castor oil, and that an addition of 10 per

cent. of curcas oil to olive oil imparts an unmistakable odour. For its detection in olive oil Hiepe recommends treating the oil with nitric acid and copper filings, the resulting elaidin being of a reddish-brown colour. The author confirms this, but shows that the reaction is not conclusive, since earth-nut and cotton-seed oils give a similar coloration. Other colour reactions are also inconclusive. In Becchi's test the commercial oil causes a slight reduction, but the fatty acids cause no reduction. In the author's opinion the best tests for curcas oil in olive oil are the characteristic odour, and the increase in the specific gravity, refractive index, and iodine value. The oil was found to contain 9·59 per cent. of solid fatty acids melting at 57·5° C., and with a molecular equivalent of 269·5, from which data they were judged to consist of 20 per cent. of stearic and 80 per cent. of palmatic acid. No myristic acid could be detected. The liquid fatty acids (80 per cent.), separated as lead salts with ether, yielded on oxidation by Hazura's method equal quantities of sativic and dihydroxy-stearic acid, from which it was concluded that they consisted of equal parts of oleic and linolic acids. No ricinoleic or linolenic acid was found.

C. A. M.

Oil of Paradise Nuts, Oil of Brazil Nuts, Maize Oil. G. de Negri. (*Chem. Zeit.*, 1898, xxii., 961, 976.)—Paradise nuts are the seeds of the *Lecythis sapucaia* (*zabucajo*), a large tree belonging to the *Myrtaceæ* found in Brazil and Guiana. The seeds are edible, having a pleasant taste resembling Brazil nuts. On extraction with petroleum ether, 50 to 51 per cent. of a clear, colourless, or faintly yellow oil is obtained, which quickly turns rancid, but not so fast as oil of Brazil nuts. The latter begins to solidify at 4° or 5°, and is quite solid at 0°; oil of paradise nuts yields a white deposit at 12°, and solidifies completely at 8°. It is soluble in ether and chloroform, insoluble in cold absolute alcohol, hardly soluble in hot water; it is insoluble in cold acetic acid, but dissolves in an equal volume of the hot acid.

When maize is ground the germs are usually removed, and the yield is about 1 per cent. They show the following composition: water, 11·55 per cent.; nitrogenous matter, 39·07 per cent.; fat, 12·5 per cent.; carbohydrates, 31·76 per cent.; mineral matter, 5·3 per cent. On extraction with petroleum spirit 8 per cent. of oil is obtained, which is clear, yellowish-brown, and possesses a characteristic odour. It solidifies at 15° to a yellow crystalline mass. It is soluble in ether, chloroform, and carbon disulphide, insoluble in cold absolute alcohol, soluble in 30 parts of hot spirit. At 65° it dissolves in an equal volume of glacial acetic acid. It saponifies slowly with alcoholic potash. Maize oil quickly becomes rancid; one sample kept for a year in a half-filled flask finally contained 43·86 per cent. of free (oleic) acid. According to their place of origin, the germs differ widely in composition; one specimen of oil remained liquid at 0° for several hours; the iodine and acid numbers also vary. Its colour reactions are: Haydereich, orange-yellow with violet spots; Brullé, black, afterwards blood-red, solid in twenty-four hours; Schneider, no colour; Becchi, very faint brown; Milliau, faint brown; Baudoin, no colour. On distilling maize, a residue containing 11 per cent. of solid matter and 5·5 per cent. of oil is recovered (Villon). Maize itself yields 0·5 per cent. of oil, rather darker in colour than that obtained from the embryos. The constants of these three oils are:

	Oil of Brazil Nuts.	Oil of Paradise Nuts.	Maize Oil.
Specific gravity	0·918	0·895	0·9245
Solidifying point	0°	4°	15°
Saponification number	193·36	173·63	182·81
Iodine number	106·22	71·64	115·17
Acid number (calculated as oleic).	1·433	3·19	5·65
Acetyl number	—	44·08	—
Melting point of fatty acids .	28°–30°	37·6°	39·5°
Solidifying point of fatty acids .	—	28·5°	29·7°
Iodine number of fatty acids .	106·04	72·33	123·27
Refractometer number at 15° (Zeiss-Wollny)	—	61·3–61·5	74·5

F. H. L.

[Oil of paradise nuts must not be confused with oil of grains of paradise. Grains of paradise, guinea grains, or Melegueta pepper (*Semina cardamomi majoris*) are the seeds of *Amomum melegueta*, an African plant of the ginger species. This oil is volatile (*cf.* ANALYST, 1898, xxiii., 12). Paradise nuts are also known as sapucaia nuts, or "monkey pots."—F. H. L.]

Henriques' Process for the Analysis of Indiarubber Articles. R. Thal. (*Chem. Zeit.*, 1898, xxii., 974.)—This process (*Chem. Zeit.*, 1892, xvi., 1644) consists, *inter alia*, in a separation of the true rubber from rubber substitutes by the action of boiling 8 per cent. alcoholic soda, filtering off the dissolved matter through paper to avoid contamination of the solution with particles of loosened loading material, etc. Thal observes that an error is introduced into the operation by the partial solubility of filter-paper in the reagent; and he finds that Schleicher and Schull's extracted papers "No. 589," previously dried to constant weight at 100° C., lose between 4·86 and 6·88 (mean 5·63) per cent. of their weight when 100 c.c. of 8 per cent. alcoholic soda and the necessary amount of water to remove alkalinity pass through them. Rubber goods which are not loaded and only lightly dusted with talc need not be actually filtered to separate the soluble from the insoluble portion; but loaded articles must be filtered for the reasons just mentioned. He suggests, therefore, that the "No. 589" papers 12·5 cm. in diameter be always employed, and that 5·5 per cent. of their weight be added to the extracted rubber residue as a correction for solubility; taking 4 grammes of the sample for analysis, this loss, if not allowed for, would lead to a deficit of about 1·42 per cent. in the residue calculated on the crude material.

F. H. L.

Vanillin Mixed with Acetanilide. R. Hefelmann. (*Apoth. Zeit.*, 1898, No. 49; through *Deutsche Chem. Zeit.*, 1898, xiii., 358.)—In this product (which has already been referred to, ANALYST, 1898, xxiii., 266) the acetanilide was detected by a nitrogen estimation. The adulterated vanillin began to melt at 61°, instead of between 79° and 82°. It was only partially soluble in dilute caustic soda, whereas it should have been easily and completely soluble. To isolate the impurity, an ethereal solution was repeatedly extracted with strong sodium bisulphite, when the vanillin passed entirely into the aqueous liquid in combination with the bisulphite; the ether was washed in a little water and evaporated. The residue exhibited the correct crystalline form, melted at 111° to 113°, yielded drops of aniline on warming with

concentrated potash, and gave a strong odour of isonitrile on addition of chloroform to the alkaline liquid. Acetic acid was also to be recognised by the ordinary tests.

F. H. L.

INORGANIC ANALYSIS.

The Assay of Telluride Gold Ores. C. H. Fulton. (*School of Mines Quarterly*, 1898, xix., 419-426.)—From the results of a series of experiments on the assay of gold ores containing tellurium, the author has come to the following conclusions: In order to obtain good results, it is essential to have a large excess of litharge, but in the case of rich telluride ores this should be obtained by reducing the amount of ore, rather than by increasing the litharge, since otherwise the lead button may be too large to cupel directly. In the crucible assay, with direct cupellation, which is considered the best, the fire should be moderately hot, and the length of time in the furnace should be from forty to fifty minutes. The assay should be conducted so as to give a button of good size (from 20 to 28 grammes). The cupellation should be made at a low heat with crystals of litharge forming on the cupel, and in accurate assays the crucible slag should be re-melted, the button cupelled, and the amount of gold added to the first assay.

Scorification of any kind leads to bad results with telluride ores, and the loss of gold on cupelling a large or brittle button directly is much less than if it were first rescorified. The amount of gold lost in the slag on scorifying directly is very great, amounting to as much as 5·6 per cent. in the assays described.

The loss of gold in a rich telluride ore is greater than in a low-grade ore, but the percentage of loss decreases with the richness of the ore.

These conclusions agree with the experience of F. C. Smith, who found that the loss of gold in the assay of ores containing tellurium was very great, if the charge was not prepared with the correct proportion of litharge. C. A. M.

Separation of Zinc, Copper, Mercury, or Bismuth from Aluminium. F. S. Havens. (*Zeits. anorg. Chem.*, 1898, xviii., 147.)—The process which the author has already described (ANALYST, xxii., 194, and xxiii., 109) for the precipitation of aluminium chloride in presence of ether and hydrochloric acid, is equally available for the removal of the other metals mentioned in the title. The residual zinc chloride is preferably converted into nitrate by repeated evaporations with nitric acid, then ignited in a platinum crucible and weighed as oxide. Copper is converted into sulphate, rather than nitrate, and also weighed as oxide.

The figures recorded by the author in two tables are highly satisfactory, showing maximum errors of −1·3 and +0·9 milligrammes in estimating about 0·5 gramme of alumina; −0·8 and +0·4 milligrammes (corrected) in the direct estimation of the accompanying zinc oxide (0·1 to 0·2 gramme); and −0·7 and +1·3 milligrammes in the case of copper oxide; while all the mean results are practically identical with those demanded by the theoretical composition of the several mixtures analysed.

F. H. L.

Analysis of Ferro-Tungsten. A. G. McKenna. (*Proc. Eng. Soc. Western Pennsylvania*, 1898, xiv., 171.)—0·5 gramme of the finely-powdered sample is mixed with 3 grammes of sodium peroxide in a copper* crucible, and the mass is raised for a minute to a dull-red heat, holding the crucible in tongs so as to agitate its contents and prevent the alloy from sinking to the bottom. The melt is extracted with water, a few c.c. of alcohol added to render manganese insoluble, and the whole filtered. The filtrate, containing the tungsten and part of the silica, is evaporated to dryness twice with hydrochloric acid, taken up in weak HCl, boiled, filtered, and the residue washed with 1 : 10 nitric acid (water would cause it to pass through the paper). The insoluble matter from the fusion, which contains the iron, manganese, copper, and some of the silica, is dissolved in hot dilute nitric acid and evaporated to dryness. It is dissolved in weak HCl, and the silica is collected on the same filter that already holds the tungsten, washing as before with nitric acid. The combined precipitate is ignited and weighed as $WO_3 + SiO_2$; then treated with 0·5 c.c. of sulphuric and 5 c.c. of hydrofluoric acid to volatilize the latter in the usual way. The iron and manganese are subsequently separated.

In the presence of chromium and aluminium, the filtrate from the tungsten should be precipitated with ammonia, the mixed oxides weighed together, dissolved in strong nitric acid and potassium chlorate, and the alumina thrown down alone by a small excess of ammonia. After adding nitric acid, the chromium in solution can be titrated with ferrous sulphate and permanganate, or reduced with peroxide and weighed as Cr_2O_3. Part of the aluminium will be found in the iron precipitate, and must be allowed for.

Carbon may be conveniently estimated by the same process, for it is entirely converted into sodium carbonate, which can be decomposed with acid, absorbing the gas in barium hydrate. Corrections must be made for the several impurities, carbonate, silica, and iron, in the sodium peroxide, for which reason a known amount must always be used. F. H. L.

Estimation of Molybdenum. H. Brearley. (*Chem. News*, 1898, lxxviii., 203.)—The author has investigated Chatard's gravimetric process, which depends on the precipitation of sodium molybdate with lead acetate; and also Schindler's volumetric method of titrating an acidified solution of a molybdate with lead acetate, using tannin as an external indicator. To the former, various limitations were ascribed by Fresenius and by Chatard himself; but the present experiments widen its range of usefulness and bring out the following points: It is not necessary to employ neutral solutions; some free acetic acid is advantageous, as it obviates any danger of precipitating lead if faint alkalinity has been overlooked. Two c.c. of 33 per cent. acid may safely be used when dealing with 0·1 gramme of molybdenum; but an excess tends to change the molybdate from a granular to a powdery nature, and

* The author finds that copper resists the action of sodium peroxide quite as well as nickel, while adventitious salts of the former metal are less troublesome in the course of an analysis.

renders it liable to pass through the filter. This may be overcome by washing with a mixture of 1 c.c. of lead acetate solution (7·896 grammes per litre) and 500 c.c. of water just acidified with acetic acid. It is not necessary to separate the precipitate from the paper before ignition; they can be burnt together, wet or dry, in a muffle. It is advisable, however, to carbonize the paper at the lowest possible temperature, because extreme heating to remove refractory carbon is disallowed by the instability of the lead molybdate. The precipitate is not reduced nor appreciably altered in weight by ignition in presence of carbon. It can be safely ignited at a moderate red heat; even at full redness, or the melting-point of sodium carbonate, it only loses about 1 per cent. in six hours.

The chlorides and nitrates of sodium and ammonium do not affect the process; ammonium acetate, as made by neutralizing 0·880 ammonia with 33 per cent. acid, in large amounts simply involves a second filtration of the precipitate. It does not appear to retain alkaline salts, and prolonged washing is therefore unnecessary. If the ignited precipitate is dissolved in hydrochloric acid, neutralized with ammonia, treated with excess of acetic acid and a little more lead acetate, the purified molybdate is never sensibly different in weight. Manganese, copper, cobalt, nickel, zinc, magnesium, and mercury (ic) exert no practical interference, and occasion no trouble beyond more careful washing or a reprecipitation of the ignited molybdate. Even the unpurified precipitate carries down with it but little of these metals; and their presence can generally be detected by a variation from the normal (creamy) colour of the product. Cobalt requires a second precipitation. Zinc molybdate is mostly dissolved by the usual excess of acetic acid; if only an opalescence remains, it may be neglected; if the liquid is distinctly cloudy, the free hydrochloric acid of the original molybdenum and zinc solution must be partly replaced by acetic. In presence of mercury, the liquid must be warmed or ammonium acetate added. Uranium contaminates the molybdate of lead more seriously; by one reprecipitation the error may be reduced to 0·5 per cent.; but repeated operations are needed to separate the last traces.

Schindler's volumetric process is quicker and gives equally correct results with pure alkaline molybdates; but as the end of the titration is approached, the colour eaction between the molybdate and the tannin becomes rather uncertain. The method may be made more accurate by employing the tannin indicator as long as it is available (generally this is to within 1 per cent. of the truth), then filtering off a little of the hot liquid and testing it with lead acetate and sodium molybdate; more of the necessary reagent is added to the bulk, and the test is repeated with the same filter until the titration is complete. The influence of other metallic salts has not been investigated.

The reaction between lead acetate and molybdenum is so delicate that in a solution faintly, but decidedly, acid with acetic acid, 1 part of molybdenum in 4 million produces a distinct cloudiness. F. H. L.

The Analysis of Commercial Chrome Yellow. Willenz. (*Bull. de l'Ass. belge.*, 1898, xii., 163-167.)—The author's objection to Wittstein's method of examining chrome yellow (*Dingl. polyt. Jour.*, ccx., 280) is that the lead chromate is not

completely decomposed by the digestion with sodium carbonate, and hence the residue cannot be correctly taken as barium sulphate. He has found, in fact, that the residue from pure lead chromate may amount to as much as 49 per cent.

The following method is recommended as giving satisfactory results. One gramme of the powdered material is digested with 100 c.c. of dilute hydrochloric acid (1·20) at a gentle heat, and the residue transferred to a filter and washed with hot water. The total calcium in the filtrate is precipitated as oxalate, the calcium present in the form of sulphate calculated from a determination of the sulphuric acid, and the calcium in the form of carbonate obtained by difference. The lead sulphate is determined by digesting the residue with 50 c.c. of a neutral or slightly alkaline solution of ammonium acetate (specific gravity, 1·04), filtering, and evaporating the filtrate to dryness with an excess of sulphuric acid.

After the addition of 50 c.c. of water, the residue is boiled for about ten minutes with 25 c.c. of a solution of potassium hydroxide, containing 112 grammes of KOH per litre. This converts the lead chromate into potassium plumbite, which dissolves, leaving behind the barium sulphate and clay.

A separate estimation of the amount of chromic acid is made by Bunsen's iodometric method. C. A. M.

The Analysis of Incandescence Mantles. E. Hintz and W. Weber. (*Zeit. anal. Chem.*, 1898, xxxvii., 94-111.)—The mantles which have come under the authors' notice during the last three years have been composed almost without exception of thoria (96·42 to 99·26 per cent.) and ceria (0·49 to 2·02 per cent.), whilst the other rare earths, neodymia, lanthana, yttria, and zirconia, have only been present in minute quantities. Lime (0·1 to 1·05) and magnesia (trace to 0·21) were almost invariably present, and in some cases traces of silica.

With the object of determining whether these minor constituents had any influence on the light-emitting properties of the mantles, one of the authors (Hintz) has made a series of photometric experiments, from which he has arrived at the following conclusions:

1. Zirconia, lanthana, and yttria added in small quantities up to 1 per cent. do not increase the illuminating capacity of pure thoria mantles, but, on the contrary, tend to lower it. A very small addition of neodymia is also without much effect, but when the amount reaches 1 per cent. there is a slight increase in the quantity of light emitted.

2. The addition of neodymia, lanthana, or yttria (up to 1 per cent.) to mantles composed of thoria (99 per cent.) and ceria (1 per cent.) does not increase their illuminating power. Similarly, an addition of from 0·2 to 1 per cent. of zirconia has no effect, but the influence of 0·1 per cent. is doubtful.

3. An addition of zirconia, neodymia, lanthana, or yttria (up to 1 per cent.) to thoria-ceria mantles containing 0·5 per cent. of lime is without effect.

The authors have examined Knorre's volumetric method of determining ceria (ANALYST, this vol., 191), and find that the results thus obtained are as reliable as those of the gravimetric method. For the volumetric estimation of ceria in the

quantity in which it occurs in mantles they proceed as follows: 100 c.c. of the solution containing about 1 gramme of thoria and 0·1 gramme of ceria are acidified with from 5 to 7·5 c.c. of dilute sulphuric acid (1 : 6), diluted to 200 c.c., and the cerium compounds oxidized into the ceric state by adding three small successive portions of ammonium persulphate in the cold, and then boiling for one or two minutes after the first two additions, and finally for from ten to fifteen minutes after the final addition (about 3 grammes of persulphate are required to oxidize 0·2 to 0·3 gramme of cerium). At the conclusion of the boiling an additional 2 c.c. of the dilute sulphuric acid is added. When completely cold a dilute solution of hydrogen peroxide is run in, and the liquid rapidly titrated with potassium permanganate.

The authors recommend the following simplified method for the analysis of unburnt mantles. A number of the stockings—not less than twelve—are weighed, and their upper and lower ends cut off, since the former are often dipped in a hardening solution, and the latter into a solution of a cerium salt, in order to make the total percentage of ceria appear higher. The middle portions are weighed and completely extracted with water containing a few drops of nitric acid. The fabric remaining is ignited, the ash fused with potassium bisulphate, the melt dissolved in water containing hydrochloric acid, ammonia added, the precipitate dissolved in nitric acid, and the solution added to the main solution, which is then made up to definite volume.

1. Neodymia is tested for spectroscopically in a portion of the concentrated solution.

2. An aliquot portion is treated with oxalic acid after removal of the free acid by evaporation.

a. The precipitate is collected on a toughened filter, washed, and tested for neodymia, lanthana, and yttria as follows: The precipitate is washed into a beaker, heated with a concentrated solution of ammonium oxalate, the liquid diluted, allowed to cool, and filtered after standing for a long time. As the authors have shown in a former communication (ANALYST, this vol., 81), the residue left after extraction with ammonium oxalate contains a little thorium oxalate, so that even in the absence of neodymia, yttria, and lanthana, the percentage of ceria obtained will be higher than the truth. The presence of lime has also an influence on the result. If, however, the amount calculated from the weight of the precipitate does not exceed that of the actual quantity of cerium present by more than 1 per cent., it may be at once concluded that neodymia, lanthana, and yttria are not present in sufficient quantity to affect the illuminating capacity.

If, on the other hand, the excess is more than 1 per cent., a further examination is required. The weighed precipitate is dissolved by heating with sulphuric acid in a platinum crucible and the solution tested for these earths.

b. The filtrate from *a* is evaporated to dryness, the residue gently ignited, dissolved in hydrochloric acid, the excess of acid removed by evaporation, and the zirconia tested for microchemically by evaporating a drop of the solution on the object-glass after the addition of a drop of a solution of potassium binoxalate. In the presence of as little as 0·1 per cent. of zirconia characteristic crystals of potassium zirconium oxalate are to be observed.

3. An aliquot portion of the solution after removal of the free acid is precipitated with oxalic acid, and the precipitate, consisting of the total rare earths excepting zirconia, ignited and weighed. Lime has an influence on the result, but for practical purposes the authors consider that it is not of great importance if, in a mantle containing, say, 98·4 per cent. of thoria and 1·2 per cent. of ceria, 0·4 per cent. of lime is calculated with the thoria (= 98·8 per cent.).

4. The ceria is determined volumetrically in another aliquot part of the solution. The result deducted from that obtained in (3) gives the amount of thoria, provided that not more than negligible quantities of neodymia, lanthana, and yttria are present. C. A. M.

Estimation of Carbon in Iron by Combustion. Rozycki. (*Monit. Scient.*, 1898, [4], xii., 636; through *Chem. Zeit. Rep.*, 1898, 254.)—2·3 grammes of steel, or 0·25 gramme of ferrochrome, in fine powder, are mixed with 20 grammes of pure alumina, placed in a boat inside a combustion-tube 60 cm. long, and ignited in a current of pure oxygen. The gas is led over red-hot copper oxide, and finally absorbed in baryta water. The baryta is decomposed with nitric acid in Wiborgh's apparatus, and the carbon dioxide measured. The combustion occupies thirty-five minutes with steel, 1½ hours with ferrochrome. F. H. L.

A Reaction of Metallic Sulphides soluble in Ammonium Sulphide. J. Ducommun. (*Schweiz. Woch. Pharm.*, 1898, 434; through *Deutsche Chem. Zeit.*, 1898, xiii., 346.)—When yellow ammonium sulphide is mixed with a small quantity of formaldehyde, the colour disappears, and after a short time a copious white precipitate is thrown down, which is entirely soluble in strong sulphuric acid. If the sulphide is first diluted till it is only faintly yellow, formaldehyde produces no precipitate, and the liquid remains perfectly clear. In the presence of arsenious sulphide, the solution is bleached by the formalin, while sulphuric acid yields a white precipitate insoluble in excess. Antimony gives an orange-red precipitate on addition of acid; stannous or stannic sulphide, a white; gold, a yellowish-white; platinum, a brownish-red; the latter metal also prevents the previous decolorization. The precipitates are evidently some organic compound of the respective metals, for they turn black on ignition. In all cases the liquids should be cold and highly dilute; and then the reaction is capable of detecting 2 milligrammes of arsenious acid, and somewhat more of either gold or platinum. Arsenic acid only behaves in a similar fashion after it has been reduced by boiling the ammonium sulphide.

The process may be employed in the course of ordinary qualitative analysis to avoid the use of sulphuretted hydrogen. The solution containing various metals is neutralized with ammonia, treated with ammonium sulphide, and boiled to dissolve platinum and reduce arsenic compounds. One part of the filtrate is diluted and mixed with formaldehyde and acid. If a precipitate is produced, the remainder of the filtrate is analysed in the regular way; but if no precipitate is formed, arsenic, antimony, and tin are absent, and the first sulphide precipitate, together with the mother liquor, is concentrated slightly, and boiled with strong hydrochloric acid in order to separate the mixture into a solution containing those metals whose sulphides

are acid-soluble and a residue of the heavy metals, such as copper, etc., which yield insoluble sulphides; these are then severally examined as may be necessary.

The reaction shows that many sulphides, usually considered to be insoluble in ammonium sulphide, are really a trifle soluble therein—viz., copper, iron, lead, mercury. It should also be useful for detecting arsenic in pharmaceutical preparations like bismuth subnitrate. F. H. L.

Estimation of Sulphides, Sulphites, and Thiosulphates. W. Feld. (*Chem. Industrie*, "17/1898"; through *Deutsche Chem. Zeit.*, 1898, xiii., 322.)—The fundamental reactions underlying the author's processes are as follow: (1) Sulphides of the alkalis and alkaline earths, whether dissolved or suspended in water, are decomposed by a strong solution of magnesium chloride, forming sulphydrate and hydroxide, which are broken up on boiling in a current of carbon dioxide into magnesium carbonate and sulphuretted hydrogen. The latter is absorbed in standard iodine. (2) Sulphites yield the theoretical amount of sulphurous acid on distillation with hydrochloric acid, and the gas is also absorbed by iodine. Thiosulphates cannot be estimated in this way, for on heating with hydrochloric acid they produce sulphuretted hydrogen and sulphurous acid, with the deposition of free sulphur. (3) But if a thiosulphate is treated with iodine, it is converted into tetrathionate, and the latter distilled with HCl in presence of aluminium is reduced to H_2S, which can be determined in standard iodine as before. Any sulphite present at the same time is oxidized at once to sulphate, and takes no further part in the operation. (4) Thiosulphates are decomposed by mercuric chloride, yielding mercuric sulphide and a sulphate. Sulphites are not attacked, so that they can be boiled with HCl, and the SO_2 absorbed as before. Excess of mercuric chloride is advantageous, and it may be employed in the solid state.

An Erlenmeyer flask, holding 300 to 350 c.c., is fitted with a rubber cork having two holes. Through one is introduced a stoppered tube-funnel reaching to the bottom of the vessel; its upper opening can be closed with a cork bearing a bent tube connected to a supply of pure carbon dioxide (conveniently a cylinder of liquid). Through the second hole of the main cork is passed a short tube joined to four Geissler's potash bulbs, the ends of the several pieces of apparatus being made to touch within the rubber connecting tubes. The last set of bulbs is joined to a 10-litre aspirator to maintain and regulate the current of gas, and to measure roughly the volume passed. The first bulbs are empty, serving as water-condensers; the second are charged with a sufficiency (5 to 40 c.c.) of decinormal iodine to absorb all the gas evolved; the third contain some more (2 to 15 c.c.), diluted if necessary with water; the fourth are filled with 5 or 10 c.c. of decinormal thiosulphate to catch any volatilized iodine. To analyse a mixture of sulphide, sulphite, and thiosulphate, the sample in solution or fine powder mixed with water is brought into the flask, the cock on the funnel closed, and the whole apparatus tested for leaks. If satisfactory, the funnel tube is raised out of the liquid, and about 1 litre of CO_2 is passed to drive out air (were this precaution omitted, part of the H_2S might be oxidized to free S, which, however, would be noticed in the empty bulbs). Twenty c.c. of a 25 per cent.

solution of magnesium chloride (specific gravity, 1·22) are run in through the funnel without admitting air, the tube is pushed down again to the bottom of the flask, the liquid is heated, and the gas turned on at such a speed that the aspirator is emptied in about forty-five minutes. The potash bulbs are then rinsed out and titrated, 1 c.c. of $\frac{N}{10}$ iodine being equal to 0·00895 gramme of BaS or to 0·0039 gramme of Na_2S. The bulbs are charged once more, mercuric chloride and hydrochloric acid added to the contents of the flask, and the whole distilled again; the amount of iodine consumed represents the sulphite, 1 c.c. being equal to 0·0063 gramme of Na_2SO_3. A fresh portion of the original sample is titrated with $\frac{N}{10}$ iodine till it turns blue (the quantity used need not be noted); the mixture is placed in the same flask, together with rolls of thin pure aluminium foil which partly project above the liquid, acid is added, the gas turned on, and finally the solution is gently warmed; this gives the thiosulphate; 1 c.c. of iodine is equal to 0·00395 gramme of $Na_2S_2O_3$. It is highly desirable to check the purity of the several reagents employed throughout the process, lest reducing gases be produced among them. F. H. L.

Direct Conversion of Potassium Iodide and Bromide into Chloride. F. W. Küster. (*Zeits. anorg. Chem.*, 1898, xviii., 77.)—Dry potassium iodide can be safely and quantitatively converted into chloride by ignition in a stream of chlorine at a moderate temperature, heating it (about 2·5 grammes) for half an hour in a porcelain crucible over a luminous gas-flame about 2 cm. high, the top of which is kept 3 cm. from the base of the vessel. Even if the temperature be raised for a time till the crucible begins to glow, the loss is very minute (0·3 milligramme), and it is doubtful whether this is actually caused by volatilization of chloride. Dry potassium bromide cannot be decomposed in this manner; but if the sample be moistened, a similar reaction takes place more slowly, and by the following modification becomes equally available for analytical purposes. 2·5 grammes of the bromide are brought into an Erlenmeyer flask 7 cm. in height, together with 1 c.c. of water and 1 drop of 10 per cent. hydrochloric acid; and a current of chlorine is admitted through the porcelain tube of a Rose's crucible. The flask is placed on a sheet of asbestos, with a second sheet 2 cm. beneath, on which plays a small pilot gas-flame. The temperature is raised till the bromine evaporates quickly without boiling. After an hour or an hour and a half, one of the asbestos shields is removed and the water driven off; then the heat is gradually increased until the remaining asbestos is visibly red. The whole operation is repeated once or twice to obtain constant weight; but if a smaller quantity of bromide is taken in the first instance, the reaction is often complete the first time. The result may be most simply calculated by the use of the formula

$$\%KBr = a + b\frac{g'}{g}$$

where $a = 267{\cdot}59$; $b = -267{\cdot}59$; g' the weight of the potassium chloride; g that of the original bromide.

The examples quoted by the author show yields of 100·00 and 100·01 per cent. when working on pure potassium iodide. A specimen of Kahlbaum's bromide gave

99·07 and 99·08 per cent. of KBr by the above method; 99·06 and 99·20 per cent. by ignition of the silver halide in chlorine (calculating from the potassium bromide itself); 99·16 and 99·10 per cent. by similar treatment (calculating from the silver compound).

Commercial iodide seldom contains any impurity except water; bromide contains nothing except moisture and chloride. F. H. L.

Volumetric Estimation of Combined Sulphuric Acid. M. Reuter. (*Chem. Zeit.*, 1898, xxii., 357.)—The author has submitted Andrews' method for the titration of sulphate solutions to a careful examination; and he finds, provided the operation is carried out exactly in the following manner, that its accuracy, speed, and simplicity leave nothing to be desired. 10 c.c. of the original solution, which should contain about 0·14 gramme of anhydrous sodium sulphate, are boiled with 150 c.c. of a solution of barium chromate prepared by dissolving 3 or 4 grammes of pure precipitated chromate in 1 litre of water by the aid of 30 c.c. of strong hydrochloric acid. The acid is neutralized with powdered chalk, and the precipitate filtered off and washed; the filtrate is thoroughly cooled, acidified with 5 c.c. (not more) of strong HCl, treated with 20 c.c. of a 10 per cent. solution of potassium iodide, allowed to rest for five minutes in a covered vessel and an atmosphere of carbon dioxide (to give time for the complete reduction of the chromic acid, yet to prevent oxidation of the HI), then diluted to 1 or 1½ litre, and finally titrated with decinormal thiosulphate. Three atoms of iodine correspond to one molecule of sulphuric anhydride. F. H. L.

Method of Preparing an Exactly Neutral Ammonium Citrate Solution. A. D. Cook. (*Jour. Amer. Chem. Soc.*, 1898, xx., 585-586.)—It has been stated by several chemists that an exactly neutral ammonium citrate solution for agricultural analysis may be obtained by allowing the solution to stand after ammonia has been added to the citric acid and the proper dilution made. The author, however, finds that this is only the case when the solution has a sufficient temperature to expel the excess of ammonia. By vigorous stirring sufficient heat for the purpose is caused by the chemical action, but if this is neglected the solution will be slightly alkaline. The method recommended for the preparation of the reagent is as follows: 740 grammes of commercial citric acid are mixed with 1,900 c.c. of 10 per cent. ammonium hydroxide. After vigorously stirring the liquid until the acid has all dissolved, the solution is made up to 4,000 c.c. with water. It is then again stirred and transferred to a large evaporating dish, where it is allowed to stand over-night. Finally, it is transferred to the reagent bottle, brought to 20° C., and water added until the specific gravity is 1·09. C. A. M.

Estimation of "Available" Phosphoric Acid in Thomas Slag. J. Freundlich. (*Chem. Zeit.*, 1898, xxii., 974.)—Wagner has lately shown (ANALYST, 1897, xxii., 334) that in slags containing much silica, this substance may be prevented from contaminating the precipitate of ammonium magnesium phosphate, if the freshly

prepared citrate extract be treated with magnesia mixture previously mixed with alkaline citrate solution. Many slags, however, also contain sulphide of iron and calcium; and these bodies, being decomposed by the citric acid, yield sulphuretted hydrogen, which does not entirely escape, but, combining with the ammonia afterwards added, precipitates the iron once more, producing a blackish phosphate that becomes red on ignition. To avoid this error, a second precipitation should be resorted to whenever the slags contain much sulphur; and the ferrous sulphide in the first precipitate should be oxidized with nitric acid or aqua regia. F. H. L.

Estimation of Perchlorate in Chili Saltpetre. O. Foerster. (*Chem. Zeit.*, 1898, xxii., 357.)—The ordinary method of reducing the chlorates and perchlorates in commercial sodium nitrate by heating the mass to a red heat has several disadvantages. If the temperature be too low, they are not completely decomposed; while on the other hand, chlorine is apt to be lost by volatilization of the sodium chloride. The author's process is very exact, and does not demand the use of any particular degree of heat. 10 grammes of the sample are mixed with an equal weight of dry sodium carbonate (free from chlorine), and the whole is heated in a covered platinum or capacious porcelain crucible over a large flame for about ten minutes, till the mass is in tranquil fusion and no more bubbles of gas are given off. The melt does not creep up the walls of the vessel, and it is readily soluble. It is finally dissolved in excess of nitric acid, and the total chlorine is determined as usual. F. H. L.

(*Cf.* Abstract, ANALYST, xix. 221.)

Estimation of Perchlorate in Saltpetres. N. Blattner and J. Brasseur. (*Chem. Zeit.*, 1898, xxii., 589.)—Five or ten grammes of the dried potassium or sodium nitrate are heated for fifteen minutes over a Bunsen flame with 8 or 15 grammes of calcium oxide, carbonate, or preferably hydroxide. The mass is dissolved in pure nitric acid, the total chlorine determined by any of the usual methods, and deducted from that already existing as chloride in the original sample. The process is more convenient than those in which alkali-metal carbonates are employed, because the mixture does not melt, and thus is more readily soluble, while there is no danger of loss by volatilization, etc.

In three different ship-loads of "refined" Chili saltpetre, supposed to contain at least 96 per cent. of sodium nitrate and less than 1 per cent. of sodium chloride, the authors discovered from 0·12 to 1·01 per cent. of NaCl, and from 0·42 to 0·77 per cent. of $NaClO_4$; while a sample of potassium nitrate, "pure for analysis," contained 0·47 per cent. of perchlorate, but no chloride. F. H. L.

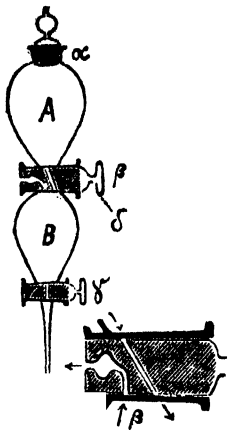
(*Cf.* ANALYST, xix., 221.)

Microscopic Detection of Perchlorate in Chili Saltpetre. M. van Breukeleveen. (*Rec. trav. chim. des Pays-Bas*, 1898, xvii., 94; through *Chem. Zeit. Rep.*, 1898, 145.)—Behrens' test for a perchlorate, which depends on the recognition under the microscope of the rhombic and almost insoluble crystals of rubidium perchlorate, can only be used in the examination of sodium nitrate when the impurity (calculated

as potassium perchlorate) amounts to at least 0·6 per cent. To detect smaller quantities (0·2 to 0·6 per cent.) 10 grammes of the sample are dissolved in 10 c.c. of hot water, diluted with 50 c.c. of 95 per cent. alcohol, raised to the boiling-point, and allowed to cool for one or two hours. The clear liquid is then poured off, evaporated to dryness on the water-bath, the residue taken up in as little water as possible, and Behrens' test applied. If the rubidium salt is coloured with permanganate, only enough of the latter must be added to give the liquid a faint pink tint when it is placed on the microscope slide and held over a sheet of white paper; or crystals of rubidium permanganate may be mistaken for those of the perchlorate.

F. H. L.

A False Nitrous Acid Reaction in a Drinking Water. A. Bömer. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 401.)—The attention of the directors of a waterworks having been called to a strong nitrous acid reaction given by the water, the matter was referred to the author for report. The addition of zinc iodide and starch and sulphuric acid certainly produced a deep blue colour. On careful examination, however, the water was found to contain some suspended matter which proved to be manganic dioxide, the presence of which, in conjunction with the chlorides in the water and the added sulphuric acid, would be sufficient to account for the reaction. After separating the suspended matter from the water the reaction was not produced.

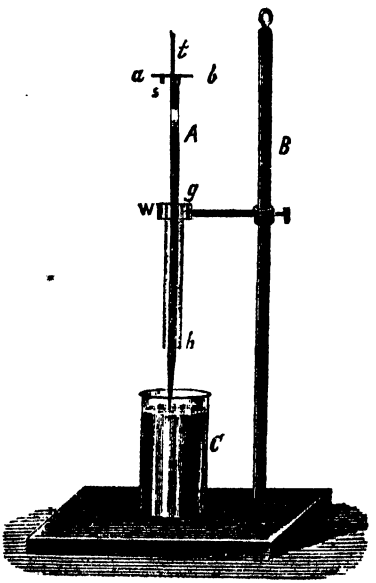


A short time afterwards the author received from the same company for examination a piece of lead pipe containing a brownish-black incrustation, which proved upon analysis to consist principally of oxides of manganese. H. H. B. S.

The Advantage of using "Normal Volumes" in Analysis. M. Monhaupt. (*Chem. Zeit.*, 1898, xxii., 806.)—In the ordinary routine work of a laboratory, it is customary to weigh out such a quantity of the substance under examination that the final figures (weights, volumes, etc.) shall give at once the percentage of the ingredient sought; the author pleads that the same device should be adopted when the sample is measured at the commencement of the test. For instance, in the potash trade, where determination of the proportion of potassium chloride in raw products, etc., is constantly required, the original ("normal") weight is always a multiple of 0·3056 gramme—the factor which converts K_2PtCl_6 into KCl—and the final weight multiplied by 100 is the percentage desired. Similarly, when the analysis has to be conducted on a liquid, 30·56 c.c. (the "normal volume") may advantageously be measured in a special pipette, and tedious calculation be avoided here also.

F. H. L.

APPARATUS.



Apparatus for the repeated Extraction of Liquids with Immiscible Solvents. T. Posner. (*Chem. Zeit.*, 1898, xxii., 868.)—The idea of this apparatus is to avoid the loss of material which often accompanies the use of a separating

funnel when a solution has to be extracted more than once with the same liquid. It is essentially a combination of two separating-funnels joined together by means of the stop-cock β. The plug of the latter has two passages lying in the same plane: one serves to place A and B in connection, the other simultaneously allows the air in B to escape—the bulb shown in the enlarged section being intended to catch any splashes. The liquid to be extracted is placed in A; if the solvent is specifically heavier, it is simply run off into B, which acts as a reservoir, while a fresh portion is brought into A and agitated once more. When the solvent is lighter than the liquid, extraction takes place in A, the aqueous portion is passed into B, A is emptied into a beaker or flask, the whole apparatus is inverted, and the liquid run back into A for treatment again. To prevent mistakes one end of the crutch handle of β is made of coloured glass.

F. H. L.

Apparatus for Determining the Consistency of Grease and Similar Articles. **R. Kissling.** (*Chem. Zeit.*, 1898, xxii., 867.)—This is an improved form of the apparatus originally devised for estimating the viscosity of a grease by noting the time occupied by a weighted rod to sink into the mass. A is an aluminium rod weighing exactly 50 grammes, 300 mm. long, 9 mm. in diameter, and tapered from a point 55 mm. above its lower extremity to its end. ab is an X-shaped plate of brass fastened to the rod, having a pin t, on which three annular weights of 50, 100, and 200 grammes respectively can be dropped; s is a stop that at the end of the test rests upon W. gh is a glass tube 150 mm. long and 9·5 mm. in internal diameter, supported vertically by the metal ring W. C is filled with the material under examination to a height of 120 mm. When making a test, it is desirable so to arrange the apparatus that the rod shall fall in between 10 and 60 seconds; if this be done, by adding the number of seconds to the total weight of A (including the brass weights, if one or more be employed), a "consistency number" is given directly. But whenever the period of fall exceeds 100 seconds, if the weight of A is 50 grammes the number of seconds must be divided by ten, and if the weight is 100 grammes divided by two before adding the time to the weight. In this manner greases and gelatinous preparations can be valued simply and with fair accuracy, for the apparatus is capable of differentiating such bodies according to their viscosity into materials having "consistency numbers" ranging between 94 and 405.

F. H. L.

THE ANALYST.

FEBRUARY, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

An extraordinary general meeting was held on Wednesday, January 4, 1899, in the Rooms of the Chemical Society, Burlington House, Piccadilly, for the purpose of amending the constitution and rules of the Society.

The President (Dr. Dyer), who occupied the chair, explained the amendments suggested by the council, which, in addition to minor alterations, included a re-modelling of the conditions under which candidates might apply for admission to the membership of the Society. The chief amendment in the rule bearing upon this point was in the omission of the hitherto existing provision that candidates for membership should be analysts in actual practice, a qualification which it had always been difficult to define, and one which it had been frequently necessary to interpret with some degree of elasticity. Notwithstanding this, the rule had formed a technical barrier to the inclusion within the ranks of the Society of a number of qualified analysts who otherwise would have been glad to join the ranks of the Society. The council believed that the new and wider definition would, by removing this difficulty, be advantageous to the Society, as well as to the profession from the ranks of which its members were drawn.

The adoption of this new definition of qualification would render the existence of the class of associates, viz., assistants to analysts in actual practice, no longer necessary, and it was therefore proposed that the Society should not in future include associates. The present associates who had attained the age of twenty-one would at once be eligible for admission to full membership by election in the usual way, while the remainder, whose number, he believed, was but very small, would become eligible on reaching that age.

After a discussion, in which Messrs. A. E. Ekins, E. W. Voelcker, S. Rideal, E. J. Bevan, H. Droop Richmond, C. H. Cribb, and Leo Taylor took part, the new constitution and rules were unanimously adopted, on the motion of the President, seconded by Mr. A. E. Ekins.

The monthly ordinary meeting of the Society was held on Wednesday, January 4, 1899, after the extraordinary meeting, the President (Dr. Dyer) being in the chair.

The minutes of the previous ordinary meeting were read and confirmed.

Mr. F. G. J. Bird, analyst to Messrs. C. R. Harker, Stagg and Morgan, London,

and Mr. J. H. Heywood, Heywood (Lancs.), were proposed for election as members.

On the proposition of Dr. Rideal, seconded by Mr. A. C. Chapman, Mr. B. Kitto and Mr. C. H. Cribb were appointed auditors of the Society's accounts for the past year.

The following papers were read:

"The Occurrence of Barium Compounds in an Artesian Well Water," by John White;

"A New Test for Formaldehyde," by Norman Leonard, B.Sc., and Harry M. Smith;

"On Caper Tea," by Charles Estcourt; and

"The Adulteration of Sweet Spirit of Nitre with Potassium Nitrate," by W. F. Lowe, A.R.S.M.

Messrs. Lester Reed, F.I.C., Harry Broadbent, F.I.C., W. T. Burgess, F.I.C., and T. S. Goodwin were elected members of the Society.

ON CAPER TEA.

By Charles Estcourt, F.I.C.

(*Read at the Meeting, January* 4, 1899.)

In the early days of the Food Adulteration Act it was found that tea of all kinds was largely adulterated. Caper tea especially was found to show evidence of gross fraud on the part of the Chinese growers, and as this kind of tea was much used in the North, and especially in Lancashire, I then examined a large number of samples, the analyses of which demonstrated that this tea, as then sold, contained quartz and magnetic iron ore nodules in quantities varying from 1 per cent. up to as much as 35 per cent. Other analysts also turned their attention to caper tea, the result being that gross adulteration was practically stamped out, as shown by the very few cases of caper tea certified by public analysts as adulterated since 1875. Out of a large number of samples of caper tea analysed in my laboratory from 1876 to 1897, only one contained more than 1 per cent. of mineral impurity. Mr. G. W. Wigner, in 1875, analysed a number of samples of caper tea drawn from bond. The lowest total ash that he found was 5·75 per cent., and the highest 7·02 per cent. The ash insoluble in hydrochloric acid varied from 0·70 per cent. to 1·67 per cent. In seven out of the nine cases which he records the ash insoluble in hydrochloric acid was less than 1 per cent. Dr. Bell, in 1881, in two samples of caper tea from bond, found that the total ash (calculated on the dry tea) was 6·38 and 6·63 per cent., and the ash insoluble in hydrochloric acid 0·68 and 0·93 per cent. In 1882 Mr. Carter Bell published in the Analyst the results of analyses of seventeen samples of caper tea purchased in Salford. The total ash of nine of these was less than 7 per cent., in only three cases exceeded 7·5 per cent., and in only one case exceeded 8 per cent.

Dr. Bell, the late Principal of the Inland Revenue Laboratory, in his book on "The Chemistry of Foods," says, in reviewing his analyses of genuine imported teas,

"the percentage of ash in no case, except one, . . . reaches 8 per cent. . . ." on the dried tea. This last ash, when calculated on the original undried sample, is equivalent to 7·7 per cent. With regard to mineral adulterants, Dr. Bell says, speaking of tea generally: "If the insoluble ash exceeds much more than 1 per cent., there is evidence of the addition of either sand, quartz, or other earthy impurities."

On August 24, 1898, I certified a caper tea as containing "2·25 per cent. of sand and ferruginous earth." At the hearing of the summons, the magistrates, without my analysis being questioned, sent the third portion of the sample to Somerset House. The following certificate (which, it will be observed, is not signed by either the Principal or Deputy Principal), was in due course received:

"GOVERNMENT LABORATORY,
"Clement's Inn Passage,
"Strand, London, W.C.

"The sample of caper tea marked 532, and referred to in your letter of the 7th instant, was received here on the following day securely sealed. We hereby certify that we have analysed the tea with the following results:

Total mineral matter	7·50	per cent.
Mineral matter soluble in water	2·36	,,
,, ,, in acid	3·12	,,
Silica (less sand)	1·38	,,
Sand	0·64	,,

"With the view of ascertaining how far the sample in question differs from caper tea now met with in commerce, and of fair commercial quality, we have procured a number of authentic samples of such teas out of bond. On analysis they furnish the following results:

Per Cent.	A.	B.	C.	D.	E.	F.	G.
Total mineral matter ...	6·74	7·90	7·26	7·20	6·44	7·08	8·00
Soluble in water ...	2·58	2·38	2·30	2·54	2·14	2·46	2·30
Soluble in acid	2·98	2·84	2·90	2·88	3·08	2·14	4·06
Silica (less sand) ...	1·04	0·32	1·76	1·40	1·06	1·26	1·08
Sand	0·14	2·36	0·30	0·38	0·16	1·22	0·56

"It is evident that the amount of foreign mineral matter in the case of the sample referred to us is not higher than that which may be present in genuine caper teas. We are of opinion, therefore, that the small proportion of extraneous matter present has become unavoidably mixed in the process of collection and preparation.

"As witness our hands this twenty-first day of September, 1898.

"(Signed) "G. LEWIN.
"H. W. DAVIES.

"THE CLERK TO THE MAGISTRATES,
"City Police Court, Manchester."

The summons was dismissed.

It will be seen that in the certificate the whole question of what genuine caper tea is, is begged. Samples of tea are taken out of bond and are assumed to be *authentic*, or (as in the term used lower down in the Somerset House certificate)

These teas, as compared with those imported in 1875, appear to me to be genuine only inasmuch as they have not been stopped by the Customs, but have been, improperly, allowed to go into consumption. The proportion of mineral matter insoluble in hydrochloric acid—not stated as a separate item in the official analyses, but calculated by deducting the water-soluble and acid-soluble ash from the total—would be as follows:

	A.	B.	C.	D.	E.	F.	G.
Mineral matter insoluble in hydrochloric acid ...	1·18	2·68	2·06	1·78	1·22	2·48	1·64

Deduced in the same way, the ash insoluble in hydrochloric acid found at the Government Laboratory in the third portion of my sample was 2·02 per cent. It will be seen that in these teas, taken from bond, in three cases the ash insoluble in hydrochloric acid exceeded 2 per cent., being in one case 2·68 per cent., and in another 2·48 per cent.; whereas Dr. Bell, the former Principal of the Inland Revenue Laboratory, laid down the dictum that if the insoluble ash much exceeded 1 per cent., there was evidence of the addition of either sand, quartz, or other earthy impurities. In my sample I found nodules of quartz rolled up in the leaves, and therefore cannot consider that the quartz had been, as is suggested in the certificate from the overnment Laboratory, unavoidably mixed with the tea. It appears desirable that public analysts should be aware of the fact that the limit of earthy impurity fixed by Dr. Bell is no longer adopted at the Inland Revenue Laboratory, and that, apparently, any sample of caper tea containing not more than 2·68 per cent. of ash insoluble in hydrochloric acid is to be regarded as genuine.

Attention may also be directed to the proportion of ash soluble in water in caper tea. Mr. Wigner, in 1875, found the proportion of ash soluble in water to vary from 2·64 to 3·66 per cent. in caper tea, the average of nine samples showing 3·07 per cent. In Dr. Bell's two samples, analysed in 1881, the proportion of ash soluble in water, on the dry tea, were 3·21 and 3·47 per cent., equivalent to 2·98 and 3·23 per cent. in the moist tea. Since the sample which gave rise to this paper contained, according to the analysis made in the Government Laboratory, only 2·36 per cent. of mineral matter soluble in water, it might, on the basis of the foregoing figures, be reasonably regarded as containing exhausted leaves. But the figures found for soluble ash in the seven samples quoted in the report from the Government Laboratory as authentic samples of caper tea out of bond range from 2·58 down to 2·14 per cent.; and if these figures are to be accepted as fixing a standard of genuineness in the matter of the admixture of exhausted leaves, the limit of 3 per cent. virtually adopted by Dr. Bell presumably also disappears.

RAPID ESTIMATION OF SMALL QUANTITIES OF FREE PHOSPHORUS IN PHOSPHORUS PASTES, ETC.

BY LESTER REED, F.I.C.

WHEN a solution of bromine in carbon disulphide is added gradually to one of phosphorus in the same liquid, the colour of the bromine is discharged almost instantly until a certain point is reached. At this point the phosphorus and bromine consumed appear to stand to each other in the proportion $P : Br_3$. If, however, a small quantity of alcohol containing a little water is present, the reaction is equally definite, but the proportion appears then to be $P : Br_5$, the end of the reaction in this case being when the alcoholic layer retains a decided yellow colour for a minute or two. The reaction does not appear to be at all affected by the presence of wheat-flour or glucose.

To apply this principle to the estimation of free phosphorus in phosphorus paste, we can proceed as follows: A solution of bromine is to be prepared containing from 5 to 10 grammes in 50 c.c. of carbon disulphide. This is standardized by a weighed quantity of yellow phosphorus dissolved in about 20 c.c. of carbon disulphide. To do this a stoppered bottle, such as is used for the determination of the hardness of water, is taken, and in it is placed about 1 c.c. of paste, made of flour, glucose, and water, then 5 c.c. of absolute alcohol (which should be shaken with the paste till it is disintegrated), and then the phosphorus solution, thus imitating the conditions of the actual estimation to follow. The bromine solution is now added from a burette in small quantities at a time, with shaking, until a decided and permanent yellow colour is obtained in the floating layer.

A weighed quantity of the sample of phosphorus paste is then taken in the same or a similar bottle, 5 c.c. of absolute alcohol added and well shaken until the paste is thoroughly disintegrated, 20 c.c. of carbon disulphide are then added, and the titration proceeded with as above. The method of calculating the result is, of course, obvious.

In the presence of phosphites, resulting from the slow oxidation of phosphorus, an allowance would have to be made for the quantity of bromine solution decolorized by a filtered extract of the paste made with cold 50 per cent. alcohol.

I desire to submit this process quite tentatively, although the results appear, from my own experiments, to be reliable when the conditions are carefully observed. Its extreme simplicity and rapidity seem to me strong points in its favour. I should be very pleased to hear of anyone's experience with it.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Determination of Dirt in Milk. R. Eichloff. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 678-683.)—The following method is proposed: 300 grammes of milk are weighed and transferred to eight test-glasses 15 cm. long by 1·5 cm. wide. These are then placed in a centrifugal apparatus, which is rotated at a speed of about

thirty revolutions a minute for five minutes. The dirt settles completely to the bottom. The cream and the greater part of the milk are now carefully removed, leaving the sediment undisturbed, and the remainder of the milk with the sediment is then washed out into a fresh tube and again centrifuged. The sediment is finally filtered off, with the help of a filter-pump, through a dried and weighed asbestos filter-tube, which is then thoroughly washed, dried, and re-weighed. H. H. B. S.

On the Changes which take place in Milk Fat during the Ripening of Cheese. A. Kirsten. (*Zeit. für Untersuch. der Nahr. und Genusmittel*, 1898, 742.)—The results obtained are shown in the following table. They are in every case the mean of duplicate experiments:

	Date.	Number Days Ripening.	Refractometer Number at 25° C.	Reichert-Meissl-Wollny Number (c.c. $\frac{N}{10}$ BaO for 5 Grammes of fat).	Köttstorfer Number (Milligrammes KHO required for saponifying 1 Gramme).	Hehner Number (Insoluble Fatty Acids from 100 Parts of Fat).	Remarks.
			I.—Fat from Camembert Cheese.				
1	17, 5, '96	0	53·0	27·1	227	87·6

H. H. B. S.

Detection of Cane-Sugar in Wine, Saccharine Liquids, etc. G. Papasogli. (*Giorn. di Farm. di Trieste*, 1898, iii., 301; through *Chem. Zeit. Rep.*, 1898, 320.)—An aqueous solution of cane-sugar gives a fine permanent amethyst colour when it is mixed with a cobalt salt and a small excess of caustic soda, and the tint is visible even in 0·05 per cent. solutions. Grape-sugar yields a blue which rapidly bleaches

and finally becomes dirty green. Dilute glycerin only produces a faint green. Solutions containing 20 per cent. of alcohol, 10 per cent. of cane and 10 per cent. of grape sugar respectively, coloured with caramel, were prepared. 15 c.c. were decolorized with 0·5 gramme of animal charcoal, filtered, treated with 0·5 c.c. of a 5 per cent. solution of cobalt nitrate, shaken, and then 2 c.c. of 50 per cent. caustic soda were added: the reactions appeared in every case. The amethyst colour characteristic of cane-sugar can be recognised even when the sugars are composed of 9 parts of grape to 1 of cane sugar. Wines must be bleached with lead acetate to remove colouring matter and tartaric acid. Condensed milk may be diluted with twice its volume of water, and treated with lead acetate. Gum and dextrin must be removed either with the normal or ammoniacal acetate of lead. F. H. L.

The Detection of Starch in Black and White Mustard Seed. J. W. Lloyd. (*Amer. Jour. Pharm.*, 1898, lxx., 433-439.)—The ordinary method of testing for starch by adding iodine solution to the aqueous decoction may fail with black mustard, owing to the liberation of mustard oil when the mustard comes in contact with water. This oil combines with the iodine, and when only a small quantity of starch is present no blue colour is obtained. The author has found that copper sulphate has the property of preventing the formation of the oil of mustard even when used in a solution of 0·2 per cent. strength, and also that on boiling the mustard seed with a solution of potassium iodide the same result is attained.

C. A. M.

The Estimation of Gelatin in Gums and Food Substances. A. Trillat. (*Ann. de Chim. Anal. Appl.*, 1898, iii., 401, 402.)—The property which formaldehyde possesses of forming insoluble compounds with proteid substances was applied by Beckmann (ANALYST, xx., 44) to the estimation of gelatin and albumin in peptones. A similar process is here advocated for the detection and estimation of gelatin in general, and especially when mixed with gums. The substance under examination is dissolved in water, the insoluble matter removed by filtration or decantation, and the solution evaporated to the consistence of a syrup. About 1 c.c. of commercial formalin is then added, and the evaporation continued till the mass becomes pasty. The residue is taken up with boiling water, which dissolves the gum and leaves the insoluble gelatin compound. After standing for twenty-four hours, the clear or slightly opalescent supernatant liquid is decanted, and the precipitate washed with boiling water, dried on the water-bath, and weighed.

In a test analysis of a mixture consisting of 85 grammes of gelatin, 20 grammes of gum arabic, and 10 grammes of sugar, the gelatin was determined within 1 per cent. of the actual quantity.

The gelatin of the jellies of commerce is determined in a similar manner. In all cases the substance should be brought to a pasty consistence before adding the formaldehyde, since in a dilute solution no precipitate is obtained. C. A. M.

Glazed Coffee. E. Hanausek. (*Oesterr. Chem. Zeit.*, 1898, i., 482.)—A new substance for glazing coffee-berries, in order (so the makers assert) to prevent loss of aroma and of caffeine, and improve the material commercially, chemically, and physiologically, consists of shellac. This is being put on the German and Austrian markets in small angular orange fragments by G. Schneider Nachfolger, of Ludwigshafen a/R., and is to be employed in amounts of 0·5 to 1·0 per cent. according to the time of preservation desired. F. H. L.

The Occurrence of a Ptomaine in Coffee. S. Bein. (*Zeits. angew. Chem.*, 1898, 658-661.)—A sample of coffee which had caused symptoms of poisoning in the members of a family which had drunk the infusion was examined by the author. It was found to contain none of the usual metallic or alkaloidal poisons, and was free from artificial beans. It consisted of a mixture of black, over-burnt beans, including fragments of husks, etc., with about 18 per cent. of beans of a lighter colour, containing about 18 milligrammes of caffeine in 100 grammes. The black part of the mixture contained no caffeine, and had a coating on the surface in which was 0·42 per cent. of sodium chloride.

On testing, the coffee gave indications of the presence of a ptomaine.

As to the origin of the ptomaine, the following explanation is suggested: There are in commerce a number of worthless products, consisting of mixtures of various kinds of spoilt coffee, such as that damaged by sea-water, etc., and known as "*Triage.*" These are commonly mixed with a small proportion of a better substance, in order to render the article saleable as coffee. Since normal coffee only contains about 0·01 per cent. of sodium chloride, the author regarded the presence of the large percentage of that salt in the black part of the mixture as proof of its having been damaged by salt-water in transit. If such coffee were then stored in a damp condition in a badly-ventilated room, a decomposition of the proteid substance of the bean would soon be brought about.

That under these circumstances ptomaines may be produced was proved experimentally.

The authors suggest as a further cause, the roasting of the damaged coffee until black, with the object of concealing its decomposed appearance. On over-roasting, deep-seated changes occur; there is decomposition of the fat, of the proteids, of the coffee-tannin, and of the woody fibre, and bodies with objectionable smell are produced in considerable quantity. From the proteids especially pyrrol substances are derived, and these do not escape completely, but are partially condensed on the beans. The caffeine also is destroyed, and methylamine and its derivatives are formed in sufficient quantity to impart their characteristic objectionable odour.

From an experimentally over-roasted coffee the author prepared an aqueous extract, from which he succeeded in isolating pyrrol bodies and amine bases. The fact that no caffeine was found in the black portion of the coffee mixture can thus be accounted for by too high a roasting. The author points out that these products of over-roasting (amine bases pyrrol derivatives, etc.) are capable of producing very similar symptoms in animals to those produced by the products of putrefaction, even when in very dilute condition. C. A. M.

An Adulterated Gamboge. J. F. Woolsey. (*Amer. Jour. Pharm.*, 1898, lxx., 446, 447.)—Powdered gamboge as usually obtained is of a bright orange yellow colour, and contains 70 to 80 per cent. of resin, 3 to 4 per cent. of ash, 4 to 6 per cent. of moisture and gum. A good gamboge contains 75 per cent. of resin. The trace of starch usually met with is not regarded as an adulteration, and is due to the method of collecting and packing.

The author has recently met with a sample of a dull ochre colour, which was heavily adulterated. On treatment with 95 per cent. alcohol less than 40 per cent. dissolved. The added substance was found to consist of starch or flour (*cf.* ANALYST, xxi., 266). C. A. M.

ORGANIC ANALYSIS.

Detection of Iodoform in Aqueous Fluids. L. von Stubenrauch. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, 737.)—The method proposed by the author rests upon the following experiment. Two equal portions (one or two crystals) of iodoform are mixed into an emulsion with equal quantities (3 to 5 c.c.) of water. One portion is reduced by warming with zinc dust and a drop of acetic acid and afterwards filtered, whilst the other portion is left unreduced. On now adding a single drop of nitric acid and a little starch solution to each portion, a blue colour is produced in the reduced portion, but not in the other. It is necessary to limit the nitric acid added to a single drop. If a large quantity be used, the iodoform is decomposed and the blue colour produced without the reduction with zinc dust and acetic acid. On applying the test, if a blue colour be produced on addition of a drop of strong nitric acid and some starch, potassium iodide, hydriodic acid, or a soluble, easily decomposable organic compound of iodine may be present; but if, on the contrary, the blue colour appear only after reduction with zinc dust and acetic acid, the presence of iodoform is indicated. A solution of iodoform in water behaves in the same way as an emulsion. A difficulty, however, arises when hydriodic acid, an iodide of an alkali metal, or a soluble organic compound of iodine, is present in conjunction with iodoform. In this case the test is only available when the proportion of the other bodies to the iodoform is relatively small, so that the difference in the depth of the blue colour produced before and after reduction is distinctly apparent. The presence of albumin, except in very small quantities, also interferes with the test.

The author's experiments with the method show that iodoform taken internally is not excreted as such in the urine, but is converted into an organic iodine compound or into an iodide of an alkali metal. H. H. B. S.

Preparation of a Standard Solution of Ethyl Aldehyde. X. Rocques. (*Annal. de Chim. Anal.*, 1898, iii., 365.)—The preparation of an alcoholic solution of aldehyde for use as a standard in the colorimetrical determination of aldehyde is not an easy matter, owing to the readiness with which polymerization occurs and the difficulty of obtaining a pure substance.

The author obviates this difficulty by using aldehyde ammonia $CH_3 - CH\begin{matrix}HO\\NH_3\end{matrix}$

as the starting-point. This substance, as met with in commerce, is in the form of rhombohedral crystals melting at 70° to 80°. It is very soluble in alcohol, is insoluble in ether, and is decomposed by dilute acids with the re-formation of aldehyde. It is purified by trituration in a mortar with successive portions of anhydrous ether, the liquid being decanted each time. The final residue is dried in the air, and afterwards *in vacuo* over sulphuric acid.

1·386 grammes of the dry compound are dissolved in about 50 c.c. of pure alcohol (96 per cent.), and 22·7 c.c. of normal sulphuric acid (mixed with more of the same alcohol) added, an immediate precipitate of ammonium sulphate being formed. The liquid is made up to 100 c.c. with the alcohol, and an additional 0·8 c.c. added to compensate for the volume of the ammonium sulphate. It is then shaken, allowed to stand overnight, and filtered. The filtrate contains 1 per cent. of aldehyde, and is diluted with the necessary quantities of water and 50 per cent. alcohol, so as to obtain a solution containing 50 milligrammes in a litre of 50 per cent. alcohol. C. A. M.

Reaction between Ferric Chloride and Phenol in presence of Alcohol. F. Peters. (*Zeits. angew. Chem.*, 1898, 1078.)—It is generally believed that the violet colour produced when ferric chloride is mixed with an aqueous solution of phenol does not appear if the latter be dissolved in alcohol. The author finds that on dropping a 10 per cent. aqueous solution of ferric chloride into a solution of phenol in dilute spirit, the colour is not prevented from appearing if the proportion of alcohol does not exceed 3·19 v/v, or 2·53%; but as the amount rises to 3·44 v/v, or 2·73%, the reaction becomes indistinct, and above that limit it does not occur at all.

F. H. L.

Reactions of Some Common Phenols. G. Deniges. (*Bull. Soc. Pharm. Bordeaux*, 1898, 241; through *Ann. de Chim. Anal.*, 1898, iii., 381, 382.)

Reactions with Mercuric Sulphate.—Five centigrammes of the polyphenol are dissolved in 2 c.c. of water, 3 c.c. of the author's mercuric reagent (ANALYST, xxiii., 216) added, and the whole shaken.

A lemon-yellow precipitate is obtained	Pyrogallol.
A yellowish-white ,, ,, ...	Phloroglucinol.
No precipitate. The liquid becomes yellow, changing to yellowish-red and to reddish-brown	Pyrocatechin.
No precipitate. The liquid remains colourless, or has a slight greenish-yellow tint	Hydroquinone.
On boiling becomes yellowish-red	
On boiling no perceptible change	Resorcin.
After immersion of the tube in cold water and prolonged standing a yellowish precipitate	

Reactions with Soda.—From 15 to 20 centigrammes of the substance are dissolved in 3 to 4 c.c. of alcohol, 1 c.c. of a solution of soda allowed to flow down the side of the tube and the zone of contact observed.

(*a*) A coloured zone is produced immediately.		
Red	surmounted by a green ring. On shaking the liquid becomes green	Hydroquinone.
Red	surmounted by a white ring. On shaking the liquid becomes brown	Pyrogallol.
Yellow, with a yellow coloration of the supernatant alcohol		Pyrocatechol.
White		Phloroglucinol.
(*b*) No immediate coloration, but after some time a green ring appears		Resorcin.

(*Cf.* ANALYST, xxi., 295.) C. A. M.

Humble-Bees' Wax. E. E. Sundvik. (*Zeits. Physiol. Chem.*, 1898, xxvi., 56; through *Chem. Zeit. Rep.*, 1898, 321.)—From 130 grammes of comb the author obtained, by extraction with ether or chloroform, about 30 grammes of crude wax, melting between 35° and 40° C. The odour was pleasant, resembling honey, and not at all rancid. The wax bleached almost perfectly when exposed to daylight in thin layers; but became very rancid in smell. Treated with weak caustic potash, and crystallized six or seven times from alcohol, it melted at 69°-70°; finally it melted at 74° or 75° C. The intermediate product possessed the sticky nature of ordinary beeswax; the purest did not. The crystals form fine, soft, woolly needles. Even in the cold it is more or less soluble in the regular fat-solvents. Its empirical formula is $C_{34}H_{70}O$. Heated to 150° or 160° with benzoic anhydride, it gives a substance easily soluble in hot or cold alcohol, which, after several recrystallizations, melts at 55° C.

F. H. L.

The Estimation of Pentoses. A. Grégoire and E. Carpiaux. (*Bull. de l'Ass. Belge*, 1898, xii., 143-151.)—This paper gives an account of the authors' investigation on the different methods of determining pentoses, and describes various modifications which they have adopted.

For the estimation of pentoses, after conversion into furfural, two methods are employed: that of Tollens, in which the furfural is precipitated by means of phenylhydrazine; and that of Councler, in which phloroglucol is used as the precipitant. Several chemists have been unable to obtain satisfactory results by the second method, and hence the precipitation of the pentoses as hydrazones is the one in general use:

$$C_5H_4O_2 + C_6H_5NH.NH_2 = C_6H_5NH.NH.C_5H_3O + H_2O.$$

The hydrazone was formerly determined volumetrically (Tollens and Günther) or gravimetrically (Tollens and Chalmot), but Flint and Tollens' recent researches (*Landw. Vers. Stat.*, xlii., 395) have shown that in the volumetric method the distillation of the substance with hydrochloric acid yields small quantities of substances (acetone, etc.), which combine with the phenylhydrazine, although they do not form an insoluble compound, and hence the results are too high.

In the gravimetric method the distillate containing the furfural is diluted to 400 c.c. with hydrochloric acid, neutralized with sodium carbonate, slightly acidified with acetic acid, the furfural precipitated with an acetic acid solution of phenylhydrazine, the solution brought to 500 c.c., and, after being mechanically stirred for thirty minutes, the precipitate collected on a filter of glass wool, washed with water,

dried in a current of air, and weighed. The weight of the hydrazone multiplied by 0·538 gives the furfural.

The authors find that there is a slight source of error in this method, owing to the hydrazone dissolving to a slight extent in the water required to wash the precipitate. To obviate this they have devised a gas-volumetric process, in which the nitrogen in the phenylhydrazine is determined before and after the precipitation, and the difference calculated into the amount taken up by the furfural.

The original phenylhydrazine is decomposed by means of copper sulphate :

$$C_6H_5NH.NH_2 + 2CuSO_4 = H_2SO_4 + C_6H_6 + N_2 + Cu_2SO_4,$$

but this is not possible in the presence of sodium chloride, as in the filtrate from the precipitated hydrazone, unless the process is modified. Phenylhydrazine acetate, like ammonium acetate, decomposes on boiling, but the authors' experiments show that by making the liquid strongly acid with hydrochloric acid, the phenylhydrazine can be boiled without alteration.

In the gas-volumetric process finally adopted the nitrogen in the phenylhydrazine reagent was determined in the following manner : From 4 to 4·5 grammes were dissolved in 250 c c. of water, 25 c.c. of the solution were mixed with 20 c.c. of concentrated hydrochloric acid, boiled for several minutes to remove all air, and introduced while hot into a Schloesing's (nitric acid) apparatus containing 25 c.c. of a 20 per cent. solution of copper sulphate and several c.c. of hydrochloric acid, from both of which all air had been expelled by boiling. The reaction took place instantaneously, in accordance with the equation :

$$C_6H_5N.NH_2 + 4CuSO_4 + HCl = 2H_2SO_4 + C_6H_5Cl + 2Cu_2SO_4 + N_2.$$

The liberated nitrogen was collected and measured in the usual manner, corrections made for the vapour tension of water and chlorbenzene at the temperature of observation, and the calculated weight of nitrogen multiplied by 3·857. Thus in a typical case 94·8 c.c. of gas were obtained at a temperature of 19° C. and a pressure of 748 m.m., which corrected for temperature, pressure, tension of the water vapour, and chlorbenzene vapour was 721 m.m., corresponding with 88·51 per cent. of the phenylhydrazine taken.

For the precipitation of the furfural, 81·5 grammes of sodium chloride (the quantity corresponding to the amount of hydrochloric acid which distils over in the estimation of pentoses) were dissolved in about 400 c.c. of water, 2 drops of acetic acid added, and a quantity of furfural not exceeding 0·6 gramme. After the addition of an *aqueous* solution of phenylhydrazine (4 or 4·5 grammes in 250 c.c.), the liquid was made up to 500 c.c., and shaken for at least an hour in a Witt agitator.

The filtrate was at once mixed with hydrochloric acid, which was found to prevent the decomposition of phenylhydrazine acetate. It was then boiled to expel the air, and 200 c.c. containing 20 c.c. of hydrochloric acid were introduced into Schloesing's apparatus, and the nitrogen determined as before and deducted from the amount found in the first determination. The result multiplied by the factor 3·429 gave the amount of furfural.

In seven analyses of furfural by this method the percentages found varied from 99·4 to 102·4 per cent., the mean being 100·5 per cent. C. A. M.

A Method of Analysing Natural and Artificial Organic Colouring Matters. **A. R. Rota.** (*Chem. Zeit.*, 1898, 437-442.)

I. *Identification of Individual Colouring Matters.* — In this paper the author draws up a scheme of analysis based upon the recent views of Nietzki, Witt, Armstrong, and others, as to the relationship which exists between the constitution and colour of these substances.

Regarding organic colouring matters as quinone derivatives (Armstrong, Nietski), those which are based upon mono- and di- amido-quinone are reducible by stannous chloride; while those which are regarded as derivatives of a quinone, in which an oxygen atom is replaced by a di-valent hydrocarbon group in the quinone ring, are not reducible. Thus, if O = R = O represent an ortho- or para- quinone, the nitroso- azo- and imido- quinone colour derivatives are reducible:

$$\underset{\text{oximido-quinone}}{O=R=N-} \quad \text{or} \quad \underset{\text{di-imido-quinone,}}{-N=R=N-}$$

but not such derivatives as oxyquinone- and triphenyl- methane colouring matters:

$$\underset{\text{oxycarbo-quinone}}{O=R=C=} \quad \text{and} \quad \underset{\text{imido-carbo-quinone.}}{-N=R=C=}$$

The reduced colouring matters can be subdivided into two groups, according as to whether the colour is restored on oxidation with ferric chloride or atmospheric oxygen; and the unreduced colouring matters can also be subdivided according to their behaviour on treatment with caustic potash. Four main groups are thus obtained, as shown in the subjoined scheme.

The aqueous or alcoholic solution of the substance is diluted to about 1 : 10,000, and 5 c.c. treated with 4 to 5 drops of concentrated hydrochloric acid and about the same quantity of a 10 per cent. solution of stannous chloride. The mixture is shaken, and, if necessary, warmed to the boiling point. If no decolorization occurs, the solution of the colouring matter should be again tested with stannous chloride after still further dilution.

A.

Classification of Organic Colouring Matters.

A portion of the aqueous or diluted alcoholic solution is treated with HCl and $SnCl_2$.

Complete decolorization. Reducible colouring matters. The colourless solution is treated with Fe_2Cl_6, or shaken with exposure to the air.		The colour is changed no further than with HCl alone. Non-reducible colouring matters. A part of the original solution is mixed with 20 per cent. KOH and warmed.	
The liquid remains unchanged. Colouring matters not reoxidizable.	The original colour restored. Reoxidizable colouring matters.	Decolorization or a precipitate. Imido-carbo-quinone colouring matters.	No precipitation. The liquid becomes more coloured. Oxy-carbo-quinone colouring matters.
Class I.	Class II.	Class III.	Class IV.
Nitro-, nitroso-, and azo-colouring matters, including azoxy- and hydrazo- colours.	Indogenide- and imido-quinone colouring matters.	Amido-derivatives of di- and tri- phenylmethane, auramines, acridines, quinolines, and colour derivatives of thiobenzenil.	Non-amide diphenylmethane colouring matters, oxy-ketone colouring matters (most of the natural organic colouring matters).

The individual colouring matters in the four main groups may often be identified by reference to one of the published tables of their physical, chemical, and tinctorial properties, which, however, only describe a part of the dyes now met with in commerce. In doubtful cases resort must be made to the spectroscope. A differentiation can often be made in the case of halogen derivatives of similar phthaleins, for instance, by determining the halogen after igniting the colouring matter with lime. The detection of sulphur by fusing the dye with potassium nitrate, and testing the melt for sulphuric acid, often enables one to differentiate between two substances, as, for instance, between the thiazines and oxazines. When the colouring matter was reduced by stannous chloride, the decomposition product may be further examined after removing the tin with sulphuretted hydrogen. Picric acid, for example, gives the colourless tri-amido-phenol, which on treatment with ferric chloride gives the blue amido-di-imido-phenol. The azo colouring matters give on reduction with stannous chloride at least two primary amines in accordance with the equation :

$$R - N = N - R_1 + 2H_2 = R - NH_2 + R' - NH_2 .$$

These amines can often be separated by means of ether. The reduced solution, from which the tin has been removed by means of sulphuretted hydrogen, is treated with caustic potash and the liquid shaken with ether, which dissolves the non-sulphonated amine, and leaves the sulphonated amine in the aqueous layer. The latter can be identified by the characteristic azo-compound which it forms with certain diazo-derivatives. Sulphanilic acid, for instance, obtained by the reduction of naphthol orange, combines with diazo-benzidine-chloride to form a yellow tetrazo-colouring matter. Naphthionic acid yields Congo-red ; and certain oxy-sulphonated amines, such as $C_{10}H_5\begin{cases}NH_2(2)\\OH(8)\\SO_3H(6),\end{cases}$ give a violet colour (diamine black R (C), etc.). Since the NH_2 group resulting from the azo groups must be in the para-position to another amido group in the radicle, a para-diamine is produced, and this can be easily recognised by the thiazin reaction (treatment of the solution freed from tin with hydrochloric acid and ferric chloride in the presence of sulphuretted hydrogen). A para-diamine is also obtained from those colouring matters which contain not the amido group, but two diazo groups, since the middle radicle contains the two azo groups in the para-position. Thus, Sudan III. (A), on reduction with stannous chloride, gives :

$$C_6H_4\begin{cases}N=N-C_6H_5\\N=N-C_{10}H_6(OH)\beta(4)\end{cases}^{(1)} + 4H_2 = C_6H_4\begin{cases}NH_2(1)\\NH_2(4)\end{cases} + C_6H_5.NH_2 + C_{10}H_6\begin{cases}OH(\beta)\\NH_2\end{cases}.$$

By this reaction it is possible in the absence of an amido substance to determine whether a mono-azo or a diazo colouring matter is present.

A scheme of the characteristics of members of the four groups is shown in the following tables :

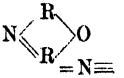
B.

Class I.—Reduced by $HCl + SnCl_2$ and not Reoxidizable.

Nitro-colouring Matters: $R-NO_2$. Yellow or orange. Soluble in water. Wool and silk dyed directly, but not cotton. The aqueous solution shows tendency to decolorization with HCl. With $HCl + SnCl_2$ partially reduced, giving red nitro-amido derivatives (nitramines) or nitro-phenols turning red in KOH.

- **Nitramines.** Soluble in ether in presence of KOH. $-N=R=N\langle^{O}_{OH}$ *e.g.*, Aurantia.
- **Nitro-phenols.** Insoluble in ether in presence of KOH.
  - *Non-sulphonated.* Soluble in ether in presence of acetic acid. $O=R=N\langle^{O}_{H}$ Victoria yellow.
  - *Sulphonated.* Insoluble in ether. Naphthol yellow.

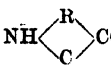
Nitro-colouring Matters: $O=R=N-OH$. Brown or green, usually insoluble in water. Indirect for fibres. With $H_2SO_4 + C\ HOH$ give blue colour (Liebermann's reaction).

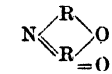


- *Non-sulphonated.* Insoluble in water. Soluble in alcohol. Soluble in ether in presence of acetic acid. Dioxine (L).
- *Sulphonated.* Soluble in water. Insoluble in ether. Naphthol green.

Azo-colouring Matters: $R-N=N-R$. Their aqueous solution decomposed with KOH and extracted with ether, gives an ethereal extract with the annexed characteristics.

- Coloured; shaken with dilute acetic acid yields to it the original colour. **Basic Colouring Matters.**
  - **Non-sulphonated. Amido-azo Colouring Matters.** $-N=R=N-NHR_1$ Bismarck brown.
- Coloured solution; not yielding its colour to dilute acetic acid. **Neutral Colouring Matters.**
  - **Oxyazo-colouring Matters, without Carboxyl.** $O=R=N-HR_1$ Sudan I. (A).
- Colourless solution. Yields nothing to acetic acid. **Acid Colouring Matters.**
  - *Non-sulphonated.* Extracted by ether from dilute solution in acetic acid.
    - **Oxyazo-colouring Matters with Carboxyl Group.**
      - Indirect for cotton wool. Diamond yellow (By).
      - Direct for cotton wool. Chrysamine.
  - *Sulphonated.* Not extracted by ether from solution in dilute acetic acid.
    - **Non-amido Compounds.** Unaltered by HNO_2.
      - Indirect for cotton wool. Bordeaux B (A).
      - Direct for cotton wool. Azo-blue (A).
    - **Amido Compounds.** Changed by HNO_2.
      - Indirect for cotton wool. Solid yellow N (P).
      - Direct for cotton wool. Congo red (A).

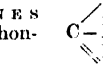




Class II.—Reduced by $HCl + SnCl_2$ and Reoxidizable.

The aqueous or alcoholic solution is treated with KOH and extracted with ether. The ethereal solution washed with water has the annexed characteristics.

- The ethereal solution is coloured or colourless, and yields the original colour to 5 per cent. acetic acid.
  - The solution is readily reduced by $HCl + SnCl_2$ in the cold.
    - **Oxyazines** (no sulphur).  Nile blue A (B).
    - **Thiazines** (sulphur).  Methylene blue.
- **Basic Colouring Matters.** Fixed on wool in alkaline bath.
  - The coloured solution is reduced but slowly and incompletely, even on warming, and with the addition of much $SnCl_2 + HCl$.
    - **Indulines.** Blue colour with conc. H_2SO_4. Blue on dilution.  Induline. Soluble in alcohol.
    - **Safranines.** Green colour with H_2SO_4. On dilution blue, then violet.  Safranine T. Extra (A).



Class II. (continued).—Reduced by $HCl + SnCl_2$ and Reoxidizable.

The aqueous or alcoholic solution is treated with KOH and extracted with ether. The ethereal solution washed with water has the annexed characteristics.

Coloured. Does not yield the colour to acetic acid.	Blue colouring matters changed by HCl on warming.	INDOPHENOLS.		Indophenol.
NEUTRAL COLOURING MATTERS. Insoluble in water. Soluble in alcohol. Fixed on fibres in bath.	Red or blue colouring matters. Unaltered by HCl. With HNO_3 yield isatin.	INDOGENIDES.		Indigotin.
Uncoloured. Yield nothing to acetic acid.	*Non-sulphonated.* Soluble in ether in presence of acetic acid.	OXAZONES.		Fluorescent bl orcein.
ACID COLOURING MATTERS. Soluble in water. Fixed on wool in acid bath.	*Sulphonated.* Insoluble in ether under all circumstances. — Reduced by $SnCl_2$+HCl.	SULPHONATED INDOGENIDES.		Indigo carmine.
		SULPHONATED THIAZINES.		Thiocarmine (C).
	Not reduced by $SnCl_2$+HCl.	SULPHONATED INDULINES.		Soluble nigrosin.

Class III.—Colouring Matters not Reduced by $SnCl_2 + HCl$. Containing the Imido-quinone Carbon Chromophore $-N=R=C=$.

The aqueous or alcoholic solution treated with KOH and extracted with ether.

The ethereal solution is colourless or coloured. The colour is yielded to 5 per cent. acetic acid. BASIC COLOURING MATTERS. Fixed on wool in alkaline bath (NH_3).	Colourless, non-fluorescent, ethereal solution. Yellow colour yielded to acetic acid non-fluorescent. The aqueous solution is decolorized by KOH and decomposed by HCl.	AURAMINES.		*e.g.*, Auramine O (B).
	Colourless, ethereal solution. Green fluorescence. Aqueous solution precipitated by KOH, hardly altered by HCl. Turns red with HNO_3.	ACRIDINES.		Phosphine.
	Colourless, or coloured ethereal solution. Non-fluorescent. Colour yielded to acetic acid — reddish-violet, blue, and green without fluorescence. Aqueous solution usually decolorized on warming with KOH, and coloured yellow by HCl (excepting fuchsin).	FUCHSINES (non-sulphonated).		Fuchsine.
	Ethereal solution colourless and non-fluorescent. Acetic acid coloured rose and fluoresces. Aqueous solution decolorized with KOH. — PYRONINES (coloured yellow by HCl. Direct for cotton wool).			Pyronine (G).
	— RHODAMINES (non-sulphonated. Unaltered by HCl.			Rhomamine S (By).
The coloured ethereal solution does not yield its colour to acetic acid. NEUTRAL COLOURING MATTERS. Insoluble in water. Soluble in alcohol.	The ethereal solution is yellow, and non fluorescent. Alcoholic solution yellow, non-fluorescent, and unaltered by aqueous acids and alkalies.	QUINONEPHTHALONES.		Quinoline yellow A (soluble in alcohol).
Ethereal solution colourless. Yields nothing to acetic acid. ACID COLOURING MATTERS. Soluble in water. Fixed on wool in acid bath (HCl). — The aqueous solution heated with fat-free wool to boiling. — Does not dye the wool.	Yellow colouring matters. No fluorescence in water. Unaltered by aqueous acids and alkalies.	SULPHONATED QUINONEPHTHALONES.		Quinoline yellow A (soluble in water).
	Reddish-violet, blue, or green colouring matters. Usually decolorized by KOH, little changed by HCl.	SULPHONATED FUCHSINES.		Fuchsine S (B).
	Red or violet colouring matters. Soluble in water with fluorescence. Precipitated by HCl. Changed but little, or not at all, by KOH.	SULPHONATED RHODAMINES.		Violamine R (M).
	Dyes the wool. — Brownish-yellow or orange colouring matters. Aqueous solution ± fluorescent. Fixed directly on silk, wool, and cotton.	THIAZOLES.		Primulin (B).

Class IV.—Colouring Matters not Reduced by $SnCl_2 + HCl$. Containing the Oxy-quinone Carbon Chromophore $O=R=C=$.

The alcoholic solution of the colouring matter, treated with a few drops of a dilute solution of Fe_2Cl_6 (1 : 1000).

Remains unaltered.

Non-amido Triphenyl-methane Colouring Matters usually soluble in water and direct for wool.

The colouring matter is dissolved or suspended in boiling water.

Not directly fixed on wool. Most of them insoluble in water. Soluble in alcohol without fluorescence.	Aurins.	$C(R^1)(R^1)(=R=O)$	Aurin.
Fixed directly on wool. Most of them soluble in water and alcohol. Fluorescence.	Phthaleïns.	$C(R^1)(R^1)(=R=O)$	Eosin.

Changes to green or olive-green.

Oxy-ketone Colouring Matters. Most of them insoluble in water, and indirect for fibres.

The original colouring matter is treated with faintly alkaline water (KOH. 1 per cent.).

Dissolves with yellow or reddish-yellow colour. — **Monoketones.**

The alkaline solution treated with excess of HCl.

Inclined to decolorization, especially on warming (with decomposition).	Benzophenones.	$CO(R)(R)$	Alizarin yellow A (B).
Coloured intense yellow without decomposition.	Flavones.	$CO(R)(O)(C=C)$	Quercetin.

Dissolves with red, reddish-violet, violet, green, or blue colour. — **Diketones (quinones).**

The alkaline solution acidified with acetic acid.

The free colouring matter precipitated. Usually soluble in ether, and indirect for fibres.	Non-Sulphonated Anthraquinones.	$CO(R)(R_1)CO$	Alizarin.
Colouring matter remains in solution. Insoluble in ether, fixed directly on wool.	Sulphonated Anthraquinones.		Sulphonated alizarin (alizarin-red).

II. *The Separation of Colouring Matters in a Mixture.*—It is sometimes possible to effect a separation by treating the mixture with water or alcohol at the ordinary temperature, or with the aid of heat; but as a rule extraction with ether or by fixing the dye on wool or other fibre is the most promising method. The behaviour of ether and wool is very similar, both extracting the free colouring matters, but not their salts. At the same time, not all colours soluble in ether can be fixed upon wool.

Extraction with Ether.—It is possible to separate basic from acid colouring matters by adding potash to a dilute aqueous solution of the dye and shaking with ether, when the free bases dissolve in the ether, leaving the acids in the aqueous layer. The details of the process are as follow: 100 c.c. of the aqueous solution of the colouring matter are decomposed with 1 c.c. of a 20 per cent. solution of potash, and shaken with three times the volume of ether. The aqueous alkaline solution of the acid colouring matter is neutralized with acetic acid and examined subsequently. The ethereal solution of the colour base is washed with faintly alkaline water, and then shaken with one-third of its volume of 5 per cent. acetic acid. The acid layer is separated, and on evaporation on the water-bath leaves the colouring matter as a

residue. In those cases in which the colour remains in the ether, the latter is evaporated. In the presence of potash some few acid or neutral colouring matters are also extracted by the ether, as, for example, quinoline yellow, indophenol blue (soluble in alcohol), the various sudans, etc. These are all insoluble in water, but soluble in alcohol.

In the extraction of the colour bases different alkalies have different liberating powers. Thus, safranine requires caustic potash, while for fuchsine ordinary ammonia is sufficient; others, again, such as the indulines, oxyazines and acridines, have their colour bases set free by very dilute ammonia; and others, such as chrysoidine, Bismarck brown, rhodamine S(By), Victoria blue, etc., dissociate in dilute aqueous solution. Thus, separation can often be made by successively shaking the aqueous solution with ether, first alone, then together with 1 per cent. ammonia, then with concentrated ammonia, and finally with 20 per cent. potash. A further separation of the bases taken up by the ether can sometimes be effected by shaking the ethereal solution with an equal volume of water, some being taken up by the water, others remaining in the ether. In this way it is possible to separate acridine yellow from the very similar phosphine. The colour bases remaining in the ether differ in their behaviour towards 5 per cent. acetic acid, some combining with it, others remaining unaltered.

The acid colouring matters not extracted by ether from an alkaline aqueous solution can be separated by methods similar to those used with the colour bases. By successive extractions with ether, they can be separated into three groups: (1) those extracted by ether in the presence of acetic acid of 1 per cent. strength; (2) those soluble in ether in the presence of hydrochloric or sulphuric acid; and (3) those insoluble in ether. Erythrosin can thus be separated from roccellin and from Bordeaux B, and direct yellow (A) from Congo brown R (A) and from Congo red (A). By treating the ethereal solutions with water and dilute ammonia, as in the case of the basic colouring matters, a further separation can often be made, as, for instance, picric acid from Martius yellow.

Separation by means of Wool.—When a separation cannot be made with ether, it is often possible by means of wool. An aqueous solution of the colouring matter (1 : 1,000) is rendered faintly alkaline by the addition of four or five drops of ammonia per 100 c.c., some wool added, and the liquid heated to boiling with constant stirring. This is repeated with fresh supplies of wool so long as the fibres are dyed. The wool is washed with boiling ammoniacal water, then with pure water, and extracted with 5 per cent. hot acetic acid. On evaporating this extract on the water-bath, the basic colouring matters are left, and can then be further separated.

The use of wool is more effective in the separation of acid colouring matters, some of which are directly fixed by it. A 0·1 per cent. solution of the colour mixture is acidified with hydrochloric acid (three to four drops per 100 c.c.), brought to the boil, and wool immersed for from three to five minutes with continual stirring. This treatment is repeated as with the basic colours. The dyed wool is washed with acidified water, and then with pure water, and the colour extracted with 5 per cent. ammonia. By boiling the liquid until the ammonia is expelled, the direct colours are obtained in neutral solution. Since some of the indirect colours are taken up to

a slight extent by the wool fibre, this solution should also be treated with the wool in order to effect complete separation. In this way the following colours can be separated from each other:

Direct. { Bordeaux B (A). { Biebrich scarlet. { Acid yellow (A).
Indirect. { Œnocyanin. { Cochineal. { Saffron.

The direct colours have a great difference in their affinity for wool, and with some it is dyed readily in a strongly acid solution (*e.g.*, those with oxysulpho- groups), while others, of both acid and basic character, also dye in a neutral solution. The following colouring matters can thus be separated:

Fixed in neutral bath. { Alkali violet (B). { Acid violet 4BN. { Orseille
,, acid ,, { Ponceau 6RB (A). { New coccine (A). { Bordeaux B (M).

By using a strongly acid solution (1 c.c. HCl to 200 c.c.) the following separations can be made:

Fixed in strongly acid bath. { Bordeaux S (A). { Bordeaux B (A).
,, slightly ,, { Orange G (A). { Methyl orange.

When a separation of the constituents of a mixture cannot be effected by means of wool, cotton-wool must be tried. It has the property of fixing some of the direct dyes for wool, leaving others in the bath. Thus:

Direct for cotton-wool. { Carbazol (B). { Cotton yellow R (B).
Indirect ,, ,, { Diamond yellow R (By). { Phloxin B (B).

With cotton also some of the dyes are more readily fixed than others, especially under varying conditions of the acidity and concentration of the bath. Thus, in slightly acid bath (HCl) brilliant Congo (A) is readily fixed, but brilliant yellow (A) only with difficulty.

If none of these means have effected a separation, other solvents, such as petroleum spirit, amylic alcohol, chloroform, etc., should be tried. With petroleum spirit, for example, eosin can be separated from Martius yellow. C. A. M.

Use of Basic Lead Acetate in the Polarimetry of Sugar Solutions. Prinsen-Geerligs. (*D. Zuckerind*, 1898, xxiii., 1753; through *Chem. Zeit. Rep.*, 1898, 320.)—Although basic lead acetate does not precipitate pure lævulose, yet from impure solutions, and notably such as contain much saline matter, it carries down more or less sugar with it. On preparing artificial liquids from honey and common salt to imitate natural juices (13·44 per cent. of invert sugar and 7·68 per cent. of sodium chloride), and adding increasing proportions of basic lead acetate, the amount of lævulose precipitated varied between 3·43 and 23·14 per cent., thus causing a corresponding increment in the dextro-rotatory power of the solution. When sufficient of the reagent is introduced to decompose all the salts present in the juice, further additions have no effect on the sugar. As lead nitrate, normal acetate, bone-charcoal, and zinc dust are all unsatisfactory, it is necessary to employ basic acetate; and in order to obtain comparable results, the author suggests that the quantity of lead required to render molasses fit for optical examination shall be determined, and the same quantity used for all other kinds of syrup and crude sugars. The precipitated

lævulose also contains glucose, but the proportion of the latter never exceeds 25 per cent. of the total sugar thrown down. F. H. L.

The Estimation of Indigo on Fabrics. A. Binz and F. Rung. (*Zeit. angew. Chem.*, 1898, 904-905.)—Renard (*Bull. Soc. Chim.*, xlvii., 41, 1887) proposes to heat a weighed portion of the fabric with a measured quantity of hydrosulphite solution, and determine the indigo white in an aliquot portion of this. His method is objectionable, since indigo white is obstinately retained by the tissue. The method of extracting the fabric with aniline in a Soxhlet apparatus, as proposed by Hönig (*Zeit. ang. Chem.*, 1889, 280), is much simpler. As, however, boiling aniline exercises a destructive action on indigotin, glacial acetic acid, as proposed by Brylinski (*Rev. génér. mat. color.*, 1898, 52), forms a better solvent.

The paper contains an account of the authors' comparative experiments with Brylinski's method slightly altered, and with a modification of the hydrosulphite method. In the latter the fabric was treated with the hydrosulphite solution on the water-bath until completely decolorized, and the indigo-white removed from the tissue by repeated washing out with hot water, of which from 2·5 to 3 litres were required to remove only a few decigrammes of the dye. The whole of the solution of indigo white thus obtained was oxidized by means of a current of air, and the indigo collected on a tared filter-paper, dried and weighed.

In the experiments on the glacial acetic acid method a suitable quantity (10 grammes) of dyed cotton was heated for three or four hours over a naked flame with 150 c.c. of glacial acetic acid, and then poured into 300 c.c. of water. Instead of now filtering off with a suction-pump, as Brylinski directs, the authors found it preferable to add 150 c.c. of ether. The whole of the indigotin remained in suspension in the ethereal layer, and this was separated from the diluted acetic acid by means of a separatory funnel. The former was filtered off, the precipitate washed with alcohol and ether, and dried at 110° C.

The results obtained by the acetic acid method were somewhat higher than those of the hydrosulphite process, and this the authors considered might be due to over-reduction by the hydrosulphite, or to an acetyl derivative of cellulose dissolving in the acetic acid. Brylinski states that the latter body is soluble in ether, and the authors found that this was the case; for, on extracting two equal weights of a dyed fabric, to one of which about forty times its weight of bleached cotton-wool had been added, the amounts of indigotin obtained were practically the same. C. A. M.

The Determination of Sulphur in Asphalt. E. H. Hodgson. (*Jour. Amer. Chem. Soc.*, vol. xx. [11], pp. 882-889.)—Various samples were examined by the methods of Carius (heating with strong nitric acid in sealed tubes), Peckham (deflagration), Eschka (ignition with calcined magnesia), and by fusion with sodium peroxide. From the results the sealed tube method appears the most accurate, but is a lengthy operation, and the tubes are liable to explode. Of the others, that of Eschka is probably the best, giving good results and requiring least time and attention.

C. S.

Use of Persulphates to Detect Albumin in Urine. C. Strzyowski. (*Schweiz. Wochs. Chem.*, 1898 [48]; through *Deutsche Chem. Zeit.*, 1899, xiv., 2.)—A 10 per cent. aqueous solution of potassium, sodium, or preferably ammonium persulphate, precipitates albumin from either acid or alkaline urine, and does not throw down peptones or urates. By means of a pipette the reagent is brought underneath a layer of the suspected urine contained in a test-tube, when even in dilutions of 1 : 100,000 a grayish-white turbidity is produced at the line of contact. In presence of bile pigments the colour is bright green. F. H. L.

Estimation of Chlorides in Urine, Wine, Beer, and Cider. Loubiou. (*Rep. Pharm.*, 1898 [3], x., 493; through *Chem. Zeit. Rep.*, 1898, 319.)—Lead peroxide oxidizes in the cold those constituents of urine which act on silver nitrate, and decolorizes it sufficiently to enable potassium chromate to be used as an indicator in the titration of chlorides. 20 c.c. are shaken with 2 or 3 grammes of the peroxide and filtered; 10 c.c. of the filtrate are mixed with 5 drops of saturated potassium chromate, diluted to 50 c.c., and titrated as usual. Similarly, employing Blarez's process, 50 c.c. of white or red wine (beer, cider, or vinegar) are treated with 3 c.c. of chromate, 50 grammes of salt, 100 c.c. of water, and 5 grammes of lead peroxide; the whole is shaken, filtered, and an aliquot portion titrated. F. H. L.

Separation of Albumoses from Peptones. P. Muller. (*Zeits. Physiol. Chem.*, 1898, xxvi., 48; through *Chem. Zeit. Rep.*, 1898, 320.)—After experiments with the salts of various heavy metals, and especially with uranium acetate, the author prefers ferric hydrate for this purpose. The liquid to be treated is mixed with an equal volume of 30 per cent. ferric chloride solution, and alkali is added till it is only just acid. The precipitate is removed, two or three pinches of zinc carbonate are thrown into the filtrate, which is shaken thoroughly and again filtered. It will be clear, colourless, and free from albumoses, giving no turbidity (or only a very slight one visible against a dark background) when saturated with ammonium sulphate. The method has proved successful in all cases where it was tried except with Witte's peptone, which involved a concentration of the filtrate to one-fourth or one-fifth of its volume, followed by a second treatment with a few drops of ferric chloride and zinc carbonate as before. F. H. L.

Sicilian Sumach and its Adulterants. F. Andreasch. (*Gerber*, 1898; through *Zeits. angew. Chem.*, 1898, 1154.)—True sumach is the product of *Rhus coriaria*, an Arabian plant; but it is blended with the leaves of the Sommacco fimeneddu, which contain less tannin. Inferior specimens are mixed with stalk, earth, sand, and already extracted sumach. As adulterants there are added leaves of the carobbe, of *Cistus salvifolius* (very frequently in Sicily), of the fig, vine, of *Ailanthus glandulosa*, *Pistacia lentiscus* (Stinco sondro, Lentisco), and of *Tamarix Africana* (Bruco, albero di Giuda): the two latter being the most common. The amount of tannin and non-tannin in sumach and its chief adulterants is shown in the annexed table. The average proportion of tannin in pure sumach may be taken at 23 or 24, seldom falling

below 22: a yield of under 20 per cent. points either to the presence of other parts of the plant or to sophistication. Large additions of stalk, etc., can usually be detected by the eye, if not by examination of the aqueous extract; for the bulk of the red colouring matter in the woody fibre passes into solution, and on acidification with acetic acid yields a weak but distinct red tint.

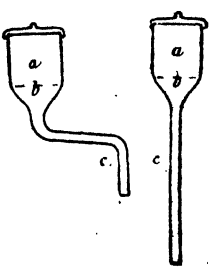
	Tannins.	Non-tannins.
Silician sumach ...	21–27·5 per cent. ...	16–22 per cent.
Pistacia	13–17 ,, ...	20–26·6 ,,
Tamarix	8·3–9 7 ,, ...	23–26·5 ,,
Ailanthus	10 ,, ...	17·5 ,,

When a little formaldehyde is dropped into a neutral decoction of pistacia, a pale-yellow precipitate is produced. Even if the material is chiefly genuine sumach, a yellowish-coloured cloud forms, which appears as a precipitate in time, but only settles after several days. The deposit is gelatinous and coheres on the filter, so that it can scarcely be washed. The substance is insoluble in cold water; but it does not represent a quantitative separation of the pistacia. If the test be carried out on very old samples of sumach, which perhaps have fermented, or if much tamarix be present, the formalin may produce a precipitate even in the absence of pistacia; but the latter cannot be mistaken for the real deposit: it is only small in amount, never gelatinous, and settles in twelve hours.

When solid potassium cyanide, or its strong solution, is stirred up with a decoction of tamarix, or sumach adulterated with tamarix, a flocculent dark-yellow precipitate is formed which settles rapidly. Pure sumach gives no deposit or a mere trace, and the reaction is characteristic of tamarix alone among the possible adulterants. The reagents in both tests must be pure, and the solution examined should be perfectly clear, and must not exceed industrial strength, viz., about 0·75 gramme of tannin per 100 c.c. F. H. L.

Estimation of Oil of Bergamot. A. Soldaini and C. Berté. (*Boll. chim. farm.*, 1898, xxxvii., 577; through *Chem. Zeit. Rep.*, 1898, 311.)—The usual adulterants added to bergamot oil are turpentine and (or) lemon oil. To detect them, 15 c.c. of the sample should be distilled at a pressure of 20 or 30 mm. till 5 c.c. have passed over, and the opticity of the oil, the distillate, and the residue determined. The annexed table indicates the influence of both or either of the impurities mentioned:

	Temperature.	Oil.	Residue.	Distillate.
Pure bergamot oil	14° C.	+14° 50′	−0° 56′	+41° 20′
+5% of turpentine	14° C.	+12° 36′	−0°	+35° 28′
+5% of lemon oil	14° C.	+17° 11′	+3° 20′	+42° 28′
+2·5% of turpentine and 2·5% of lemon oil	13·5° C.	+14° 55′	+2° 40′	+40° 20′



F. H. L.

INORGANIC ANALYSIS.

Bacterial Detection of Arsenic. F. Abba. (*Centralbl. Bakteriol.*, 1898, [2], iv., 806; through *Chem. Zeit. Rep.*, 1898, 310.)—Gosio has already shown that when *Penicillium brevicaule* is cultivated in presence of arsenic a garlic-like odour is produced. The present author finds that this process is not only simpler than chemical methods of detecting arsenic, but, after investigating fifty other substances, that it is quite characteristic. It is also more delicate, for a piece of Indian fur 1 square millimetre in area gave the reaction, whereas even 5 square centimetres did not show the Marsh test. The material to be examined is placed in sliced potato, sterilized at 115° for twenty minutes, inoculated with 0·5 c.c. of sterilized water containing spores of the *P. brevicaule* in suspension, and cultivated either at 37° or at ordinary temperatures. Fresh cultures of the penicillium need only be prepared once a year. F. H. L.

Colorimetric Estimation of Iron in Water. A. Seyda. (*Chem. Zeit.*, 1898, xxii., 1086.)—Lunge's colorimetric process for determining traces of iron in aluminium sulphate is very suitable for the examination of water. Instead of matching the colour of the aqueous solutions as in the usual method, each is shaken up with a measured quantity of ether, and after the layers of ether have been adjusted to the same length, the colour comparison is made in these. If the water under examination contains much organic matter an error may be introduced; in this case the samples must first be evaporated in platinum, ignited, fused with sodium carbonate, and the melt dissolved in hydrochloric acid. F. H. L.

Remarks on the Determination of Zinc and Manganese as Sulphide. E. Murmann. (*Monatshefte für Chemie*, xix., 404.)—On account of the difficulty of filtration, the determination of zinc or of manganese as sulphide is rarely resorted to, though the method is capable of yielding very accurate results. The author overcomes this drawback by adding mercuric chloride to the solution before precipitation. The precipitated mercuric sulphide enables the finely divided zinc or manganese sulphide to be filtered off and washed without difficulty, whilst in the subsequent ignition of the precipitate the mercuric sulphide is completely expelled. The author has also devised a new form of crucible specially adapted for the ignition of such precipitates in a current of hydrogen gas. Its construction is shown in the accompanying figure. The crucible *a* has a perforated bottom *b*, to which is attached a tube *c*, which can be either straight or bent at right angles. A perforated plate fits into the bottom, and between the perforated bottom and the perforated plate is a plug of asbestos as used in the Gooch crucible. The mouth of the crucible is covered by an ordinary crucible lid. The precipitate is filtered off and also dried and ignited in the crucible, whilst by means of the tube at the bottom a current of hydrogen can be passed through it during the ignition. The crucible can, of course, be used for other similar purposes. H. H. B. S.

Estimation of Manganese as Phosphate. E. A. Gooch and M. Austin. (*Zeits. anorg. Chem.*, 1898, xviii., 339.)—In this process the metal is thrown down as trimanganese orthophosphate, the precipitate converted into ammonium manganese orthophosphate, and finally weighed as manganese pyrophosphate. Its accuracy, therefore, depends upon the rapidity and completeness with which the $Mn_3P_2O_8$ is changed into $MnNH_4PO_4$, and the degree of insolubility of the latter, which, as Fresenius and Munroe have shown, is considerably affected by the presence of ammonium chloride. The present authors have investigated the method under various conditions, ultimately finding that a very large excess of ammonium chloride (200 molecules of NH_4Cl to 1 of $MnNH_4PO_4$ in 100 or 200 c.c. of liquid) is absolutely indispensable to a quantitative conversion of the original precipitate into the double phosphate, and, moreover, that $MnNH_4PO_4$ is not appreciably dissolved by ammonium chloride solution, provided excess of the soluble phosphate employed as a precipitant is always present.

Details for the successful operation of the process are as follows: The original faintly acid liquid (containing not more than 0·2 gramme of metallic manganese) is mixed either in a platinum or a glass vessel with 20 grammes of solid ammonium chloride, 5 or 10 c.c. of a cold-saturated solution of microcosmic salt, and diluted to 200 c.c.; dilute ammonia is then added in the cold drop by drop until it forms a slight excess. The whole is heated till the precipitate becomes crystalline, allowed to cool for half an hour, filtered quickly through a Gooch crucible with the aid of a pump, and washed (preferably) with very weak ammonia. The filtrate is always quite free from manganese, and if the precipitate retains traces of ammonium chloride, this can only lead to the formation of equally minute quantities of manganese chloride. It is better to arrange for a precipitate weighing about 0·4 gramme; but even with smaller amounts the final error will average not more than 1 mgm. of manganese.

F. H. L.

The Determination of Chromium Oxide in Algerian Phosphates. G. Schüler. (*Zeits. angew. Chem.*, 1898, 1101-1103.)—With the exception of Shephard's chromium phosphate ($Cr_2P_2O_8$) chromium has hitherto only been found in traces in phosphates, and never, to the author's knowledge, in calcium phosphates. In Algerian phosphates, however, which have recently become of considerable importance in commerce, chromium appears to be a constant though small constituent.

For the quantitative estimation of the chromium the author employs a modification of J. Clarke's method of oxidation with sodium peroxide (*Journ. Chem. Soc.*, lxiii., 1079). Ten grammes of the phosphate are dissolved in the usual mixture of hydrochloric and nitric acids, and the filtrate and washings evaporated to a pasty consistency, in order to expel the excess of acid. The moist residue is taken up in as small a quantity as possible of hydrochloric acid, oxidized by boiling with sodium peroxide, and the residue again treated in the same manner. The united filtrates and washings (containing the chromium as sodium chromate) are boiled down, and in order to completely remove the excess of sodium peroxide are again strongly diluted and evaporated. The liquid is then acidified, and the chromic acid titrated in the usual manner.

In this way the author found 0·057 per cent. of chromic oxide in a large representative sample of Algerian phosphate. C. A. M.

Volumetric Estimation of Molybdenum. **F. A. Gooch and J. T. Norton.** (*Zeits. anorg. Chem.*, 1898, xviii., 312.)—The iodometric method of estimating molybdenum outlined by Friedheim and Euler (ANALYST, 1896, xxi., 25) suffers from the defect that the precautions taken to avoid the disturbing influence of atmospheric oxygen are by no means sufficient. To be fairly accurate, the process requires carrying out as follows: The amount of molybdate taken for analysis must not contain more than 0·3 gramme of MoO_3; the excess of potassium iodide over that decomposed by the molybdate must not be greater than 0·5 gramme; the liquid should consist of 20 c.c. of the strongest hydrochloric acid and 20 c.c. of water; it must be boiled down till only 25 c.c. are left in the flask; and the distillation must be conducted in a current of carbon dioxide carefully freed from air. Even under these conditions an error, corresponding to some 0·3 milligramme of molybdenum trioxide, is introduced by the oxygen dissolved in the water and acid; to obtain the best results, therefore, these reagents should be boiled before use.

As an alternative way of determining molybdenum, the molybdate may be reduced to pentoxide by heating it with acid and an iodide in an Erlenmeyer flask lightly closed with a bulb-tube, boiling off the excess of iodine, making the liquid alkaline, and finally titrating it with standard iodine solution. F. H. L.

Note on Drown's Method of Determining Silicon in Steel. **G. Auchy.** (*Jour. Amer. Chem. Soc.*, 1898, xx., 547-549.)—There is some reason to believe that in determining the silicon in steel by Drown's method some of it escapes dehydration owing to the fact that, as the sulphuric acid becomes more concentrated, part of the iron salts separate out and form a protecting envelope round the gelatinous silica.

To obviate this the author suggests evaporating with *aqua regia* and sulphuric acid, instead of with nitric and sulphuric acids, the liquid being rapidly boiled down in a small porcelain dish on a very hot plate, with a watch glass suspended over the basin by means of glass rods. In this way the iron salt is kept in solution until the very last moment, when it suddenly crystallizes out and fumes of sulphuric acid appear. If a second similar evaporation be made before filtering, it is hardly likely that any appreciable quantity of silica will escape dehydration.

A number of test analyses were made in this way with steels containing 0·25 per cent. of silicon, and not more than an additional 0·005 per cent. was obtained by the second evaporation. A steel which gave 0·122 per cent. with one evaporation gave 0·126 per cent. on repeating the analysis and evaporating twice before filtering.

It is also stated that the evaporation proceeds quietly and without bumping or spurting, even at the moment of solidification and after, so that no attention is required. C. A. M.

APPARATUS.

A New Form of Water Blast. (*Amer. Chem. Journ.*, 1898, xx. 577-580.)—The essential parts of this apparatus are: (1) A receiver *A* in the form of a cylinder (8 inches long and 6 inches in diameter) divided into three compartments *b*, *c*, and *d* by the partitions *p* and *p'*. Between *b* and *c* is a circular opening 2 inches in diameter, and two smaller openings are placed between *c* and *d*. (2) An injector tube, *l*, 7½ inches long and ⅝ inch outside diameter, provided at the top with the funnel-shaped projection *g*. (3) An outlet tube *f* with a diameter equal to that of *l*, extending upward from *c* and curving over and downward to *g*. The tube *t* ($\frac{7}{16}$ inch in diameter) opens into *f* and extends to *g*. *S* is a stopcock opening into *d*, and *K* a nozzle with an orifice $\frac{1}{16}$ inch in diameter attached to the upper part of *f*. The axes of *K* and *l* are made to *exactly* coincide.

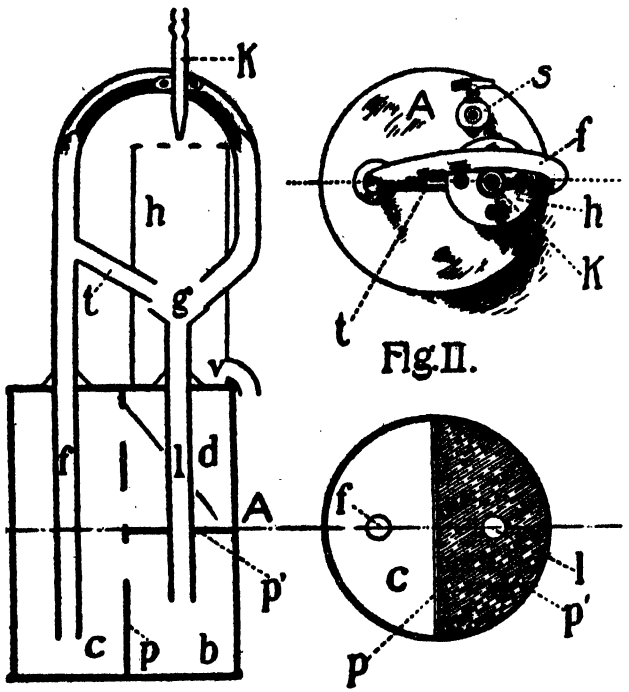


Fig. I.

Fig. II.

Fig. III.

In action the cock *S* is opened, and the water turned on. The jet of water issuing from *K* passes through *l* and falls into the compartment *b*. When the level of the water in *b* rises above the lower end of the tube *l*, a considerable volume of air is swept into *A*, escaping through *f* and *S*, and later through *S* only. The water flows from *b* into *c* through the opening in the partition. The cock *S* is now closed, and the increase of pressure in the receiver forces the water up through *f* and into *g*. The jet from *K* now strikes on the surface of the water in *g* and drives it down into *A*, together with a large volume of air. If the cock *S* be now opened a current of air of sufficient pressure to supply a large blast lamp will be obtained. Spurting is prevented by surrounding *g* with a cylindrical case *h*, having openings in the top to allow air to enter, and an overflow pipe *v* for the escape of water.

Fig. 1 is a vertical section of the complete apparatus; Fig. 2 is a projection from above; and Fig. 3 a section through the middle of the receiver.

The advantages claimed for this blast over that of Richards and that of Muenke are: That the orifice for the entrance of air and water is of such ample size that any

considerable friction is avoided; that owing to the injector tube being perfectly straight the jet of water is not deflected, and the maximum effect is obtained; and that the energy is transmitted to a much greater volume of water, which circulates continuously from *f* through *l* and acts as a piston which completely fills the cross section of the tube.

This apparatus can be obtained from Eimer and Amend, New York. C. A. M.

Apparatus for Increasing the Speed of Filtrations. H. von Winkler. (*Chem. Zeit.*, 1898, xxii., 1066.)—This apparatus is specially suitable for the filtration of minute quantities of liquid where the use of the filter pump is impracticable. It consists essentially of a glass plate, one side ground true, having at its centre a tube projecting at right angles to which a rubber tube can be affixed. A funnel with a ground edge is carefully fitted with a strong paper and filled with the liquid; the disc is placed on top and held in position with the fingers, while air is blown through the tube by means of the mouth, thus increasing the effective pressure. The disc may be of vulcanite, with a soft bearing surface if preferred; or the glass may be moistened (in order to make a better joint) with some of the same liquid as that under treatment. F. H. L.

REVIEW.

AN ATLAS OF BACTERIOLOGY. By CHARLES SLATER, M.A., M.B., M.R.C.S. (Eng.), F.C.S.; and EDMUND J. SPITTA, L.R.C.P. (Lond.), M.R.C.S. (Eng.), F.R.A.S. (London: The Scientific Press, Limited.) Price 7s. 6d.

This work consists of 111 original photomicrographs, together with explanatory text, a photographic introduction, and a bacteriological introduction. The photographic introduction will be found very useful to anyone who desires to keep a permanent record of his bacteriological results, containing as it does many practical hints on the selection of objectives and general optical apparatus. The results obtained by the authors show evidence of much patience and manipulative skill, while the process reproduction is excellent. In the bacteriological introduction a description is given of the morphology and reproduction of the *Schizophytes*. The photographic illustrations of cultures and microscopic appearances of the more important bacteria follow, together with a résumé of the chief characteristics of each. Amongst other organisms, *Bacillus anthracis*, *B. tuberculosis*, *B. typhosus*, *B. coli communis*, *B. diphtheriæ*, *Spirillum choleræ Asiaticæ* are very fully illustrated. Attention is to be directed to plates 16 (*B. anthracis*, envelope), 17 (*B. anthracis*, spore formation), 18 (*B. anthracis*, stab culture), 53 (*B. typhosus*, gelatine streak culture), 60 (*B. coli communis*, gelatine streak culture), 69 and 70 (*B. diphtheriæ*, culture), and the plates illustrating the differentiation of *Sp. choleræ Asiaticæ* (79 and 80), and *Sp. Finklerii* (84 and 85). In a future edition it may be hoped that illustrations of colonies of many of the more important pathogenic and non-pathogenic organisms, as they appear when grown on phenolized agar jelly at 37° C., will be added, for although they lose many characteristics, yet it is in this form that they are generally met with in the bacteriological examination—for instance, of water. The appearance of actual colonies and characteristic growths

would seem to be of equal importance with the microscopical appearance of the organisms themselves. As it is, the book is one which every analyst should possess for reference who systematically examines water bacteriologically. J. F. H. G.

INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND.

THE following is a list of the names of the candidates who passed the examination of the Institute of Chemistry held in January, 1899:

PRACTICAL EXAMINATION FOR THE ASSOCIATESHIP (under regulations in force prior to October 1, 1893).—Chapman, Arthur Jenner, Finsbury Technical College, London; and with Messrs. F. and A. C. Claudet, FF.I.C. Forster, Ferdinand Edward Paul, Finsbury Technical College; registered student under Messrs. F. E. Lott, F.I.C., and C. G. Matthews, F.I.C. Lishman, George Percy, B.Sc. (Edin.), Surgeons' Hall, Edinburgh; registered student under Professor W. Ivison Macadam, F.I.C.

INTERMEDIATE EXAMINATION (under new regulations).—Aston, Stafford, University College, London. Blackman, Walter Lionel, Royal College of Science, London, and St. Bartholomew's Hospital. Coysh, Basil Radcliffe, King's College, London. Hewitt, Henry Dixon, Finsbury Technical College; registered student under A. C. Chapman, Esq., F.I.C. Hill, Alfred, University College, Nottingham. Kinnersley, Henry Wulff, Merchant Venturers' Technical College, Bristol, under Professor Julius Wertheimer, B.A., B.Sc., F.I.C.; registered student under Dr. E. H. Cook, F.I.C.; and at King's College, London. Rogers, John, Glasgow and West of Scotland Technical College. Shedden, Frank, B.Sc. (Lond.), Mason University College, Birmingham. Wright, Leonard Victor, B.A. (Cantab.), Sidney College, Cambridge.

FINAL EXAMINATION FOR THE ASSOCIATESHIP (under new regulations). — *In Branch A (Mineral Chemistry)*: Golding, John,* School of the Pharmaceutical Society; Laboratory of the Royal Agricultural Society of England; University College, Nottingham. Hancock, Walter Charles,* B.A. (Cantab.), Caius College, Cambridge; with Messrs. C. F. Cross, F.I.C., and E. J. Bevan, F.I.C.; and at King's College, London. Marshall, Arthur, A.C.G.I., City and Guilds of London Institute. *In Branch B (Metallurgical Chemistry)*: Imrie, John, Glasgow and West of Scotland Technical College. Wild, Roland Cecil, King's College, London; registered student under C. J. Head, Esq., F.I.C. *In Branch D (Organic Chemistry)*: Gilles, William Setten, A.C.G.I., City and Guilds of London Institute. Hinks, Percy John, A.R.C.Sc. (Lond.), Royal College of Science, London. Joyce, Thomas Goode, B.Sc. (Lond.), Mason University College, Birmingham. *In Branch E (the Analysis of Food and Drugs and of Water)*: Gilbard, John Francis Hutchins,* Finsbury Technical College; and with Dr. Bernard Dyer, F.I.C. Hackman, Charles Adolphus, King's College, London; and with A. C. Chapman, Esq., F.I.C. Young, Francis Samuel, M.A. (Oxon.), Queen's College, Oxford, and Caius College, Cambridge.

The examiners were Professor Percy F. Frankland, F.R.S., F.I.C., and Otto Hehner, Esq., F.I.C.

* For the Fellowship.

THE ANALYST.

MARCH, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE annual general meeting of the Society was held on Wednesday, February 1, in the Rooms of the Chemical Society, Burlington House, the President (Dr. Bernard Dyer) occupying the chair.

The minutes of the extraordinary general meeting and of the ordinary general meeting, held on January 4, were read and confirmed.

Certificates of proposal for election to membership in favour of the following candidates were read for the first time: Percy T. Adams, assistant to Dr. Matthew A. Adams, Maidstone; Arthur French Angell, assistant to Mr. Arthur Angell, Southampton; John B. Ashworth, assistant to Mr. Alfred Smetham, Liverpool; Alfred Joseph Bull, assistant to Mr. Wm. Chattaway, and senior assistant in the Physical Laboratory, Birkbeck Institution, London; Charles Crocker, assistant to Messrs. Morgan, Son and Seyler, Swansea; John S. Ford, analytical chemist, Edinburgh; C. A. Hackman, A.I.C., assistant to Mr. Alfred C. Chapman, London; Norman Leonard, B.Sc., F.I.C., assistant to Dr. Stevenson, Guy's Hospital, London; J. F. Liverseege, F.I.C., assistant analyst to the Corporation of Birmingham; Richard Murray, chemist to Messrs. Brotherton and Co., Leeds; G. E. Scott-Smith, F.I.C., assistant to Mr. Alfred H. Allen, Sheffield; W. P. Skertchly, assistant to Mr. Otto Hehner, London; Harry Metcalfe Smith, F.I.C., assistant to Dr. Stevenson, Guy's Hospital, London; Lionel W. Stansell, assistant to Dr. Matthew A. Adams, Maidstone; and W. Northfield Yarrow, assistant to Mr. A. W. Stokes, London. All of these candidates were former associates of the Society, applying for election to membership under the revised rules recently adopted.

Mr. F. C. J. Bird and Mr. J. H. Heywood were elected members of the Society.

The HON. TREASURER (Mr. E. W. Voelcker) presented his report for the past year. He stated that the Society had a balance of £40 5s. 5d. standing to its credit, as against £32 12s. 8d. shown in the balance-sheet for 1897. The items most calling for attention were those classed as "General Expenses," and relating to postages, petty disbursements, etc., and the printing and stationery account. It would be seen, from the copies of the accounts which had been placed in the hands of the meeting, that these items showed a considerable increase as compared with the previous year. During 1898, however, the Council had considered it desirable to circulate among Members of Parliament, and among County Councils and other local authorities, a

report of the Council of the Society of Public Analysts dealing with the Sale of Food and Drugs Bill introduced by the President of the Local Government Board at the close of the session of 1897. This had involved a considerable outlay in printing, and a very heavy expenditure on postage. The securities of the Society on December 31 were the same as in the previous year; but since that date he had been able to make a further investment on behalf of the Society, so that its invested funds were now increased by £105. He was pleased to be able to announce that only one subscription remained outstanding.

A vote of thanks to the Hon. Treasurer and Auditors was proposed by Mr. CHAPMAN, seconded by Dr. SCHIDROWITZ, and carried unanimously.

The President then delivered his retiring address.

Mr. ALFRED H. ALLEN proposed a vote of thanks to the President for his address.

Mr. HEHNER seconded the proposition, which was put to the meeting by Mr. Allen and carried unanimously.

The PRESIDENT, having responded, moved from the chair that a vote of thanks should be passed to the President and Council of the Chemical Society for allowing the Society of Public Analysts the use of their rooms during the past year. The motion was seconded by Mr. CHATTAWAY and carried unanimously.

The PRESIDENT announced that the officers and Council for 1899 had been elected in accordance with the nominations made by the Council at the December meeting of the Society. He then vacated the chair in favour of the newly-elected President, Mr. W. W. Fisher, M.A.

Mr. FISHER, having assumed the chair, expressed his appreciation of the honour which the Society had done him in electing him to occupy that position, and the proceedings then terminated.

The following is a list of the officers and Council of the Society for 1899:

President.—W. W. Fisher, M.A.

Past-Presidents.—M. A. Adams, F.R.C.S.; A. H. Allen; Sir Charles A. Cameron, M.D., F.R.C.S.; A. Dupré, Ph.D., F.R.S.; Bernard Dyer, D.Sc.; Otto Hehner; Alfred Hill, M.D., F.R.S.E.; J. Muter, M.A., Ph.D., F.R.S.E.; Thomas Stevenson, M.D., F.R.C.P.

Vice-Presidents.—Charles E. Cassal; E. W. T. Jones; S. Rideal, D.Sc.

Hon. Treasurer.—E. W. Voelcker, A.R.S.M.

Hon. Secretaries.—E. J. Bevan, Alfred C. Chapman.

Other Members of Council.—Bertram Blount; Sidney Harvey; Arthur R. Ling; C. A. Mitchell, B.A.; C. G. Moor, M.A.; James Nimmo; Thomas A. Pooley, B.Sc.; F. Wallis Stoddart; R. T. Thomson; John White; Rowland Williams; W. C. Young.

ADDRESS OF THE RETIRING PRESIDENT.

(Delivered at the Meeting, February 1st, 1899.

In addressing you at the close of 1897, I had the melancholy duty of recording the deaths of an illustrious honorary member of the Society and of three ordinary members. This year, I regret to say, we have again to record the death of an illustrious honorary member, Lord Playfair, whose chemical career is sufficiently well known to chemists to render it unnecessary for me now to do more than call attention to the fact that it was in recognition of his interest in the question of food adulteration, and of his successful exertions in the House of Commons for the improvement of the Bill passed in 1875, that he was elected an honorary member of this Society. During the past year also we have again lost by death three ordinary members. One was our late lamented Vice-President, John A. R. Newlands, a chemist of remarkable ability, whose name will long live in connection with the history of the development of chemical thought during our time, on account of his early enunciation of what has since become known as the Periodic Law of Newlands and Mendelejeff. He was a very old and universally beloved member of this Society, and the rooms of the Chemical Society and other haunts of London chemists have been sadder and duller during the present session by reason of the disappearance from among us of his bright face and genial voice. Mr. J. Napier and Mr. F. P. Perkins, whom we have also lost during the year, were both old members of the Society, though they had not been in the habit for many years of attending its meetings. Mr. Napier was well known as Public Analyst for the borough of Ipswich and for the county of Suffolk, while Mr. Perkins had for many years occupied the position of Public Analyst for the city of Exeter.

Seven members of the Society resigned their membership during the year, and four associates were elected to the full membership of the Society. In addition to these, we elected five other new members and five associates. The net consequence of these changes is that we numerically lost one honorary member and one ordinary member, gaining one associate. The following figures show the numerical condition of the Society for the last four years:

	January, 1896.	January, 1897.	January, 1898.	January, 1899.
Honorary members ...	10	11	11	10
Members	210	218	223	222
Associates	26	29	31	32
	246	258	265	264

This is perhaps a fitting place for congratulating the Society upon having recently adopted, on the advice of the Council, a considerably modified scheme of constitution and rules. The changes which have been made had been for a long time under the consideration of the Council and officers of the Society, and I hope and believe that they will result in a gain on the part of the Society, in efficiency as well as in numerical strength.

It is scarcely necessary to remind you, except for historical purposes, of the

principal change which has been made. I told you that at the close of 1898 we had thirty-one associates; now we have no associates. It was formerly our rule that only the practising analyst, or the analyst having such control of a laboratory as to render him virtually a practising analyst, as distinct from an assistant, was eligible for election to our membership. The consequence was that many of our associates were well qualified chemists approaching middle age, and the position of some of them was becoming every year more and more anomalous; and we had also reason to believe that a number of chemists who could not technically qualify for membership without unduly straining our old rules, had remained outside of the Society rather than join the junior ranks of the associates. In this way, we considered that, if the Society had not actually suffered, it had at all events unnecessarily limited its strength. The range of our work has gradually grown wider, and the very large variety of analytical questions now dealt with in the pages of the ANALYST, and the always increasing circulation of that now indispensable journal, have attracted many friends and sympathizers at home and abroad, to whom we have felt that it would be graceful to open the doors of the Society, should they care to enter into closer and more friendly intercourse with us than existed in merely studying the literature which we placed before them month by month in our journal. We have therefore repealed our old enactment as to the qualifications for membership, substituting a simpler requirement, so that anyone not less than twenty-one years of age, engaged in the profession of analytical chemistry, shall be eligible for proposal for the full membership of the Society, under the conditions laid down in the rules, which will shortly be distributed among you. Additional copies of these you may obtain from the honorary secretaries, in case any of your chemical friends express to you a desire to become acquainted with them.

That the change is not generally distasteful to our old associates may be gathered from the fairly long list of those whose names have been proposed this evening for transference to the rank of members.

I need not detain you by much reference to our financial condition. This has been already ably placed before you by our honorary treasurer. The thoroughness with which he discharges his duties is evidenced on the one side of the account by his success in gathering in our subscriptions, while on the other side, despite the many calls on his purse, he is able to show a sufficient saving to increase, even though not to a very large extent, the Society's funded property. The ANALYST is necessarily an expensive undertaking, and, in addition to our other normal or necessary expenditure, we have during the past year expended a great deal of money in printing and postage, in connection with the distribution among members of Parliament, county councils, borough corporations, and other local authorities, of the views of the Society, as represented by its Council, on matters connected with proposed new legislation on the question of adulteration. The ANALYST, with its present large circulation, is, even from a purely business point of view, no light undertaking; and, with the exception of those who have served on the Council—or rather on the Editorial Committee—few of you probably fully realize the labour necessarily spent, both by our editor, Dr. Sykes, and by our honorary treasurer, Mr. Voelcker, on the mere accounts of the journal,' and matters incidentally relating thereto. The

treasurership of the Society in early days was a very light task, but it has now grown to very serious proportions, and is really a very formidable consumer of the time that is so faithfully and ungrudgingly given to it by the present occupant of what I now regard as the most important office on the Council.

Although I have thus ventured to crave your recognition of the care given to your business affairs by our treasurer and by our editor, it would seem hardly necessary that I should mention, as a self-evident subject for our gratitude, the literary labour spent by the latter on our monthly journal. We have an editorial committee, and that committee works loyally, and works hard, in the duties allotted to it; and we have an industrious and able staff of abstractors. But the success of such a journal must always necessarily depend mainly upon the constant daily work of its editor—work which, in the case of Dr. Sykes, may be almost said to be gratuitous; for, although we give him an honorarium for his services, it is an honorarium which has no relation whatever to the work that he does. Happily, he is a man of leisure, and still more happily, he is willing to devote that leisure to the good cause of editing and managing this journal.

Our editor has had still more to do during the past year than heretofore in the editing of abstracts. I cannot help wishing, however, that we had given him more original papers to edit. During the past year only twenty-one original papers have been read before the Society. Most of these have been published in the ANALYST, together with three other original papers. Of abstracts of papers of interest to the analytical profession, published abroad, or elsewhere than in the ANALYST, we have during the year published 296, as against 283 in 1897, and 246 in 1896.

The following table shows the respective numbers of abstracts in each of these years, published under the various headings of Food and Drugs Analysis, Toxicological Analysis, Organic and Inorganic Analysis, and Apparatus.

ABSTRACTS PUBLISHED IN THE ANALYST.

	1896.	1897.	1898.
Food and Drugs Analysis	55	86	72
Toxicological Analysis	9	5	3
Organic ,, ...	86	87	109
Inorganic ,, ...	86	91	89
Apparatus	9	14	23
	245	283	296

The following were the papers read before the Society during the year:

"Copper 'Pure for Analysis.'" By J. W. Westmoreland.

"Note on the Tests for Distinguishing Boiled from Unboiled Milk." By Henry Leffmann, M.D.

"The Composition of Milk and Milk Products." By H. Droop Richmond.

"The Calculation of Added Water in Adulterated Milk." By H. Droop Richmond.

"Japanese Wood Oil." By John H. B. Jenkins.

"A Typical North-East Lancashire River." By F. R. O'Shaughnessy.

"The Analysis of Marmalade." By L. Kidgell Boseley.

"A New Form of Condenser." By Cecil H. Cribb.

"Water Supply in Relation to the Maidstone Epidemic." By Matthew A. Adams, F.R.C.S.

"Note on Some Apparatus." By H. Droop Richmond.

"Sewage Analysis, and Standards of Purity for Effluents." By C. G. Moor, M.A.

"Note on Certain Resins." By Rowland Williams.

"The Proportion of Oxygen Present in Linseed Oil, both before and after Oxidation." By Rowland Williams.

"Chicory, and Variations in its Composition." By Bernard Dyer, D.Sc.

"The Sulphuric Acid in Portland Cement." By Eug. Ackermann.

"A Curious Meat Preservative." By Alfred C. Chapman.

"A Method for the Quantitative Separation of Acetic and Valeric Acids." By Alfred C. Chapman.

"Contributions to the Chemistry of Drying Oils, with a Method for the Examination of Linseed Oil." By Otto Hehner and C. A. Mitchell, M.A.

"Automatic Pipettes and Burettes." By A. W. Stokes.

"The Effects of Recent Drought on the Quality of Milk." By A. W. Stokes.

"On the Use of the Micro-Spectroscope, and the Methods of Detecting Blood in Chemico-Legal Investigations." (Lecture.) By Alfred H. Allen.

The following original papers were also published in the ANALYST.

"Note on the Volume Concentration of Condensed Milk." By A. McGill.

"Note on the Examination of Liniment of Camphor." By Norman Leonard, B.Sc., and H. Metcalfe Smith.

"The Relation between the Specific Gravity and the Insoluble Fatty Acids of Butter and other Fats." By Norman Leonard, B.Sc.

I ventured last year to point out that many chemists read before other societies, or published elsewhere, papers which I thought ought properly to be read and discussed at the meetings of this Society, which alone of the many chemical societies is the one which is mainly and essentially devoted to the study of chemical analysis. I still think that this is in some sense due to the fact that many suppose that we do not care to discuss here papers dealing with subjects other than those cognate to matters coming before public analysts in connection with their statutory duties under the Sale of Food and Drugs Acts. It has been at various times urged by many members, that we should attract more papers to our Society were we to drop the word "Public" from our title. While much is to be said for, as well as against, such a change in our title, and as the suggestion has been again made quite recently, I would repeat what I think I said at our recent Extraordinary General Meeting, viz., that the proposition to change our name has been long and seriously discussed by your Council, with the result that we have thought it better for the Society to advise you to retain the old colours under which you have now sailed well for five-and-twenty years. I hope, however, that the change recently made in the wording of our rules may induce some who are—not to use the word offensively—guilty of reading elsewhere analytical papers which ought to be read here, to at once seek to become enrolled as members of this Society, and to henceforth read their contributions to the literature of analytical chemistry at our meetings, where they

may surely expect to meet with a fairer appreciation than is often possible in other societies, which deal only occasionally and incidentally with analytical matters.

I ventured last year to express satisfaction that the Institute of Chemistry, under the able presidency of our own late President, Dr. Stevenson, was about to see its way to granting a special diploma in pharmacology and therapeutics, such as would enable candidates for public analystships to produce the evidence of qualification required by the Local Government Board in these subjects as well as in chemistry. The arrangements then in contemplation have been completed, and the Council of the Institute now holds a special examination in these subjects, for such members of the Institute as may care to present themselves. The Institute of Chemistry is now, therefore, able to furnish the full evidence of qualification required by the Local Government Board, without a candidate being obliged to have recourse to any other Society or corporation, whether medical or pharmaceutical, or to merely individual or personal testimony as to therapeutical knowledge, which was always vague and unsatisfactory, and the acceptance of which by the Local Government Board was always a matter of uncertainty and difficulty. Whether the Local Government Board is technically right in demanding therapeutical and pharmacological qualification from the candidate for a public analystship before confirming his appointment is a somewhat vexed question which I do not propose to discuss. The fact exists that the demand is made, and it appears to be satisfactory that we can now meet it from our own recognised chemical diploma-granting body, viz., the Institute of Chemistry. Certainly no public analyst can be the worse for a fair knowledge of crude drugs, even though their examination may not come within the scope of his normal duties; and it certainly appears to be educationally healthy and desirable that a student who is taking, as his final examination for the associateship of the Institute, the section which relates more especially to the analysis of food and drugs, should learn sufficient practical materia medica to enable him to pass this examination.

Not the least interesting to analysts among the chemical events of the year has been the completion, by the issue of its last volume, of the great work of our esteemed Past President, Mr. Allen, "Commercial Organic Analysis," a work which, whatever modification or extension it may have to undergo in the future, as our science develops, must necessarily live as one of the classical achievements of chemical literature, preserving the name of Allen side by side with the names of Gmelin, Watts, and Fresenius. The undertaking has been almost a stupendous one, having regard to the rapid daily growth of the subjects of which it treats. In 1875 the most comprehensive treatise of the kind, then fairly up to date, was Prescott's little manual on "Proximate Organic Analysis," a book of only about 180 small octavo pages. A glance through that little book, to the eye now familiarized to the use of Allen's splendid manual, perhaps brings home to one more cogently and more concentratedly than anything else the vast progress made by analytical chemistry during the last five-and-twenty years. Allen has not been merely the chronicler of this progress. He has largely been a contributor to it, not merely by the contributions emanating from his own laboratory, which have been many and valuable, but by the educational and stimulating influence of the publication of his book. I like

to think that, if not actually responsible for the birth of Allen's book, the Society of Public Analysts has nevertheless had no small share in indirectly encouraging and influencing its progress and development. Although, as it appeared volume by volume, it has appealed to a world-wide circle of readers, yet I venture to think that the appreciation and personal encouragement which he has found in the little brotherhood of chemical friends banded together in this Society, have done not a little towards enabling its author to persevere unflinchingly in the heavy task to which he has devoted the best years of his life; and I like to think, when reviewing the great progress made in proximate organic analysis during the last quarter of a century, that, in many directions, the lines of investigation, abroad as well as at home, were first marked out by the early work of members of this Society.

The question which has engaged the attention of the Society now for some years still remains unsettled—I mean, the question of reformed legislation with regard to food adulteration. A year ago the only progress to be chronicled was that a Bill had been introduced into Parliament by the President of the Local Government Board, at the very end of the session of 1897, and simultaneously withdrawn. The Bill was a fragmentary and incomplete one, which failed to deal with the most important of the recommendations contained in the report of the Select Committee of the House of Commons on Food Products Adulteration, and was admittedly only put forward as a tentative measure. Your Council deemed it wise to criticise this Bill somewhat severely; and the Bill met with so much severe criticism from so many other directions that it was not reintroduced. The President of the Local Government Board appears to have then come to the conclusion that the subject was too knotty a one to be dealt with as a whole, and he accordingly, after another session's reflection, proposed—and, as before, simultaneously withdrew—another tentative measure, based on quite different lines, in which he proposed to deal only with agricultural products, to the exclusion of food articles of general manufacture. Such a Bill necessarily left undealt with a great proportion of the recommendations of the Food Products Adulteration Committee, though it partially embodied the spirit of the recommendation with regard to a standing authority to lay down standards or limits of composition. The Bill contained the following clause:

> The Board of Agriculture may, after such inquiry as they deem necessary, make regulations for determining the extent to which any deficiency in any of the normal constituents of milk or butter, or the presence of any foreign matter in any sample of milk or butter, shall raise a presumption, until the contrary is proved, that the milk or butter is adulterated or impoverished.

I take it that the intention was that the Board of Agriculture should from time to time, as it deemed advisable or necessary, itself appoint a committee to take evidence and make recommendations; and it is quite possible, if the only articles to be dealt with were milk and butter, that the Board of Agriculture, acting with the assistance of a departmental committee appointed by itself, might satisfactorily take the place of the comprehensive standing committee of reference recommended in the report of the Select Committee. But, in the Bill of 1898, no machinery was provided for discharging the many other functions, connected with food generally,

which it was proposed should be assigned to the committee of reference contemplated in the Select Committee's report. It has been recently announced, on Government authority, that the President of the Local Government Board has handed over the charge of the Bill to the President of the Board of Agriculture. Mr. Walter Long, in a recent speech, announced his intention of introducing during the coming session a Bill which he hoped would reduce adulteration, though from his speech it is to be feared that it will again be a Bill dealing only with food products produced by farmers. Mr. Long, however, stated, in effect, that he had been much struck by the general unanimity of the demand for fresh legislation, and that he had been approached by traders of all kinds, and by various commercial associations, far more than by agricultural interests. He was assured that there was wholesale adulteration going on in the country, and believed there was truth in the statement. He further said that it was a remarkable fact that all the statements which were made were on one side, and that no one had suggested that there was another side to the question, every assertion being to the effect that there was a great deal of fraud being perpetrated. He was satisfied that it was not a state of things that ought to be allowed to continue, and it was the intention of the Government to introduce, through himself, in the coming session, a Bill which he hoped would enable them to deal satisfactorily with the question. Perhaps it is not too late to hope that Mr. Long will yet find himself able to enlarge Mr. Chaplin's Bill in such a way as to deal comprehensively with the question. Such a Bill we all believe must ultimately come, and to deal with the whole question piecemeal is only to prolong the unsettled condition of affairs which has been so long causing concern to so many sections of the public. The mere question of the regulation of the use of dangerous preservatives and colouring matters is at the present time so vexed a one and so pressing a one that it would be anomalous if any Bill were introduced which did not hold out some satisfactory means of dealing with it.*

The Council of this Society has more than once had its attention directed to the action of certain County Councils in undertaking to make, for the general public, in their own laboratories and at the hands of their own exclusively-engaged public analysts or medical officers, at the expense of the county rates, analyses of water and other articles at merely nominal charges, thus entering into competition with the ordinary practitioner of analytical chemistry. The Council has obtained from the Local Government Board a distinct expression of opinion to the effect that County Councils, in applying the county rates for such purposes, are exceeding their statutory powers. It is sincerely to be hoped that the effect of this declaration will be to put an end to so unfair and so unwarrantable a form of competition.

I cannot close this somewhat random dissertation without referring to the very pleasant summer meeting, in which so many of us joined, at Woburn, where Dr. J. A. Voelcker was good enough to show us over the experimental farm which has been under the charge successively of his late father and of himself for over twenty years. In historical interest the Woburn farm has now become second only to the older station at Rothamsted, and many of our members were pleased to

* Since this address was delivered Mr. Long has introduced his Bill (February 23) into the House of Commons. The scope of the Bill is wider than that of the Agricultural Bill introduced last year.

have the opportunity of visiting it. The recently established pot-culture station, established for the purpose of carrying out investigations on the influences of various chemical substances on plant growth, under the bequest of the late Mr. Hills, was very interesting to most of us; and the kindness of the Duke of Bedford in throwing open to our inspection the art treasures of Woburn Abbey added pleasantly to the attractions of a most enjoyable meeting.

Now a brief personal word. I close this evening an official connection with the Society extending over sixteen years, fourteen years as one of your secretaries, and two years as your President. And I feel that it would be unbecoming did I not now, in taking my official farewell of you, say how much of the happiness of my life has been due to friendships formed in this Society, and did I not also make some formal acknowledgment of the much kindness—and often, I fear, much forbearance—which you have extended to me in the face of many shortcomings, some of them conscious, and some of them (and usually these are the worst) not conscious. Not to make blunders, however, is a gift proverbially reserved for those who make nothing. Mine you have been good enough year after year to overlook, and my best consolation is that the Society has flourished in spite of them. My seat in this chair I now resign to an able and accomplished successor. My old secretarial chair, which during the last two years has been occupied by Mr. Cassal, will from this evening be occupied by a gentleman who is not a very old member of the Society, but who is a very loyal one. Mr. Chapman is a chemist of distinguished ability and a man of energy and industry, and he will have a good trainer in his new duties in my old colleague, Mr. Bevan, who still happily retains his post.

ANNUAL DINNER OF THE SOCIETY OF PUBLIC ANALYSTS.

The annual dinner was held at the Criterion Restaurant, after the annual meeting, under the chairmanship of the newly-elected President, Mr. W. W. Fisher, M.A. About sixty members and guests were present. Amongst the latter were Professor Odling, F.R.S.; Professor Tilden, F.R.S.; Dr. Thos. Stevenson, President of the Institute of Chemistry; Mr. Walter Hills, President of the Pharmaceutical Society; Mr. George Beilby, President of the Society of Chemical Industry; Dr. Childs; Dr. Longstaffe; Dr. Pakes; Mr. E. Holmes; Mr. F. W. Beck; and Mr. Aubrey W. Rake.

The following toasts were proposed: "The Queen," by the President; "The Institute of Chemistry," by Professor Odling, F.R.S., responded to by Dr. Thos. Stevenson, President of the Institute; "Kindred Societies," by Dr. Bernard Dyer, responded to by Mr. Walter Hills, President of the Pharmaceutical Society; "The Society of Public Analysts," by Professor Tilden, F.R.S., responded to by the President; and "The Guests," by Mr. Otto Hehner, responded to by Mr. George Beilby, President of the Society of Chemical Industry.

SECTION OF BORE-HOLE AT ILKESTON.

The lettering in these diagrams can be readily deciphered by the aid of a weak magnifying-glass.

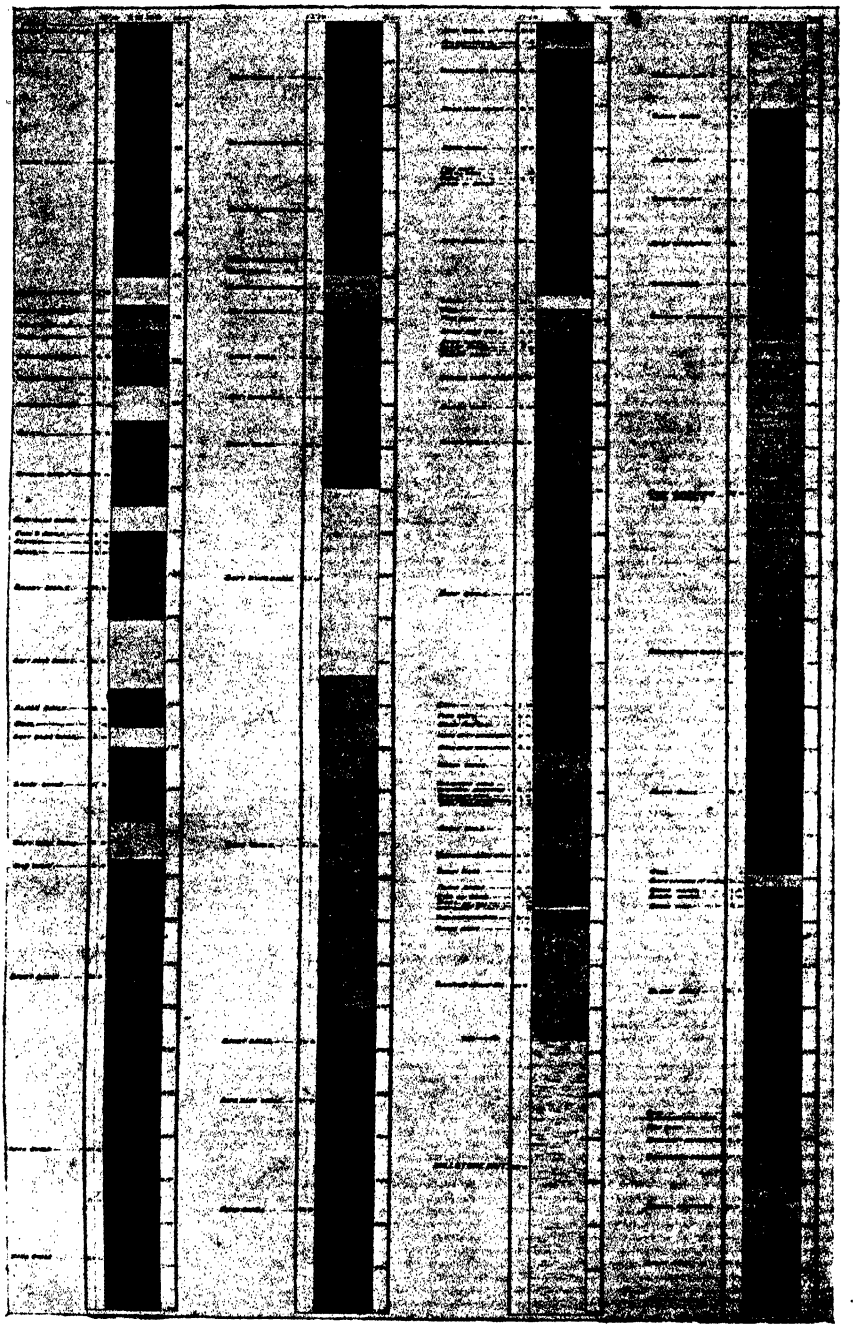

DIAGRAM No. 1.

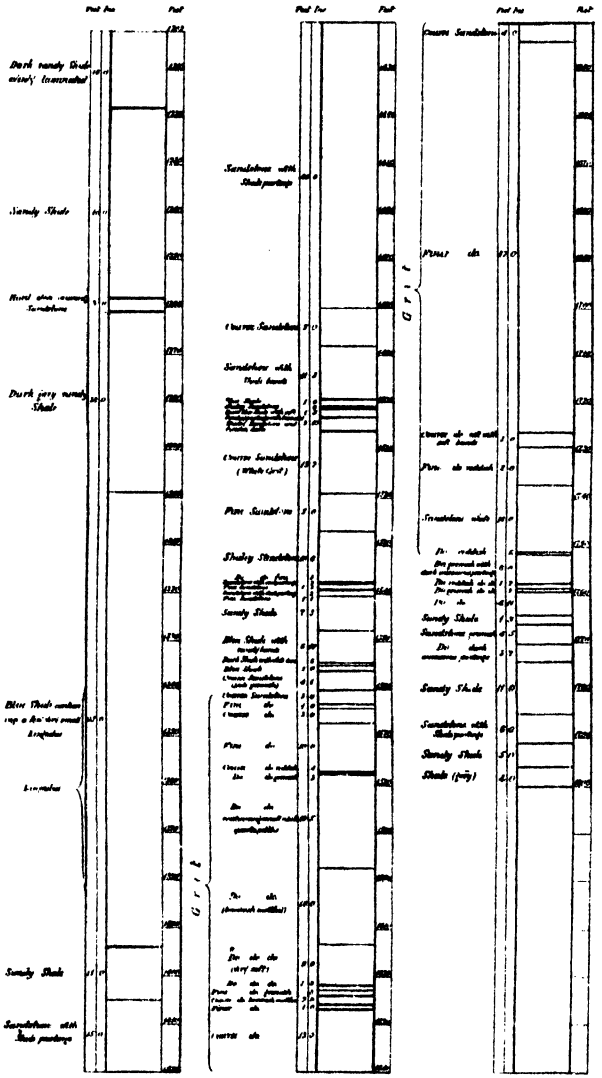

DIAGRAM No. 2.

THE OCCURRENCE OF BARIUM COMPOUNDS IN ARTESIAN WELL WATER.

By John White, F.I.C.

(*Read at the Meeting, January* 4, 1899.)

The presence of a salt of the metal barium in solution in a natural water in this country is in my experience of very rare and unusual occurrence. I can only find a few instances recorded of the existence of a soluble salt of this metal as a constituent of unartificial waters, and therefore think it desirable to lay before this Society the results of my analyses of some samples of water derived from an artesian well of very great depth at Ilkeston in Derbyshire. I give all the information I have been able to obtain respecting the bore-hole, and exhibit drawings in section of the strata passed through, which are here reproduced (see diagrams 1 and 2). For much of this information I am indebted to Mr. Henry J. Kilford, the Borough Surveyor of Ilkeston, also for the loan of the drawings.

The bore-hole, the surface of which is 160 feet above sea-level, O.D., has been carried to a total depth of 1,801 feet, water being found at 837 feet, and rising to a height of 15 feet above the surface. As only about 180 gallons per hour were obtained at the surface from that depth, the bore was deepened as stated, with the result that the yield remained practically unaltered. A pumping shaft was then sunk round the bore-hole to a depth of about 150 feet, and this is now in course of being deepened to about 300 feet. The steel tubes were removed as the sinking proceeded, and a considerable increase in the volume of water yielded has been the result, great difficulty being experienced at times in plugging up the tube. It was during the removal of a length of tube that the accident happened which caused the admittance to the bore-hole of the abnormal water presently to be described. Mr. Kilford is of opinion that the tubes split somewhere lower down, and by sinking the shaft below the Kilburn coal measures, he expects to be able to "tub out" the abnormal water. The bore-hole was lined with steel tubes to a depth of 1,040 feet.

The diagrams give exact particulars of the nature and thickness of each layer of the strata passed through. By adding together the figures given for the various layers of like material, and grouping them according to their general description and classification, arough synopsis of the formation is obtained, as shown in the following table:

Table I.

Nature of Strata.	Varieties mentioned in Section Diagram.	Total Thickness in feet.
Shale	Black, blue, light blue, dark blue, soft blue, gray, dark, sandy, variegated.	1,100
Sandstone ...	Brownish mottled, broken, coarse, close-grained, fine, greenish gray, dark gray, hard gray, open gray, reddish, shaley, streaked, variegated, white.	350
Millstone grit ...	— — — —	300
Coal	— — — —	17
Fire clay	— — — —	16
Miscellaneous ...	Beryl, blue bind, sandy bind, clay, clunch, ironstone, limestone, spar.	20

Before proceeding further to consider the nature of the strata, I give in the next table the results of my analyses of six samples of water :

A is the water originally yielded by the bore-hole.

B is the abnormal water which gained access to the bore-hole, as is supposed by the splitting of the steel lining tubes.

C is a similar sample, collected about six months later than B.

D is from the pumping shaft, collected since this abnormal water appeared.

E and F are from the pumping shaft, taken about 80 feet below the surface, before the abnormal water was found.

These waters are of peculiar and abnormal composition. Samples E and F are of no great interest, and are only included as indicating the kind of water occurring in the neighbourhood of the bore-hole; they are typical examples of water such as is frequently found in or near the coal measures, containing, as these samples do, a comparatively high amount of free ammonia and chlorine, with traces of iron and a considerable quantity of sodium carbonate.

The first four samples contain barium in varying amount, and there is consequently an entire absence of sulphates and phosphates. As compared with the total solid matter present, the proportion of chlorine is relatively exceedingly high, while the lime and magnesia are in each instance very low. There is no evidence of pollution, the free ammonia being doubtless of mineral origin, and organically the waters may be pronounced to be pure.

Sample A was decidedly alkaline from presence of sodium carbonate, a fact which renders the occurrence in the water of barium particularly remarkable, inasmuch as sodium carbonate will precipitate the chloride or other soluble salt of barium at the ordinary temperature and in very dilute solutions. The barium, therefore, must exist as the carbonate, which salt is slightly soluble in water; it is present to the extent of 1·77 parts per 100,000.

This water flowed from the bore-hole at a temperature above normal; at the date of collection the thermometer in the open registered 47° F., but the temperature of the water was 61° F.

Samples B, C, and D all contained barium chloride. B and C closely resemble each other in their phenomenal composition; they contain an amount of barium corresponding respectively to 38·55 and 40·70 parts per 100,000 of barium chloride. With the exception of a water stated by Professor Bedson (*J.S.C.I.*, vol. vi., p. 712) to contain 96·04 grains per gallon of barium chloride, this is the highest amount I have been able to find recorded as occurring in a natural water. The other features of these waters worthy of notice are the extraordinary quantity of common salt in solution, and the comparatively small amounts of lime and magnesia present.

When freshly obtained, samples B and C, upon being briskly shaken at the ordinary temperature, evolved a considerable amount of gas, which I believe mainly consisted of nitrogen.

Sample D appears to consist of some similar water to B or C, diluted to nearly ten times its volume with some other normal water; the solid matter, chlorine, barium chloride, lime and magnesia, are present approximately in about one-tenth the amount in which these constituents occur in samples B and C.

In Table III. I have combined the acids and bases to show what may probably represent the actual salts present in solution in the four waters containing barium. It frequently happens that there is a difference of opinion as to the method to be adopted in combining these acids and bases I have no wish, therefore, to insist upon the correctness of the view I have taken, but simply to follow the usual custom and state the calculated analyses:

The barium was estimated in the water without previous concentration by acidifying with dilute hydrochloric acid, and then precipitating with very dilute sulphuric acid (about 1 in 300) and heating to boiling. The filtrate and washings were subsequently used for the determination of the lime by precipitation with ammonium oxalate in the usual way.

Having proved the absence of all other metals, including potassium, the amount of sodium oxide was ascertained, which was equivalent to the sodium chloride calculated. This was then checked by sulphating the residue from a known quantity of water, igniting and weighing, and comparing the result with the sum of the salts calculated to their respective sulphates. In this way a very fair approximation was obtained.

These waters give, as I will show you, marked precipitates with potassium chromate and dilute sulphuric acid, without previous concentration. I would point out in this connection that it is not advisable, when testing waters for lead, to rely entirely upon the chromate or bichromate of potash test. This should obviously be confirmed by the use of sulphuretted hydrogen, otherwise such waters as these might be pronounced to contain lead.

And now a few words as to the possible origin of the barium salts. There is not very much of a striking character, from a geological point of view, to be discovered by an examination of the diagram of the section of the strata through which the bore-hole passes, and no direct evidence appears to be afforded as to the whereabouts of the barium compounds. Some of the seams are described as containing "spar," but I have been unable to obtain any of this for analysis, and cannot say what is its composition. Nearly one-fifth of the strata is classified under the head of sandstone, and, with millstone grit, this constitutes upwards of one-third of the whole. Clowes (*Chem. News*, 52, p. 194) states that the beds of the new red sandstone near Notting-

ham are permeated by minute crystals of barium sulphate, which acts as a cementing material. Dieulafait is also stated to have shown that all primary rocks contain barium in sufficient quantity to be easily detected. The occurrence, however, of barium sulphate in the strata, although the most likely salt to be present, does not of itself account for the barium carbonate or chloride in these waters. The only explanation that occurs to me is that the barium sulphate in the rock, etc., has by some means, possibly by the action of heat in presence of carbon or carbonaceous material, been reduced to the sulphide, and this salt has then, by coming into close contact with beds of common salt or with some strong solution of brine, been converted into the chloride. This might then react with other water containing sodium carbonate, and so become changed into barium carbonate. It is possible that the carbonate might be directly produced from the sulphide, but the first hypothesis, having regard to the enormous amount of common salt associated with the barium salts, seems to me to be the more probable.

Clowes (*Royal Society Proceedings*, vol. xlvi.) gives the results of some analyses of deposits formed in the water-boxes of coal-mines in the neighbourhood of Newcastle-upon-Tyne. These deposits consisted mainly, and in some cases almost entirely, of barium sulphate; they were soft and easily powdered, and appeared to have been produced by a process of rapid precipitation. He is of opinion that these deposits may be formed by the admixture of a water containing barium chloride, such as the one to which I have already referred, communicated by Bedson, with a water containing sulphuric acid or ferrous sulphate, produced by the oxidation of pyrites in the coal measures. The water analysed by Bedson was from a coal-mine near Newcastle-upon-Tyne.

Neither Clowes nor Bedson, as far as I know, have, however, offered any explanation of the origin of the barium chloride in solution in these waters.

Another instance of the occurrence of barium chloride in a natural water is to be found in a spring at Llangammarch, a small village in Breconshire, Central Wales. This spring has been analysed by Dupré and by S. Arch Vasey, of the *Lancet* laboratory. The former found 6·26 and the latter 6·74 and 6·49 grains per gallon of barium chloride, the total mineral matter amounting to 302 grains per gallon. Waters have also been found containing this salt at collieries near Sunderland and near Rotherham, and in a spring water near Shotley Bridge in Durham.

Barium chloride is said to possess valuable medicinal properties, acting chiefly upon the heart. As it is not, however, an official drug of the British Pharmacopœia, it is possible that its therapeutical effects are not yet properly understood. According to toxicological authorities, the minimum authenticated fatal doses recorded are of the carbonate 60 grains, and of the chloride 100 grains. From the results I have laid before you, it does not seem probable that cases of poisoning by the consumption of water containing salts of barium are likely to arise.

Discussion.

The President thought that it might be possible to account for the presence of the soluble barium somewhat less elaborately than in the manner suggested by Mr. White, viz., simply by the action of sodium carbonate, under pressure, on the

barium sulphate. Without pressure, of course, the action of aqueous solutions of alkaline carbonates on barium sulphate was very slight, even when the solutions were boiled with the sulphate. It might be, however, that the original material was barium carbonate (witherite), which would more easily be dissolved. In the red sandstone, strontium occurred as celestine, the sulphate, and as strontianite, the carbonate; and possibly barium also occurred there in the forms of sulphate and carbonate. Anyone who met with either of these waters would at once notice that there was something unusual about it, from the fact that it contained no sulphuric acid.

Mr. HEHNER inquired whether the author had examined the water spectroscopically for the presence of small quantities of strontium as well as barium. In the case of many analyses made by Fresenius it had been demonstrated that both of these metals were often present in water, of course in very small quantities, and not in any way comparable with the cases referred to in the paper.

Dr. RIDEAL remarked that an analysis made by Dr. Dupré of the Breconshire water referred to had been widely circulated for purposes of advertising the water as a specific for cardiac diseases; and, inasmuch as that water only contained six or seven grains of barium per gallon, it would appear that these Ilkeston waters, containing several times that quantity, should have a greater value in such diseases. It would be noted that the absence of alumina was a characteristic feature of all these waters.

Mr. WHITE, in reply, said that the President's suggested explanation did not appear to account for the presence of barium chloride, and he (Mr. White) thought the barium could not exist in the water otherwise than as chloride. It might, however, account for the carbonate present in sample A, which was the original water from the borehole. The only evidence he had upon which to base his conclusion that barium sulphate was the original mineral, was the information contained in the papers of Dr. Clowes. Dr. Clowes had taken much interest in the subject, and it seemed quite clear that, in the neighbourhood referred to, there existed considerable quantities of barium sulphate in the sandstone, which formed about a fifth of the total strata passed through in boring the well; and therefore he (Mr. White) thought it fairer to conclude that barium sulphate, rather than barium carbonate, was present originally, for there was no evidence at all of the occurrence of barium carbonate in the neighbourhood. Some few miles away there was a piece of millstone grit, forced up, probably, by volcanic action, known as the "Hemlock Stone," from its shape and spreading top. Dr. Clowes had published an analysis of this stone, which showed that it contained in some parts a large percentage of barium sulphate. He (Mr. White) could confirm this from his own analysis of portions of the stone. He had not used the spectroscope to prove the absence of strontium, but had tested every precipitate of barium sulphate very carefully, without getting any evidence of the presence of strontium. He had no information as to the solubility of barium carbonate in solutions of alkaline chlorides, but had already, in referring to the President's remarks, stated his reasons for assuming the original presence of barium sulphate, and the way in which he thought the chloride was to be accounted for.

FOODS AND DRUGS ANALYSIS.

Testing for a Yellow Azo-colour in Fats, etc. A. H. Low. (*Journ. Amer. Chem. Soc.*, vol. xx. [11], 889.)—A few c.c. of the pure filtered fat are treated with an equal volume of a mixture of strong sulphuric acid, 1 part, and glacial acetic acid 4 parts, the whole being then heated nearly to boiling, and thoroughly mixed by agitation. After settling, the lower stratum (mixed acids) will exhibit a strong, wine-red coloration, if the yellow azo-dye be present, whereas only a very faint brownish tinge is produced in the case of pure butter. The sulphuric acid may be replaced by strong hydrochloric acid, or a mixture of 1 part strong sulphuric acid with 3 parts water may be employed; the acetic acid mixture, however, gives the best results.

C. S.

The Detection of Horseflesh in Sausages. T. Bastien. (*Journ. Pharm. Chim.*, 1898, vii., 540-542.)—The author has examined various methods based on the colour reaction which the glycogen of the horseflesh gives with iodine. With the original process of Bräutigam and Edelmann (ANALYST, xix., 24) he has only been able to obtain certain results in the presence of a large proportion of horseflesh, and he has also found Courlay and Coremon's modification (ANALYST, xxi., 231) inconclusive.

By varying the experimental conditions he has worked out the following modification, by which, he asserts, it is possible to detect the presence of 5 per cent. of horseflesh in sausages, even in the presence of starch: About 20 grammes of the finely minced sausage are boiled for from thirty minutes to one hour with 100 c.c. of water, so that the volume of the liquid is reduced to about 30 c.c. When cold the broth is filtered, and about 10 c.c. tested with 2 or 3 drops of a solution of iodine in potassium iodide (iodine, 1 gramme; potassium iodide, 2 grammes; water, 100 c.c.) or of iodine water. A fugitive reddish violet coloration indicates the presence of horseflesh. The iodine reagent must be added carefully, since a slight excess changes the colour to reddish-brown.

If starch is also present, the broth is decanted when cold, and from 1 to 2 volumes of acetic acid added according to the quantity of starch. After standing for 5 minutes the liquid is filtered, and 10 c.c. of the filtrate tested as before with 2 to 3 drops of the iodine solution, which in this case also produces a violet colour in the presence of horseflesh.

A summary of the author's experiments is given in the subjoined table:

ORGANIC ANALYSIS.

Emetine Octo-iodide and the Extraction and Estimation of Alkaloids generally. H. M. Gordin and A. B. Prescott. (*Amer. Journ. Pharm.*, 1899, lxxi., 14-21.)—The authors consider that the simplest and quickest method of obtaining the alkaloidal solution sufficiently free from foreign matter for titration by their periodide method (ANALYST, xxiii., 324) is that of A. B. Lyons (*Manual of Pharm. Assaying*, p. 20). This consists in macerating a weighed quantity of the powdered drug in a definite volume of Prollius' fluid with frequent shaking for several hours, drawing off an aliquot portion of the clear liquid, evaporating and taking up the residue with acidulated water. To obviate the loss by evaporation of the volatile solvent, which often causes too high results, the authors prefer as a general method of extraction a process which in its main features is the same as that used by them in the assay of opium (ANALYST, this vol., 8).

This method has given very good results with all the drugs examined, with the exception of ipecacuanha root. It was found to be almost impossible to extract free emetine completely from this root by percolation with the ethereo-ammoniacal mixture.

Ether, chloroform, and acetone were also tried as solvents, but all yielded results much lower than those obtained by Lyons' process.

Emetine appears to form two periodides, that produced when the iodine is added to the alkaloid differing from that formed when the alkaloid is added to the iodine. The higher periodide, which is the only one the authors have yet examined, is obtained in the latter way. It is a dark brown powder, hardly soluble in benzene, ether, or chloroform, readily soluble in alcohol, and very soluble in a mixture of 4 parts of alcohol and 1 part of chloroform, although chloroform by itself hardly dissolves it. From the results of their analysis they conclude that it is emetine hydriodide hepta-iodide, $C_{28}H_{40}N_2O_5.HI.I_7$, and from this the iodine factor for emetine is calculated to be 0·5453.

The following table gives the comparative results of the gravimetrical and iodometrical assay of various drugs. Except in the case of the ipecacuanha root, for which Lyons' method was used, the alkaloids were extracted by the authors' general method, and titrated as described in their former paper (ANALYST, xxiii., 324). For nux vomica the mean factor of strychnine and brucine (0·47845) was taken, and for atropine the factor 0·2849.

C. A. M.

The Separate Estimation of Strychnine and Brucine. H. M. Gordin and A. B. Prescott. (*Amer. Journ. Pharm.*, 1899, lxxi., 18, 19.)—The periodide method of assaying nux vomica (ANALYST, xxiii., 324) may be used in conjunction with Dunstan and Short's method of separating strychnine from brucine (*Pharm. J. Trans.* (3), 14, 290) as a convenient method of separately estimating these alkaloids in the drug. The acidulated alkaloidal solution obtained from 4 grammes of nux vomica in

any suitable way is made up to 100 c.c. Fifty c.c. of this are run into an Erlenmeyer flask, 10 c.c. of 2 per cent. sulphuric acid added, and water to about 200 c.c. After the addition of 25 c.c. of a 5 per cent. solution of potassium ferrocyanide, the flask is closed and shaken continuously for about thirty minutes. The liquid is filtered and the precipitate washed with water containing 1 per cent. of sulphuric acid, until the washings diluted with water have no bitter taste.

The filter is then pierced, the precipitate washed into a second flask, where it is mixed with 20 c.c. of a 5 per cent. solution of zinc sulphate, and the flask kept on a boiling water-bath for about fifteen minutes. The zinc sulphate decomposes the strychnine ferrocyanide, zinc ferrocyanide being precipitated and strychnine sulphate left in solution. When completely cold the liquid is diluted to 100 c.c. Of this 50 c.c., representing 1 gramme of nux vomica deprived of the brucine, are filtered off and run into a flask containing 20 c.c. of decinormal iodine solution and about 2 c.c. of dilute hydrochloric acid. The amount of iodine consumed multiplied by 43·9 (100 times the strychnine factor) gives the percentage of strychnine.

The iodine consumed by the total alkaloids is determined in another portion of the alkaloidal extract in the same way, and the difference between the two amounts multiplied by 51·79 (100 times the brucine factor) gives the percentage of brucine in the drug.

The following results were obtained by this method with a test-solution containing 0·16 per cent. of strychnine and 0·22 per cent. of brucine (anhydrous):

Iodine consumed by 10 c.c., before the removal of Brucine. Gramme.	Iodine consumed by 10 c.c., after the removal of Brucine. Gramme.	Found, per cent.	
		Strychnine.	Brucine.
0·0843130	0·032397	0·14	0·24
0·0843132	0·032397	0·14	0·24

C. A. M.

Melzer's Picrotoxin Colour-Reaction as a Test for Cholesterin and Phytosterin. H. Kreis. (*Chem. Zeit.*, 1899, xxiii., 21.)—Melzer has shown (*Zeits. anal. Chem.*, 1898, xxxvii., 351 and 747) that when picrotoxin is treated with benzaldehyde and sulphuric acid a red colour is produced; the present author finds that cholesterin and phytosterin (indifferently) yield an analogous reaction. A few drops of a dilute ethereal solution are allowed to evaporate in a porcelain basin, when two drops of Melzer's alcoholic solution of benzaldehyde and one drop of strong sulphuric acid are added. The mixture is made to spread itself over the surface of the basin and then left to rest. Cholesterin and phytosterin develop a reddish-violet colour, afterwards changing to a dark violet; picrotoxin gives rather an "eosin-red" tint. When the colour disappears, it may be restored by more acid. The original tints shown by the fats resemble that produced in the Hager-Salkowsky test for cholesterin, for the colouring-matter is also soluble in chloroform, and may be the same substance. The latter reaction succeeds equally when Melzer's benzaldehyde is replaced by chloroform.

In view of this similarity, the author remarks that caution must be observed in toxicological analysis where picrotoxin has been apparently identified by its colour-

reactions; in the ethereal extract of the acid liquor obtained after destruction of normal organic matter by the Stas-Otto method, cholesterin may well be present.

F. H. L.

On some Recent Methods for Examining Balsams and Resins. K. Dieterich. (*Chem. Rev. Fett- u. Harz-Industrie*, vol. v. [10], 197-201.)—Reviewing his own method for determining the acetyl value, Kitt's "carbonyl number" method, and the Gregor-Bamberger "methoxyl value" method (ANALYST, 1898, 318), the author expresses the opinion that none of them is capable of replacing the usual acid-, ester-, and saponification-value methods for the identification of, and the detection of adulteration in, the balsams and resins generally. He himself is engaged in perfecting a method based on the circumstance that the saponification-products of the ester-containing resins consist principally of alcohols—*e.g.*, resinotannol, resinol, etc., with merely small quantities of acids; whilst the resins containing only resin acids, yield only acids and no alcohols under the same treatment.

A table is given of the principal physical characteristics of the resins and the contained alcohols and acids. C. S.

Notes on Colophony. R. Schick. (*Zeits. angew. Chem.*, 1899, 27.)—This article is largely argumentative. The author does not agree with Dieterich's idea of determining the "acid number" of resin by allowing it to stand for two hours in the cold with excess of seminormal alcoholic potash, and then titrating back with acid. The value so obtained is simply a number lying between the acid and the saponification values; for if the same process be continued longer, the results are practically the same as when the sample is boiled for twenty-five minutes. In fact, the proportion of cold alkali absorbed rises steadily from the immediate and true acid number during twelve hours until it reaches a maximum agreeing with the hot absorption.

The iodine number of resin varies in different grades between 137 and 173; the process is not complete in six hours, and is of little use in valuing the material. If the colophony be heated for thirty minutes in an open crucible to 300° C. the absorption falls some 44 points. Refractometer numbers, as determined with 20 per cent. solutions of resin in linseed oil at 40° C., range between 71·5 and 92·3, decreasing generally (in contrast with oils) as the iodine number rises. The refraction does not appear very useful in estimating the quality of rosin itself, but is admirably adapted for detecting and estimating its presence when mixed with oils; and the results so obtained agree fairly with the Twitchell process. The practical way of valuing resin depends rather on observations of colour and amount of impurity, such as sand and wood; but the market price depends mainly upon the colour, and therefore fixed grades have a moderately constant tint. Estimation of the matter insoluble in petroleum spirit seems of little use; for there is no evidence that such bodies as are insoluble in that solvent are objectionable to the consumer of the resin. F. H. L.

A Colour Reaction of Lignin. A. Piutti. (*Gazzetta Chim. Ital.*, 1898, xxviii., 168-170.)—The hydrochloride of ortho-bromo-phenetidin,

$$C_6H_3\begin{cases}OC_2H_5(1)\\Br(2)\\NH_2.HCl(4)\end{cases}$$

has the property of staining lignin yellow, while it has no action on cellulose, on ordinary textile fibres, such as linen, silk, cotton or wool, on chitin or on keratin. This reaction appears to be characteristic of lignin, since that substance is stained with the same intensity even after being repeatedly extracted with different solvents. By means of it, it is possible to make an approximate estimation of the amount of wood paste added to a given sample of paper, the colour obtained being compared with those of a standard scale prepared from paper containing known quantities of woody fibre.

Lignin is coloured yellow by the other hydrochloride bodies of similar composition to *o*-Br-phenetidin, such as, for instance, the hydrochlorides *o*-Br-anisidin, of *o*- and *p*-amido-phenol, of *p*-anisidin and of *p*-phenetidin, as well as by other salts of these bases, and the author considers it probable that the reaction is given by amido-phenols generally.

Colorations given by lignin with other classes of compounds have been recorded, as, for example, the violet-rose colour with dimethyl-*p*-phenylene-diamine (Wurster), and with a hydrochloric acid solution of phloroglucinol (Wiesner, *Ding. polyt.*, i., 227 and 397), the yellow colour with the hydrochlorides of naphthylamine and aniline, and the rose colour with pyrrol; but the nature of the coloured compounds formed, or on what group in the lignin molecule the reaction depends, has not yet been determined.

The supposition that the reaction is due to the presence of an aldehydic group in the lignin receives some support from the facts that aldehydes combine very readily with the NH_2 group, and form yellow coloured compounds with amido-phenols.

It is also noteworthy that the violet coloration which phloroglucinol in a hydrochloric acid solution gives with lignin which has been thoroughly extracted with solvents is also obtained with aldehydes. C. A. M

The Examination of Caoutchouc Milk. Girard and Lindet. (*Bull. Soc. Chim.*, 1898, xix., 812-815.)—In whatever manner the incision is made in the bark of the tree, the caoutchouc milk has always the same appearance, being an opaque liquid with a great resemblance to animal milk. Under the microscope it appears as an emulsion of innumerable fine globules, from 3 to 5 μ in diameter, in a "serum." As a rule the density of the milk is less than unity, with the exception of that from different species of the Algerian *ficus*. The density of the "serum" freed from caoutchouc varies from 1·037 to 1·040.

In order to determine the percentage of caoutchouc in the liquid, Girard modified the nature of the "serum" by the addition of 95 per cent. alcohol, so that the globules collected on the surface and became united. The alcohol was added little by little, with constant stirring, until, when a volume about equal to that of the milk had been added, the whole of the rubber collected on the surface, leaving below a limpid, amber-coloured liquid.

The following table gives the percentage of caoutchouc thus obtained from different caoutchouc milks :

	Density.	Per cent. Caoutchouc.
Milk from Pernambuco (*Haucornia*)	0·990	31·6
Africa	0·987	33·4
Para (*Siphonia elastica*)	0·986	42·6
Nicaragua (*Castilloa elastica*)	0·980	32·3
Algiers (*Ficus macrophylla*)	1·000	37·5
,, ,, ,, ...	1·005	37·1
,, (*F. elastica*)	1·001	17·3
,, (*F. nitida*)	0·971	31·3
,, (*F. lævigata*)	1·005	28·0
New California (*Kickxia Africana*) ...	1·005	27·0

This similarity between caoutchouc milk and animal milk suggested to Girard the possibility of extracting the caoutchouc by churning the liquid previously heated to 50° C. This was successful on a small scale in the laboratory, and was then tried on a large scale on freshly collected milk in various parts of French Guiana by Bouery, who, after two years' experience, reported that the results were satisfactory. C. A. M.

The Oxy-ferments of Milk and of Saliva. R. Dupouy. (*Journ. Pharm. Chim.*, 1898, 551-553.)—In a former communication the author described the variation in the nature of different milks as regards the activity of the oxydases which they contain, and showed that they can be classified into two groups—those which contain an active oxydase, and those in which (like human milk) the oxy-ferment is very weak.

Carnot (ANALYST, xxiii., 80) discovered the presence of an oxydase in saliva, but, as the author obtained negative results on repeating the experiments, he has made a further investigation of the subject, using exclusively a 1 per cent. solution of guaiacol as his reagent, this being very stable as compared with Carnot's reagents (tincture of guaiacum, solution of paraphenyl-diamine, 1 : 1,000, and paraphenyl-diamine with naphthol in alkaline solution).

The presence of an oxydase in saliva can be demonstrated by adding an equal volume of the guaiacol solution and a drop of a solution of commercial hydrogen dioxide diluted with nine volumes of water. There is an immediate brown coloration, becoming more intense, and finally disappearing after a considerable time. On warming the saliva, the coloration with guaiacol appears readily until the temperature reaches 92° C ; above that temperature the colour appears very slowly, and is hardly perceptible. The author therefore regards 92° C. as the temperature at which the activity of the oxydase is destroyed. It is also rendered completely inactive by an addition of a mineral acid, such as, for instance, a 0·2 per cent. solution of hydrochloric acid. C. A. M.

INORGANIC ANALYSIS.

Notes on the Electrolytic Determination of Iron. S. Avery and B. Dales. (*Ber.*, 1899, xxxii., 64.)—Three processes were investigated : that recommended by Classen, in which the electrolyte is ammonium oxalate ; Smith's method with acid sodium citrate ; and Moore's with ammonium metaphosphate. Classen's gives a

deposit of iron containing between 0·15 and 0·5 (mean 0·22) per cent. of carbon, and about the same amount of iron remains in solution. Smith's iron contains between 1·2 and 5·0 per cent. of carbon. Moore's metal shows an excess in weight of 0·2 to 0·5 per cent., and the impurity consists wholly or in part of phosphorus and carbon. To ascertain whether carbon was the sole foreign ingredient in the metal thrown down from an oxalate bath, some of the iron was burnt in a current of air, passing the gas into baryta water; the amount of carbon calculated from the carbon dioxide was from 0·21 to 0·42 per cent. of the metal examined. The by-product in the Moore process is a heavy black substance, soluble in hot strong acids, but insoluble in dilute ones. F. H. L.

Impure Iron: A Possible Source of Error in Ulsch Nitrogen Estimations. L. Brandt. (*Chem. Zeit.*, 1899, xxiii., 23.)—When a blank experiment was recently carried out to check the purity of the various reagents used in estimating nitrogen in Chili saltpetre by the Ulsch process, it was found that the acid distillate required too little caustic soda for neutralization—the error amounting to 0·8 per cent. of nitrogen on the supposed sample. The impurity was traced to the iron, which evolved ammonia when it was dissolved in acid and boiled with caustic soda, but did not itself contain ammoniacal nitrogen. Boiled with alkali alone, nitrogen could not be detected in the filtrate either as nitrate, nitrite, or cyanide; but after heating with metallic potassium, cyanide was discovered. By ignition in hydrogen the impurity was removed; whereas neither extraction with water, alcohol, nor ether affected it. F. H. L.

Volumetric Estimation of Alkalis and Acids by means of Iodine. C. F. Walker and D. N. H. Gillespie. (*Zeits. anorg. Chem.*, 1899, xix., 194.)—When iodine acts upon a solution of a metallic hydroxide at a temperature high enough to destroy any trace of hypoiodite, a perfectly neutral liquid is produced which contains 1 molecule of iodate to 5 of iodide. On adding dilute acid, these two salts interact in the well-known way, evolving 6 atoms of iodine; and by titration with thiosulphate or arsenious acid, the iodine—that is to say, the original hydroxide—may be estimated. Similarly, an acid may be neutralized by a known excess of alkali standardized as aforesaid, when determination of the surplus will give the strength of the acid. The process has been tested on the hydroxides of the alkalis and alkaline earths, on sulphuric and hydrochloric acids; and although the precautions necessary to avoid loss of iodine and carbonation of the liquid perhaps render it somewhat complicated, the reaction proceeds so smoothly that it should be serviceable for the indirect analysis of acids and probably for other suitable compounds. It cannot, however, be employed on alkali-metal carbonates. The method outlined by Phelps (ANALYST, 1897, xxii., 55) may with advantage be slightly modified. A moderate excess of decinormal iodine is placed in a lightly-covered Erlenmeyer flask, the alkali is added (or, in determining acid, the acid is added, followed by a measured excess of standard alkali), and the whole is boiled till all free iodine is volatilized. The bulk of the liquid in all tests should be uniform and as small as possible, starting with about 100 c.c. and boiling down to about 35 c.c. The vessel is cooled in a

stream of water, 10 c.c. of 1 : 8 sulphuric acid (or hydrochloric acid, if barium be the metal) are introduced, and the liquid titrated with thiosulphate and starch. Blank experiments show that the error involved by conducting this titration in an acid solution is not apparent under the particular conditions referred to. F. H. L.

Some Applications of Hydrogen Peroxide in Quantitative Analysis. P. H. Walker. (*Jour. Amer. Chem. Soc.*, 1898, xx., 513-515.)—*The Separation of Titanium from Iron.*—The cold slightly acid solution of the mixed sulphates (about 150 c.c.) is mixed with 100 c.c. of a solution of hydrogen peroxide (about 2·5 per cent.), and slowly run into a mixture of 100 c.c. of hydrogen peroxide and 30 c.c. of strong ammonia, with constant stirring. The precipitated ferric hydroxide is filtered off at once, and washed with cold dilute ammonia containing a little hydrogen peroxide. The precipitate is dissolved off the paper with a mixture of hydrochloric acid and hydrogen peroxide, again treated with an excess of hydrogen peroxide, and reprecipitated as before. This treatment is repeated a third time, after which the ferric hydroxide can be dissolved, and the iron determined in the usual way.

The filtrates containing the titanium are boiled down, and the titanium hydroxide ($Ti(OH)_4$) which precipitates is filtered off, washed with hot ammonium nitrate solution, ignited, and weighed as TiO_2.

An experimental mixture consisting of titanium dioxide fused with potassium bisulphate, and mixed with iron ammonium alum, gave the following results when analysed by this method :—

	Gramme.
Titanium oxide found by first separation	0·0872
,, ,, second ,, ...	0·0104
,, ,, third ,, ...	0·0041
Total found	0·1017
Titanium oxide taken	0·1016

The Separation of Uranium from Iron.—The presence of a large excess of hydrogen peroxide prevents the precipitation of uranium by sodium hydroxide, but does not interfere with the precipitation of the iron. A slightly acid solution of the mixed salts is mixed with 50 c.c. of hydrogen peroxide, and run slowly, with constant stirring, into a solution of 5 grammes of sodium hydroxide in 50 c.c. of water, mixed with 50 c.c. of hydrogen peroxide. The liquid is diluted to 400 c.c. with hot water, and the iron filtered off and washed. The filtrate (which contains all the uranium) is acidified with hydrochloric acid, evaporated to dryness on the water-bath, the residue heated for an hour at 110° C. to separate any silica, dissolved in hydrochloric acid, filtered, and the uranium precipitated with ammonia, washed with ammonia, ammonium nitrate solution and water, dried, ignited, and weighed as U_3O_8.

In a solution containing about equal weights of Fe_2O_3 and U_3O_8 the following amounts of uranium oxide were found :

	U_3O_8 Taken.	U_3O_8 Found.	Difference.
(*a*)	0·1129	0·1124	−0·0005
(*b*)	0·1056	0·1064	+0·0008

The Separation of Zirconium from Uranium.—The solution of the mixed sulphates is mixed with 50 c.c. of hydrogen peroxide, and run into a solution containing 5 grammes of sodium hydroxide in 50 c.c. of water, and 50 c.c. of hydrogen peroxide. No precipitate forms at first, but after heating on the water-bath for thirty minutes the zirconium oxide settles down as a heavy precipitate. This is collected, washed, and dissolved in a warm mixture of hydrochloric acid and hydrogen peroxide. The solution is boiled, the zirconium precipitated with ammonia, and the precipitate washed with ammonium nitrate solution and with water, dried, ignited, and weighed as ZrO_2.

C. A. M.

Recognition of Ozone in Presence of Nitrous Acid and Hydrogen Peroxide. G. Erlwein and T. Weyl. (*Ber.*, 1898, xxxi., 3158.)—An alkaline solution of the hydrochloride of metaphenylenediamine, which is naturally colourless, is rapidly changed to wine-red by ozone; whereas nitrites and hydrogen peroxide do not affect it, and oxygen only causes a faint coloration after the lapse of some time. The ortho- and para-diamines behave similarly, but the meta-compound is the most useful. A solution containing 0·1 or 0·2 gramme of the hydrochloride in 90 c.c. of water and 10 c.c. of 5 per cent. caustic soda should be freshly prepared each time it is wanted; 25 c.c. of the reagent are tinted yellowish-brown in 5 seconds by 0·08 milligramme of ozone. Conversely, liquids containing 6 milligrammes of diamine per litre of faintly alkaline water are yellowed by ozone, excess of gas destroying the colour. Twenty-five milligrammes of diamine yield a yellowish brown. Strong sulphuric acid changes the colour to a very dark red; nascent hydrogen (zinc and acid or alkali) bleaches it, but on agitation with air it returns to its original appearance.

F. H. L.

Preparation of Starch-Zinc Iodide Solution. A. Seyda. (*Chem. Zeit.*, 1898, xxii., 1086.)—Two or three grammes of potato-starch are rubbed down most thoroughly with 50 or 100 c.c. of water, allowed to stand for one hour under cover, then heated in a strong flask for two to four hours at a temperature of 130° C. in a bath of rape oil. The liquid is diluted to about 750 c.c. with hot water, shaken, set aside for twenty-four hours, and filtered. Twenty grammes of zinc chloride and 2 grammes of zinc iodide (made from zinc dust and iodine) are introduced; if necessary a few drops of centinormal thiosulphate are run in to destroy any blue colour, the whole is made up to 1 litre, well mixed, and finally filtered after twenty-four hours' standing into a bottle of brown glass. The solution keeps indefinitely.

F. H. L.

List of Atomic Weights for Analytical Purposes. (*Chem. Zeit.*, 1898, xxii., 1031.)—A commission, consisting of Professors Landolt, Ostwald, and Seubert, appointed jointly by the German Chemical Society and the German "Reichs-

gesundheitsamt," has recently drawn up the following list of atomic weights, which it is hoped will be uniformly adopted for all commercial analytical purposes throughout Germany. For the sake of greater convenience, the table has been based on the unit O = 16·00, and the figures are given to as many places of decimals (if any) as may insure the last being free from error. The weights of those "elements" marked with a point of interrogation are included under reserve.

TABLE OF ATOMIC WEIGHTS.

	Symbol.	Atomic Weight.		Symbol.	Atomic Weight.
Aluminium	Al	27·1	Neodymium (?)	Nd	144
Antimony	Sb	120	Nickel	Ni	58·7
Argon (?)	A	40	Niobium	Nb	94
Arsenic	As	75	Nitrogen	N	14·04
Barium	Ba	137·4	Osmium	Os	191
Beryllium	Be	9·1	Oxygen	O	16·00
Bismuth	Bi	208·5	Palladium	Pd	106
Boron	B	11	Phosphorus	P	31·0
Bromine	Br	79·96	Platinum	Pt	194·8
Cadmium	Cd	112	Potassium	K	39·15
Cæsium	Cs	133	Praseodymium (?)	Pr	140
Calcium	Ca	40	Rhodium	Rh	103·0
Carbon	C	12·00	Rubidium	Rb	85·4
Cerium	Ce	140	Ruthenium	Ru	101·7
Chlorine	Cl	35·45	Samarium (?)	Sa	150
Chromium	Cr	52·1	Scandium	Sc	44·1
Cobalt	Co	59	Selenium	Se	79·1
Copper	Cu	63·6	Silicon	Si	28·4
Erbium (?)	Er	166	Silver	Ag	107·93
Fluorine	F	19	Sodium	Na	23·05
Gallium	Ga	70	Strontium	Sr	87·6
Germanium	Ge	72	Sulphur	S	32·06
Gold	Au	197·2	Tantalum	Ta	183
Helium (?)	He	4	Tellurium	Te	127
Hydrogen	H	1·01	Thallium	Tl	204·1
Indium	In	114	Thorium	Th	232
Iodine	I	126·85	Tin	Sn	118·5
Iridium	Ir	193·0	Titanium	Ti	48·1
Iron	Fe	56·0	Tungsten	W	184
Lanthanum	La	138	Uranium	U	239·5
Lead	Pb	206·9	Vanadium	V	51·2
Lithium	Li	7·03	Ytterbium	Yb	173
Magnesium	Mg	24·36	Yttrium	Y	89
Manganese	Mn	55·0	Zinc	Zn	65·4
Mercury	Hg	200·3	Zirconium	Zr	90·6
Molybdenum	Mo	96·0			

F. H. L.

A Soda Glass Unsuitable for Chemical Apparatus. E. Hoyer. (*Chem. Zeit.*, 1898, xxii., 1033.)—Liebermann has already called attention to the fact that some chemical apparatus now on the market is made of such strongly alkaline glass that it is quite unfit for analytical purposes. A specimen of this material contained 66·52

per cent. of SiO_2, 24·52 Na_2O, 7·81 CaO, and 0·48 Fe_2O_3 and Al_2O_3. On exposure to air in fine powder it gained 0·8 per cent. in weight in five weeks, and decreased very slightly when heated to 115° C. Treated even with cold water for twenty-four hours it lost 0·56 per cent. by weight or 2·3 per cent. of its content of alkali; on boiling with water and cold or hot extraction with hydrochloric acid it lost more severely eight hours' boiling with pure hot water causing a diminution of 11·80 per cent. in the total weight of the powder. F. H. L.

APPARATUS.

An Apparatus for Determining Melting-Points. L. N. Vandevyver. (*Ann de Chim. Anal. Appl.*, 1898, iii., 397-399.)—After describing the principal methods used for determining the melting-points of substances, and pointing out the restrictions of each, the author describes an apparatus which he considers to be of more general applicability.

He takes as the melting-point that temperature at which a substance in passing from the solid to the liquid state leaves a sign of the change on an object with which it is in contact.

His apparatus consists of a rod, A B (Fig. 1), to which is attached a fixed ring C, and a movable ring, D, which can slide down on to C. A piece of white filter paper is fixed between the two rings, and a fragment of the substance of which the melting-point is to be determined is placed upon this. The rod terminates at B in a small mirror, M, placed at an angle of 135°.

Fig. 1.

The upper end of the rod is fixed in a cork which fits into a large test-tube, and a thermometer, T, is placed with its bulb close to the substance. The test-tube is immersed in a beaker, V (Fig. 2), containing water, glycerin, or paraffin, etc., which is kept in motion during the warming by means of the agitator, R. When water is used it is advisable to have a small brush, S, attached to the end of R to dispel the air-bubbles which become attached to the glass and obscure the view.

The moment the substance fuses a stain is produced on the paper, and this is reflected by the mirror. The author states that he has determined the melting-points of a large number of substances by this method, and has obtained a greater agreement in duplicate determinations than was possible by any other process.

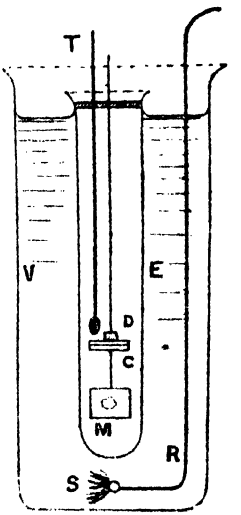

Fig. 2.

When a substance is being examined which stains paper in the solid state, a piece of ground or polished glass is substituted for the paper, and in this case also the change in the state of the substance is clearly shown in the mirror. For high temperatures the ordinary mirror is replaced by a metallic mirror. C. A. M.

THE ANALYST.

APRIL, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, March 1, in the Chemical Society's Rooms, Burlington House, the President, Mr. W. W. Fisher, M.A., occupying the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of the following candidates were read for the second time: Percy T. Adams, assistant to Dr. Matthew A. Adams, Maidstone; Arthur French Angell, assistant to Mr. Arthur Angell, Southampton; John B. Ashworth, assistant to Mr. Alfred Smetham, Liverpool; Alfred Joseph Bull, assistant to Mr. Wm. Chattaway, and senior assistant in the Physical Laboratory, Birkbeck Institution, London; Charles Crocker, assistant to Messrs. Morgan, Son and Seyler, Swansea; John S. Ford, analytical chemist, Edinburgh; C. A. Hackman, A.I.C., assistant to Mr. Alfred C. Chapman, London; Norman Leonard, B.Sc., F.I.C., assistant to Dr. Stevenson, Guy's Hospital, London; J. F. Liverseege, F.I.C., assistant analyst to the Corporation of Birmingham; Richard Murray, chemist to Messrs. Brotherton and Co., Leeds; G. E. Scott-Smith, F.I.C., assistant to Mr. Alfred H. Allen, Sheffield; W. P. Skertchly, assistant to Mr. Otto Hehner, London; Harry Metcalfe Smith, F.I.C., assistant to Dr. Stevenson, Guy's Hospital, London; Lionel W. Stansell, assistant to Dr. Matthew A. Adams, Maidstone; and W. Northfield Yarrow, assistant to Mr. A. W. Stokes, London; and in favour of the following candidates for the first time: Julian L. Baker, F.I.C., chief chemist to the Beetroot Sugar Association, London; Herbert Edward Burgess, chemist to the London Essence Co., London; Louis Charles Deverell, chief assistant to Mr. Benedict Kitto, London; Julius Lewkowitsch, analytical and consulting chemist, London; F. R. O'Shaughnessy, Associate R.C.S., analytical chemist, London; Arthur Marshall, A.I.C., analytical chemist and assayer, London; and Edward T. Shelbourn, A.I.C., assistant analyst to the London County Council, London.

The following papers were read: "Some Analyses of Ginger," by E. G. Clayton; "Note on Boric Acid in Milk Samples," by E. G. Clayton; "Caper Tea," by John White; and a "Note on a Possible Source of Error in Modifications of the Leffmann and Beam Method of Fat Estimation in Milk," by H. Droop Richmond and F. R. O'Shaughnessy.

Mr. Wm. Chattaway exhibited an apparatus for collecting samples of water in Winchester quart bottles at given depths.

A NEW TEST FOR FORMALDEHYDE.

By Norman Leonard, B.Sc., F.I.C., and H. Metcalfe Smith, F.I.C.

(*Read at the Meeting, January* 4, 1899.)

In the determination of the fat "by the Werner-Schmid process" in milk containing formaldehyde, we have occasionally noticed the production of a violet colour when the milk was heated with concentrated hydrochloric acid. This behaviour of formalized milk has also been observed by Fisher (Analyst, xx., 156), whilst other experimenters have noted the production of a *yellow* colour (*loc. cit.*, and Analyst, xxi., 97). Further study of this reaction has enabled us to explain these discrepancies, and to show that it forms a most delicate test for formaldehyde in milk.

The certain production of the violet colour requires the use of a larger proportion of hydrochloric acid than is employed in the Werner-Schmid process. In the case of milks containing such quantities of formaldehyde as are commonly added, a little of the sample should be heated gently in a test-tube with from three to five times its volume of concentrated hydrochloric acid. Under these conditions, a fine violet colour quickly appears, even if the milk contains so little as 0·0001 per cent. (1 per 1,000,000) of formaldehyde, whilst if much over 0·1 per cent. is present a *yellow* colour is produced. In the latter case, however, the violet colour is readily obtained if a large excess of hydrochloric acid is used, so as to sufficiently dilute the liquid. So far as we have been able to ascertain, the reaction is not given by other aldehydes, or by any substance but formaldehyde. We may add that the reaction takes place, though less quickly, at the ordinary temperature, and by working in this way any confusion arising from the action of the acid on the milk itself is entirely avoided.

Bearing in mind the fact, pointed out by one of us (Analyst, xxi., 157), that the presence of a trace of some oxidizing agent is an essential condition in Hehner's test for formaldehyde, experiments were made to ascertain whether such was the case in the reaction described above. The "pure redistilled" hydrochloric acid used by us certainly contained a minute trace of a ferric salt, and gave a slight blue coloration when largely diluted and added to a solution of cadmium iodide and starch paste. When, however, the acid was digested for a short time with a little metallic zinc and then poured off, it gave these reactions no longer, and had also lost the power of producing the violet colour when heated with formalized milk. On adding a trace of ferric chloride, or of bromine, the reaction was readily obtained. It seems probable, therefore, that the coloured products formed in Hehner's test, and in the reaction we have described, are one and the same, the acid employed acting, perhaps, merely as a dehydrating agent.

Discussion.

The President (Dr. Dyer) having invited discussion:

Mr. W. W. Fisher said he remembered noticing, some years previously, in testing a sample of milk somewhat liberally treated with formaldehyde, that a colour was produced on boiling with hydrochloric acid. He did not investigate the cause of the reaction, but he now had a suspicion that it might not be due to formaldehyde only, as milk heavily treated with boracic acid showed a similar colour reaction.

When milk was treated with either formaldehyde or boracic acid, the curd was obtained in such a condition as to be very insoluble in hydrochloric acid, a fact which pointed to some change in the constitution of the casein itself, produced by the addition of the antiseptic; and he thought it possible that the colour reaction referred to might arise from an alteration of the casein, and not simply from the presence of formaldehyde.

Dr. RIDEAL thought that the presence of milk would be essential to the colour being obtained. Mr. Hehner, when describing his test with sulphuric acid, had noted that formaldehyde alone gave no reaction with sulphuric acid. Fritzmann (*Chem. Centr.*, 1898, i., 218) has shown that the blue colour obtained with milk and sulphuric acid is due to the presence of an oxidizing agent, usually *nitric* acid or nitrates in the milk or acid used.

Mr. LEO TAYLOR remarked that when formalin had been added to milk which was being tested by the Leffmann-Beam or by the Werner-Schmid process, the casein was always found to be difficult to dissolve.

Mr. A. E. EKINS confirmed Mr. Taylor's experience with regard to the insoluble condition of milk to which formalin had been added, as observed in the working of the Leffmann-Beam process.

ADULTERATION OF SPIRITS OF NITRE WITH POTASSIUM NITRATE.

BY W. F. LOWE, A.R.S.M., F.I.C.

(*Read at the Meeting, January* 4, 1899.)

THE following short note on what appears to me to be an unusual form of adulteration of spirits of nitre will, I think, be of interest to the Society, as such a form of adulteration does not appear to have been recorded.

A sample of "spirits of nitre" was received in the usual way from one of the food inspectors of my district. On examination I found that it yielded no gas whatever in the nitrometer when treated with potassium iodide and sulphuric acid, but with ferrous sulphate and sulphuric acid it gave a faint brown ring. The specific gravity at 15·5° C. was 0·9073. I noticed a whitish deposit on the pipette used for transferring some of it to the nitrometer, and this led me to examine the sample for solid matter, when I found it to contain 1·12 per cent. of potassium nitrate.

I have since had several similar samples, so that this was not an isolated case, and apparently a good deal of this stuff has been made up for sale, judging from the printed label which was put in (but unsuccessfully) by the defence when one of the cases was heard in court:

"SPIRITUOUS SOLUTION OF NITRE.

"N.B.—This is not the ordinary Sweet Spirit of Nitre, and must not be sold as such; for most purposes it is a much superior article. It contains an ingredient not in the Nitre of the Pharmacopœia, making it much more effective on the Skin and Kidneys."

In spite of the label, I think it must certainly be considered a gross adulteration, as it is undoubtedly usually sold for spirits of nitre.

Mr. JOHN WHITE said that he had been told by a firm of wholesale druggists that such an article as this was actually prepared and put on the market, and since receiving that information he had always determined the total solids in samples of sweet spirit of nitre that he had to examine, but he had never met with any such sample as that referred to by Mr. Lowe.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Detection of Renovated Butter. C. B. Cochran. (*Journ. Franklin. Instit.*, 1899, cxlvii., 94-97.)—Renovated or "process" butter is prepared from stale and unsaleable butter by melting out the fat, and either simply cooling it rapidly by means of ice, or (less frequently) mixing it with milk or butter-milk, and again churning it into butter.

In order to distinguish this product from fresh butter, the author recommends the following tests: (1) Microscopic examination of the sample by means of polarized light both with and without a selenite plate. (2) Valenta test. (3) Jean's modification of the valenta test. (4) Determination of free fatty acids. (5) Reichert value.

When examined under the microscope with polarized light with a selenite plate, fresh butter shows a uniformly coloured field in any position of the analyzer, whilst the field of renovated butter is mottled and of various colours. Without the selenite plate, renovated butter gives a dark field with white patches; pure butter, a uniformly dark field. This difference is due to the state of incipient crystallization of the rapidly-cooled fat. When fresh butter is melted and allowed to cool slowly, the appearance is quite distinct from that of renovated butter, the large crystalline masses being globular in form and showing a distinct cross by polarized light.

Old butter or butter which has been exposed to changes of temperature, sometimes has a similar appearance under the microscope to that of renovated butter; but although the author has obtained the variegated field with polarized light in the case of such butters, when using the selenite plate, he has never seen the white patches which renovated butter shows without the selenite plate. In his opinion, ordinary butter does not readily assume the same crystalline form as "process" butter. The crystalline structure of oleomargarine is much more pronounced than that of renovated butter.

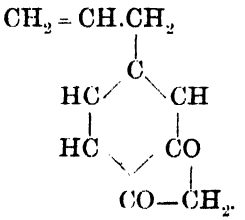
The turbidity temperature of renovated butter in the Valenta test is lower than that of fresh butter, and more acetic acid is dissolved by it in Jean's modification of the test. The percentage of free fatty acid is also usually high.

The following table gives the results of the examination of three samples of such butter and of a sample of fresh butter. Sample 4 was known to be renovated, and samples 2 and 3 judged to be so by the results of the analysis.

Sample.	Microscopic Appearance.	Valenta Test. Acetic Acid 98·7 per Cent.	Per Cent. of Acetic Acid dissolved.	N-Alkali required to neutralize 100 Grammes of Fat.
1. Fresh Butter	not crystalline	60° C.	70	1·1 c.c.
2. Renovated Butter	crystalline	48·5° C.	100	6·5 c.c.
3. ,, ,,	,,	50° C.	100	9·4 c.c.
4. ,, ,,	,,	49° C.	100	8·1 c.c.

The author also calls attention to the characteristic form in which butter crystallizes from amyl alcohol. This is quite distinct from the form of oleomargarine or lard crystals, and has enabled him in many cases to detect the presence of a small quantity of foreign fat in butter. C. A. M.

The Determination of Added Starch in Pressed Yeast. F. Dewalque. (*Bull. de l'Ass. belge*, 1898, xii., 264-269.)—The only method by which the author has been able to obtain good results is that of Maercker. Ten grammes of the yeast are mixed with 100 c.c. of water, and heated for twenty minutes at 60° to 70° C. The temperature is then brought to 60° C., ten c.c. of malt extract (prepared by extracting 100 grammes of green malt with 500 c.c. of water) added, and the temperature kept constant for half an hour. The saccharified liquid is brought to 250 c.c., filtered, 200 c.c. of the filtrate inverted with 15 c.c. of hydrochloric acid (specfic gravity 1·125), and diluted to 500 c.c. The reducing sugar in 25 c.c. of this is determined with Fehling's solution in the usual manner, and a correction made for the amount of copper reduced by the malt extract added.



The author prefers to calculate the quantity of starch on normal yeast, which, according to Hayduck, contains 74 per cent. of water, although he considers this estimate of the water too high. C. A. M.

Notes on Cazeneuve's Method of Detecting Artificial Colour in Wines. E. Comboni. (*Staz. Speriment. Agrar. Ital.*, 1898, xxxi., 490-498.)—Cazeneuve's method consists in shaking 10 c.c. of the wine with 20 centigrammes of yellow mercuric oxide and filtering, the filtrate being colourless (according to Cazeneuve) when the wine is pure. The author has made experiments with this test on different kinds of wine, from which he finds that this quantity of mercuric oxide is frequently insufficient to precipitate all the natural colouring matter, and that more certain results can be obtained by using 1·5 gramme to 10 c.c. of wine. But when the wine is of American origin or has been mixed with American wine the test is useless, and the colouring matter is not removed by the addition of as much as 8 grammes of the reagent to 10 c.c. It is preferable to use the mercuric oxide in the freshly precipitated moist condition, and to add it to the cold wine.

Treatment of the wine with amylic alcohol saturated with barium hydroxide also shows this difference between Italian and American wines, the filtrate from the former being colourless, while that from the latter is invariably rose-coloured. The author considers that the method of König and Arata (no reference given), in which

the wine is treated with fat-free wool, is the only certain test in dealing with American wine. C. A. M.

The Composition and Characteristics of Sassafras Oil. C. Kleber. (*Amer. Journ. Pharm.*, 1899, lxxi., 27-32.)—Commercial oil of sassafras is distilled exclusively from the sassafras roots, and chiefly from the bark of the root. At first it is nearly colourless, but on exposure to light and air gradually changes to yellow or brown. Its specific gravity lies between 1·07 and 1·08, and its optical rotation varies from +3° to +4°. On exposure to cold crystals of saffrol gradually deposit, and by repeated treatment in a freezing mixture about 80 per cent. of that substance can be isolated. Pure saffrol is an optically inactive colourless liquid, freezing at 8° C. and boiling at 232° C. Its formula is $C_{10}H_{10}O_2$, and it appears to be the methylene ester of an allyl catechol.

The parts of sassafras oil which remain liquid even in a freezing mixture can be separated by fractional distillation into a fraction boiling between 155° and 175°, and consisting chiefly of pinene, $C_{10}H_{16}$, with a small amount of another terpene, phellandrene, $C_{10}H_{16}$. The higher fractions contain about 0·5 per cent. of a substance which can be extracted by dilute alkali, and consists of eugenol $C_{10}H_{12}O_2$.

The fractions boiling about 200° C., yield, on cooling, colourless prisms of ordinary dextro-camphor, $C_{10}H_{16}O$, while the highest fractions contain a small quantity of a sesquiterpene $C_{15}H_{24}$ which, from its colour reactions, the author believes to be cadinene.

The percentage composition of oil of sassafras bark may thus be summarized: safrol, 80; pinene and phellandrene, 10; *d*-camphor, 6·8; eugenol, 0·5; cadinene (?); and residue, 2·7.

The resemblance between oil of sassafras and oil of camphor has led to manufacturers substituting the oily by-products of the manufacture of camphor for sassafras. According to the author, many of the commercial sassafras oils are fractions of Japanese camphor oil of the same gravity (1·07) as the natural oil. They are largely used, especially by soap manufacturers, on account of their lower price.

The oil of sassafras-leaves, which is not a commercial product, differs greatly from the root oil. The yield obtained by steam distillation amounts to about 0·028 per cent. of the weight of the fresh leaves. The oil when fresh is greenish yellow, and turns to reddish brown on keeping. Its specific gravity is 0·873, its optical rotation + 6·25, and it has an agreeable odour recalling that of oil of lemon and oil of citronella. It contains a considerable amount of citral, $C_{10}H_{16}O$, of geraniol, $C_{10}H_{18}O$, and of the isomeric linalol, the acetic and valerianic esters of the two latter alcohols,

and several terpenes, including pinene and phellandrene. In the highest boiling parts of the oil some cadinene also appears to be present, and a paraffin-like substance melting at 58° C. (*Cf.* ANALYST, xxiii., 212.) C. A. M.

Valuation of Phosphorated Oil. H. Ekroos. (*Arch Pharm.*, 1898, 627; through *Deutsche Chem. Zeit.*, 1899, xiv., 27.)—The author has unsuccessfully attempted to determine the proportion of elemental phosphorus in its solution in almond oil, which is known as *Oleum phosphoratum*. He tried treatment with bromine and iodine, followed by water, in order to obtain phosphoric acid; also the formation of silver phosphide by the aid of silver nitrate; also distillation of the phosphorus in carbon dioxide. None of the processes was accurate; and it would appear that, especially on keeping, the phosphorus enters into combination with the fatty acids of the oil, and is no longer amenable to ordinary analytical separations.

F. H. L.

The Colour-Reactions of Heroïne. G. Wesenberg. (*Journ. Pharm. Chim*, 1899, ix., 16-18.)—Heroïne is the diacetic ester of morphine—

$$C_{17}H_{17}\begin{matrix}OOC.CH_3\\OOC.CH_3\end{matrix}NO,$$

and is prescribed in place of codeïne phosphate. It is precipitated by the usual alkaloidal reagents, the most sensitive being iodine in potassium iodide, which causes a turbidity in a solution containing 1 part in 100,000. The author gives the following table of its colour-reactions in comparison with those of morphine and codeïne:

Reagent.	Morphine.	Codeïne.	Heroïne.
Concentrated H_2SO_4 ...	Nil	Nil	Nil
H_2SO_4 + 1 drop of HNO_3 ...	Blood-red	Blood-red	Yellow, becoming blood-red on warming
H_2SO_4 + 1 drop of ferric chloride in 100 c.c. On warming	Greenish-blue	Pure blue	Greenish-blue
Potassium ferricyanide + ferric chloride	Immediate blue precipitate	Nothing at first; blue coloration after some time	Like codeïne
Nitric acid	Blood-red, becoming yellow	Yellowish-red	Yellow, becoming red on warming
Iodic acid	Separation of iodine	Nil	Nil

ORGANIC ANALYSIS.

Estimation of Formaldehyde. O. Blank and H. Finkenbeiner. (*Ber.*, 1898, xxxi., 2979.)—The authors find that Legler's method of titrating formaldehyde with ammonia gives results some 1·5 per. cent. below other methods of estimation (*cf.* ANALYST, 1897, xxii., 221). The following process for oxidizing it to formic acid by means of hydrogen peroxide in the presence of an alkali is preferable and quite accurate: 3 grammes of the solution or 1 gramme of the solid are introduced into 25 c.c. of 2N sodium hydroxide solution contained in a tall flask; 50 c.c. of 2·5 or 3·0 per cent. pure hydrogen peroxide are then cautiously and slowly dropped in, the addition lasting about three minutes. After standing from two to three minutes longer, the alkali is titrated with 2N sulphuric acid and litmus. In the case of formalins stronger than 45 per cent. 30 c.c. of sodium hydroxide solution should be used; samples weaker than 30 per cent. should be allowed to stand ten minutes before titration. The volume of standard alkali used, multiplied by six, gives the formaldehyde in 1 gramme of the solid, or multiplied by two in 3 grammes of the solution.

A similar reaction occurs, but much more slowly, with benzaldehyde, especially in presence of a trace of ferrous sulphate; acetaldehyde is also oxidized, but it is doubtful whether the decomposition is complete. Paraldehyde is very slowly attacked, and even ferrous salts do not greatly quicken the action. F. H. L.

Note on Testing Formaldehyde. L. F. Kebler. (*Amer. Journ. Pharm.*, 1898, lxx., 432-433.)—In estimating the strength of a solution of formaldehyde by Legler's method (*Berichte*, xvi., 1333), in which the formaldehyde is shaken with a standard solution of ammonia and the uncombined ammonia distilled over and titrated with standard acid, the author finds that, as a rule, the reaction between the aldehyde and ammonia is rather slow, and that if they are left in contact for less than six hours, the results will probably be considerably too low. Thus, a commercial sample of formalin showed a strength of 16 per cent. when the ammonia was distilled after a fifteen minutes' reaction, but by increasing the time of contact the percentage gradually increased up to 37·5 per cent. after six hours. This result was also obtained when the mixed solutions were left overnight. The results obtained at different times under six hours were not constant in duplicate determinations of the same sample.

C. E. Smith, who was delegated by the Pharmacopœial Research Committee to investigate the efficiency of various methods proposed for the determination of formaldehyde, found that by making a suitable correction the strength could be estimated by leaving it for about fifteen minutes in contact with normal ammonia solution (*Amer. Journ. Pharm.*, lxx., 86). The author's explanation of Smith's obtaining such results is that the number of samples of formalin examined by him was too limited, and evidently not representative of the commercial article.

C. A. M.

A New Method of Detecting and Estimating Acetone. G. Denigès. (*Journ. Pharm. Chim.*, 1899, ix., 7-14.)—In a recent communication (*Comptes Rend.*,

1898, cxxvi., 1868) the author described certain insoluble or but slightly soluble compounds which mercuric sulphate forms with acetones of the fatty series. When dried at a temperature not exceeding 100° C. those compounds which are formed without secondary reactions have a composition corresponding to the formula $[(SO_4Hg)_2.3HgO]_3.4[CO.R_2]$.

The readiness with which ordinary acetone forms the insoluble compound, $[(SO_4Hg)_2.3HgO]_3 4[CO.(CH_3)_2]$, and the high molecular weight of that compound (3,952) as compared with that of the acetone which produced it (4×58), enable the formation of this substance to be used as a ready means of detecting and estimating traces of acetone.

The mercuric reagent required is prepared by dissolving 5 grammes of mercuric oxide in a hot mixture of 20 c.c. of sulphuric acid and 100 c.c. of water.

For the detection of acetone in aqueous solution, which should not contain more than 10 grammes per litre, 2 c.c. of the solution are mixed with 2 c.c. of the reagent and the tube immersed in a boiling-water bath, a turbidity or precipitate being formed within ten minutes. The lowest limit of the reaction is reached with a solution containing 2 centigrammes per litre, but the smallest traces can be detected by distilling the acetone solution and testing the first tenth of the distillate.

When the acetone is dissolved in methylic alcohol, 2 c.c. of the solution are mixed with 2 c.c. of water, and 4 c.c. of the mercuric reagent added, the dilution being necessary to prevent the precipitation of the mercuric sulphate on boiling the liquid. It is possible to detect 3 centigrammes per litre after the tube has been left for ten minutes in the boiling water.

In the case of solutions in ordinary alcohol, it is necessary to dilute so that the liquid to be tested does not contain more than 2 per cent of alcohol, since otherwise mercurous sulphate is precipitated on boiling. The limit of sensibility is thus less than with aqueous solutions, and may be taken as 1 gramme per litre.

In the quantitative determination of acetone by this method, 25 c.c. of the mercuric reagent are mixed with 25 c.c. of the acetone solution, care being taken that the amount of acetone present does not exceed 50 milligrammes and that the percentage of alcohol in methylic alcohol solutions is not more than 10 or that of ordinary alcohol solutions more than 1 per cent. The flask, with its stopper tied down, is immersed in boiling water for ten minutes. After cooling, the precipitate is collected on a weighed filter, washed with from 75 to 100 c.c. of cold water, dried at 100° C., and weighed. The weight of the precipitate, multiplied by 0·06 (the coefficient experimentally determined), gives the weight of acetone in the 25 c.c. of the solution examined.

The determination may also be made more rapidly by the author's volumetric method of estimating mercury (ANALYST, xxi., 303), the amount of that metal being determined after the precipitation, the amount precipitated being obtained from the difference between the quantity found and that originally present, and the acetone calculated from the result.

The liquid containing the precipitated acetone is diluted to 100 c.c. and filtered. Twenty c.c. of the filtrate are mixed with 15 c.c. of ammonium hydroxide, 50 to 60 c.c. of water, and 10 c.c. of a solution of potassium cyanide, equivalent to a

decinormal solution of silver nitrate. After the addition of a few drops of a solution of potassium iodide (1 : 5) the liquid is titrated with decinormal silver nitrate.

As it is necessary that the solution to be examined should not contain more than a certain amount of acetone, a preliminary approximate estimation of the quantity present may be made by observing the time required for a precipitate or turbidity to form when the mixed liquids are heated in boiling water. Two c.c. of the mercuric reagent and 2 c.c. of the acetone solution, diluted with 9 volumes of water, are mixed in a test-tube 16 to 18 cm. long and 18 mm. in diameter, which is kept in boiling water.

The time required for the appearance of turbidity in the liquid is shown in the following table :

Time.	Acetone Grammes per Litre.	Time.	Acetone Grammes per Litre.
60 seconds ...	10 grammes.	2½ minutes ...	0·20 grammes.
75 ,, ...	5 ,,	3 ,, ...	0·10 ,,
90 ,, ...	2 ,,	4 to 5 minutes ...	0·05 ,,
100 to 105 seconds	1 ,,	10 minutes ...	0·02 ,,
2 minutes ...	0·5 ,,		

C. A. M.

The Purity of Ether used as a Fat Solvent. T. Methner. (*Chem. Zeit.*, 1899, xxiii., 37.)—The *Verband landwirthschaftlicher Versuchsstationen* stipulates that the ether employed to estimate the proportion of fat in food-stuffs shall be free from alcohol and water. Even the purest ethers of commerce contain about 0·5 per cent. of alcohol; and this can only be removed entirely by repeated agitation with fresh clean sodium extended over several days. The author has prepared such ether, and has investigated the yields of fat from various materials in comparison with the same solvent mixed with known quantities (1 to 10 per cent.) of alcohol; also using ordinary ethers of the specific gravities 0·720 and 0·722. His results go to prove that extreme freedom from alcohol is not required; the fat increases slightly as the ether becomes more dilute; but in no case, save where the solvent was damp, did the error exceed 0·25 per cent. calculated on the sample, or 9 per cent. calculated on the fat itself, even when 10 per cent. of alcohol was present in the ether. Considering that food-stuffs do not contain a very large proportion of fat, and that they are not specially rich in substances soluble in alcohol, he holds that commercial ether (specific gravity, 0·720) suffices for all industrial analyses, provided it be thoroughly dried by means of powdered quicklime. F. H. L.

A Comparison of the Methods of Iodine Absorption in the Analysis of Fats. J. J. A. Wijs. (*Chem. Rev. Fett. u. Harz. Ind.*, 1899, vi., 5-11.)—In a recent communication (ANALYST, xxiii., 238) the author showed that in the Hübl process the main reaction is an addition of hypoiodous acid to the fat. He has now made a comparative examination of Hübl's method, of Waller's method (ANALYST, xx., 280). and of his own recently described iodine chloride method (ANALYST, xxiii., 240).

He finds that in the Hübl process the absorption of iodine takes place with great rapidity in the first few moments, and but slowly afterwards. In addition to the length of time, the stage at which the blank determination is titrated has a

considerable influence on the result, as is shown in the following table of iodine values obtained with a freshly prepared solution:

Time of Absorption.	Earthnut Oil. Blank Determination.		Linseed Oil. Blank Determination.	
	Before Absorption.	After Absorption.	Before Absorption.	After Absorption.
2 hours ...	87·02	—	173·74	—
7 ,, ...	88·23	85·38	177·65	170·39
24 ,, ...	90·21	82·32	181·89	163·16

In the author's opinion the results obtained by titrating the blank before the absorption are probably the more correct. For the decrease in the amount of thiosulphate required by Hübl's solution on keeping depends on the oxidation of the alcohol by the hypoiodous acid, and thus on the concentration of that acid. When a fat is present this concentration is somewhat reduced by the addition of part of the hypoiodous acid to the fat, but chiefly by the splitting off of acid (HCl) from the addition compound. Practically the whole of the changes brought about by these reactions occur in the first few moments of the absorption, and thus the oxidation of alcohol by hypoiodous acid in the presence of the fat is very much less than in the blank determination.

With regard to the time allowed for the absorption, the author prefers the iodine value obtained after seven hours, since he finds that the rapidity with which the iodine disappears (as shown by titration) reaches its lowest limit after that time, and then commences to rise again.

With a Hübl solution, five days old, it was found that the absorption occurred more rapidly during the first few moments than was the case with the fresh solution, but that the rapidity of the disappearance of iodine (*i.e.*, I + ICl + HIO) did not reach its lowest limit until after twenty-four hours. The iodine values obtained for the same linseed oil as before with this solution were:

Time of Absorption.	Blank Determination.	
	Before Absorption.	After Absorption.
2 hours	163·82	—
7 ,, ...	172·20	169·00
24 ,, ...	177·60	167·03

In this case the author regards the value 177·60 as the most probable.

Similar determinations were made with Waller's solution. Here it was found that the rapidity of disappearance of iodine (I + ICl + HIO) was considerably less, reaching its lowest point in the case of earthnut oil after twenty-four hours, and with linseed oil only after forty-eight hours. The iodine values thus obtained with the same oils were:

Time of Absorption.	Earthnut Oil. Blank Determination.		Linseed Oil. Blank Determination.	
	Before Absorption.	After Absorption.	Before Absorption.	After Absorption.
24 hours ...	86·98	86·85	170·67	170·11
48 ,, ...	—	—	171·45	170·37

With a strongly acid solution, like that of Waller, the splitting off of hydrochloric acid from the addition compound does not take place, or at most does so to

a trifling extent. Hence the concentration of the hypoiodous acid in the solution remains about the same throughout the absorption, and the author therefore considers the iodine values obtained when the blank is titrated after the absorption as probably the more correct, although the difference is small. As the results obtained by Waller's method are usually somewhat lower than the Hübl value, it is possible that the absorption is not quite complete, even after the twenty-four and forty-eight hours given in the above experiments. The statement frequently made, that the values given by the Waller solution are higher than those of the Hübl process, is to be attributed to the blank determination having been titrated at the end of the absorption.

With the author's solution of iodine chloride in glacial acetic acid (ANALYST, xxiii., 240) the experiments showed that the absorption was complete after fifteen minutes with earthnut oil and after an hour with linseed oil, the further absorption in each case being practically nil.

The following table gives the amount of iodine absorbed by the oils in one minute and its percentage of the actual iodine value in the case of the different solutions :

	Earthnut Oil.		Linseed Oil.	
	I. Absorbed after 1 Minute.	Per cent. of Iodine Value.	I. Absorbed in 1 Minute.	Per cent. of Iodine Value.
Iodine chloride in acetic acid	86·91	98·9	174·07	98·1
Hübl solution, 16 hours old	82·54	93·9	152·46	85·9
,, ,, 5 days old ...	—	—	128·90	72·6
Waller's solution	73·52	83·6	102·64	57·8

The different final values obtained in the experiments described above are thus summarized :

Solution.	Earthnut Oil.			Linseed Oil.		
	Minimum.	Maximum.	Most Probable Value.	Minimum.	Maximum.	Most Probable Value.
Hübl solution, 16 hours old	82·32	90·21	88·23	163·16	181·89	177·65
Hübl solution, 5 days old ...	—	—	—	163·82	177·60	177·60
Waller's solution	86·85	86·98	86·85	170·11	171·45	170·35
Iodine chloride in glacial acetic acid	—	—	87·93	—	—	177·37

In order to determine to what extent the iodine value serves as a measure of the compounds with two unsaturated bonds which occur in fats, the iodine values of a number of unsaturated fatty acids were determined by means of the iodine chloride solution with the following results :

	Melting-point, °C.	Acid Value.		Iodine Value.	
		Calculated.	Found.	Calculated.	Found.
Erucic acid ...	32	165·7	165·2	75·15	74·9
Brassidic acid ...	60	165·7	165·0	75·15	75·0
Elaidic acid ...	44	198·6	198·4	90·07	90·0
Oleic acid* ...	—	198·6	184·3	90·07	87·6
Undecylic acid...	—	304·3	292·9	136·6	133·1

* Bought as free from linolic acid.

The Heat of Bromination Test for Oils. A. H. Gill and J. Hatch. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 27-29.)—In order to render the results obtained with different calorimeters comparable, the authors propose to refer the rises in temperature to a standard, as in the Maumené test. They find that sublimed camphor can be obtained in a sufficient state of purity to serve as the standard material. The rise of temperature on brominating the camphor is determined in the apparatus and by the method chosen, and the rises in temperature of the various oils are divided by this number, thus giving a "specific temperature reaction."

The following results were thus obtained by a method which was substantially the same as the modification proposed by Wiley (ANALYST, xxi., 210). The factor 17·18 was obtained by dividing several of the Hübl values by this specific temperature.

Oil.	Specific Temperature Reaction.	Iodine Value.	
		Calculated.	Determined (Hübl).
Neat's-foot	3·286	56·5	59·1
Tallow	3·348	57·4	57·2
Prime lard	3·715	63·8	63·8
Sperm	4·191	72·1	73·2
No. 1 lard	4·096	70·3	73·9
Olive	4·762	81·8	82·0
Cotton-seed	5·667	97·3	103·0
Corn	6·381	109·5	107·8
Cod	8·002	137·4	135·0
Linseed	9·049	155·6	160·0

C. A. M.

The Analytical Constants of American Linseed Oil. A. H. Gill and A. C. Lamb. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 29, 30.)—The following results were obtained by the authors with samples of linseed oil representative of all the principal brands in the market. In applying the Maumené test the oil was mixed with a heavy petroleum and allowed to stand for an hour or two before adding the sulphuric acid, a correction being made for the addition. All the results are stated to be the mean of two closely agreeing determinations.

Brand.	Specific Gravity at 15° C.	Valenta Test, °C.	Maumené Test, °C.	Iodine absorbed in 4 hours. Per cent.	Iodine absorbed in 18 hours. Per cent.	Drying Test. Hours required.
Western raw... ...	0·933	79	97	174·7	180	72
,, ,, ...	0·932	70	90	169·7	180	72
,, ,, special	0·934	73	105	178·0	178	72

Usual constants ...	0·931—0·937	57—74	103—126	—	170—188	
Average	0·934	—	111	—	176	

It is pointed out that these results differ from the usually accepted values in the Maumené figure being about 10 per cent. higher and the iodine value about 4 per cent. lower. Menhaden oil was examined because it is frequently used to adulterate linseed oil. C. A. M.

The Detection and Estimation of Earthnut Oil in other Oils. J. Bellier. (*Ann. de Chim. anal.*, 1899, iv., 4-9.)—One c.c. of the oil under examination is saponified in a tube with 5 c.c. of an alcoholic solution containing about 85 grammes of potassium hydroxide per litre. 1·5 c.c. of dilute acetic acid, exactly neutralizing the 5 c.c. of the alkali, is then added, and the whole well shaken. The solution of potassium acetate and fatty acids in 70 per cent. alcohol is now cooled rapidly by shaking the tube in water having a temperature below 20° C. Owing to the presence of the potassium acetate the arachidic acid and other solid fatty acids are precipitated in a very short time. When the precipitate ceases to increase, 50 c.c. of 70 per cent. alcohol containing 1 per cent. by volume of hydrochloric acid are added, the tube shaken and placed in water at 17° to 19° C. When the oil contains more than 10 per cent. of earthnut oil, the alcohol leaves a more or less abundant precipitate of arachidic acid. If the quantity is less than 10 per cent., the liquid in the tube remains clear, or nearly so, at first, but after being left for thirty minutes in the water a cloudiness, which masks the bottom of the tube, can be observed. With pure oils, the liquid remains perfectly transparent throughout the whole time.

In this test, the majority of olive oils give a solution which remains absolutely clear even below 16° C. But with certain rare specimens of Tunis olive oil which contain a large amount of solid fatty acids, with cotton-seed oil, and with sesame oil, the liquid may be turbid after the addition of the 70 per cent. alcohol. To distinguish these oils from earthnut oil the temperature is slowly raised until the liquid just becomes clear, and the tube is then placed in water at 17° to 19° C. After thirty minutes, olive, cotton-seed, or sesame oils remain transparent, while in the case of earthnut oil the turbidity is reproduced. The author states that no mistake is possible with an oil containing more than 5 or 6 per cent. of earthnut oil.

For the quantitative determination of earthnut oil, 5 grammes of the oil are saponified with 25 c.c. of the alcoholic potassium hydroxide solution and a volume of dilute acetic acid, exactly neutralizing the alkali taken, is added. The liquid is then rapidly cooled by immersing the vessel in water. After an hour the precipitate is collected on a filter, washed with 70 per cent. alcohol containing 1 per cent. of hydrochloric acid, the temperature being maintained between 15° and 20° C., and the washing continued until the filtrate does not become perceptibly turbid on the addition of water.

The precipitate, which contains other acids besides arachidic acid, is dissolved off the filter with 25 to 50 c.c. of boiling alcohol (92 to 93 per cent.). From 8 to 16 c.c. of water are added to the solution in order to reduce the strength of the alcohol to about 70 per cent., and the liquid is then cooled for an hour in water at a temperature below 20° C. The arachidic acid which precipitates is collected on a dried and weighed filter, washed with 70 per cent. alcohol (free from hydrochloric acid) until

the filtrate remains clear on the addition of water, dried at 100° C. and weighed. The melting-point of the acid thus obtained is usually about 72° C.

From the weight of the acid obtained from pure Bordeaux earthnut oil (0·21 gramme), the coefficient of the oil is $\frac{100}{0{\cdot}21 \times 20} = 23{\cdot}81$. This figure is higher than Renard's coefficient (22). The author considers that this method is capable of rapidly estimating earthnut oil when present in greater proportion than 2 per cent. Of all the oils (other than earthnut oil) examined, only one (Tunis olive oil) gave a precipitate corresponding to about 1·5 per cent. of earthnut oil, as is shown in the following table:

Oil.	Fatty Acid. Per cent. Gramme.	Corresponding to Earthnut oil. Per cent.	Oil.	Fatty Acid. Per cent. Gramme.	Corresponding to Earthnut oil. Per cent.
Bordeaux Earthnut oil	4·20	100·00	Olive oil, Tunis (Sousse)	0·020	0·48
Marseilles ,, ,,	4·17	99·28	,, ,, ,, (Sfax)	0·010	0·24
Olive oil +5% Earthnut oil	0·21	5·00		0·060	1·44
,, ,, +10% ,, ,,	0·42	10·00	African	0·010	0·24
,, ,, +20% ,, ,,	0·84	20·00		0·040	0·95
Olive oil (Nice)	0·030	0·71	Cotton-seed oil (purified)	0·030	0·72
,, ,, ,,	0·030	0·71	Sesame oil (Jaffa)	0·020	0·48
,, ,, ,, (superfine)	0·040	0·95			

The following specimens of olive oil gave only a slight turbidity: Calabrian, Nice superfine, Tunis (Sousse), St. Denis, and Algerian. With olive oils of the following origin the liquid remained perfectly clear: Var olive oil (recent), Var (old), Corsican, Spanish, Italian, Italian (Bari), Nice (fine and superfine) and a sample of unknown origin. C. A. M.

A Method of Separating Citronellal and Citral. **J. Flateau and H. Labbé.** (*Bull. Soc. Chim.*, 1898, xix., 1012-1013.)—The aldehydes citral or geranial ($C_{10}H_{16}O$) and citronellal ($C_{10}H_{18}O$) are found together in the different essential oils of andropogon and in oil of lemon-grass. They can be prepared by the oxidation of their corresponding alcohols, but the yield is small, and in manufacturing processes they are invariably obtained from the essential oils in the form of their bisulphite compounds, and freed more or less completely from other substances by pressure.

The only method of differentiating the two aldehydes hitherto known is that of Doebner, which consists in converting them into the respective citryl- and citronnellyl-β-naphtho-cinchonic acids, which have different melting points, but according to the authors this is only applicable to qualitative work, and cannot be used as a practical means of separation. They have found that on treating an aqueous solution of the bisulphite compounds (prepared by treating the aldehydes for two or three hours with a solution of sodium bisulphite containing a third of its volume of ether, while the temperature is kept low) with a solution of barium chloride, the citryl sulphite

remains in solution, while the citronellyl sulphite is precipitated quantitatively as a barium salt with the composition $C_{20}H_{38}O_8S_2Ba$.

This salt is insoluble in hot alcohol, ether, benzene, and petroleum spirit. It does not dissolve in cold water, but is partially decomposed in boiling water. The citronellal can be recovered by saponifying the salt with a 10 per cent. alcoholic solution of potassium hydroxide, removing the insoluble barium salt by filtration, passing a current of carbon dioxide through the filtrate to remove the excess of alkali, filtering again, precipitating the aldehyde by water, washing it, extracting it with ether, and purifying it by fractional distillation.

By this process the authors found from 5 to 6 per cent. of citronellal in various oils of lemon-grass. The whole of the citral (which is employed commercially as the crude material in the manufacture of ionone) could be recovered from the filtrate from the barium precipitation. C. A. M.

The Characteristics of Essence of Neroli and Essence of Petit-grain. E. Charabot and L. Pillet. (*Bull. Soc. Chim.*, 1898, xix., 853-857.)—The essential oil of petit-grain contains limonene, $C_{10}H_{16}$; linalol, $C_{10}H_{17}OH$ (in the free state and as an acetic ester), a terpene, $C_{15}H_{24}$; and, according to Passy (*Bull. Soc. Chim.*, xvii., 519), geraniol, geranyl acetate, and other oxygenated substances.

According to Tiemann and Semmler (*Berichte*, xxvi., 271) essence of neroli contains about 20 per cent. of limonene, 30 per cent. of lævo-rotatory linalol, and 40 per cent. of linalol acetate. The saponification value given by Schimmel and Co. is 38, but the authors point out that this does not agree with the percentage of ester found by Tiemann and Semmler.

As petit-grain is the oil most frequently employed for the adulteration of oil of neroli, the authors have examined a number of authentic samples which they had themselves distilled. They find that the specific gravity of neroli varies from 0·8720 to 0·8760 at 15° C., and that of petit-grain from 0·8910 to 0·8940.

Other characteristics of the two oils are shown in the subjoined table:

Oil of Neroli.	Rotatory power at 15° C.	Refractive index n_D	Solubility in 80 per cent. alcohol at 20° C.	Essence of Petit-grain.	Rotatory power at 15° C.	Solubility in 80 per cent. alcohol.
	+3·12	1·474 at 18°	2 in 3·1	1	−5·54	2 in 2
2	+3·57	1·475 ,, 18°	2 ,, 2·9	2	−5·12	2 ,, 2·0
3	+2·15	1·473 ,, 20°	2 ,, 2·6	3	−6·15	2 ,, 2·1
4	+3·18	1·473 ,, 20°	2 ,, 2·9	4	−5·57	2 ,, 2·2
5	+4·03	1·473 ,, 20·5°	2 ,, 2·9	5	−5·33	2 ,, 2·1
6	+3·42	1·473 ,, 20°	2 ,, 3·1	6	−4·45	2 ,, 2·1
7	+1·42	1·470 ,, 21°	2 ,, 2·6	7	−6·00	2 ,, 2·1
8	+3·54	1·472 ,, 20°	2 ,, 2·7	8	−5·45	2 ,, 2·2
9	+4·06	1·474 ,, 19·5°	insoluble			

The rotatory power which, contrary to what might be expected from Tiemann and Semmler's researches, is dextro-rotatory, can thus afford a valuable indication of the purity of neroli oil, the dextro-rotation being increased by an addition of oil of

lemon, orange, or bergamot, and reduced by essence of petit-grain. The solubility in alcohol increases with the age of the oil. The insoluble sample (9) was a mixture of different specimens distilled in 1897. A further difference between the two oils is that neroli contains a large proportion of a dextro-rotatory fraction distilling at about 179° C., whereas in the first distillation of petit-grain no fraction is obtained near that temperature.

For a determination of the esters, from 2 to 3 grammes of the oils were heated on the water-bath for thirty minutes with semi-normal alcoholic potassium hydroxide, the residual alkali titrated, and the amount corresponding to the esters expressed as linalol acetate, $C_{10}H_{17}OCO.CH_3$. The following results were thus obtained:

PERCENTAGE OF ESTERS AS LINALOL ACETATE.

No. of sample	1.	2.	3.	4.	5.	6.	7.	8.	9.
Essence of neroli	14·4	10·1	18·0	16·8	13·4	15·1	16·7	12·1	14·5
Essence of petit-grain	54·9	55·9	60·7	59·2	69·6	51·5	61·1	63·7	—

Oil of bergamot contains about 38 per cent. of esters, and an addition of it to neroli would also be shown by the increase in the quantity thus determined.

Since both the oils lost their odour on saponification and acquired that of linalol, the authors consider that their characteristic perfumes are due to the different natures of the esters, the alcoholic constituents of each being apparently identical.

C. A. M.

The Composition of Oil of Thyme. H. Labbé. (*Bull. Soc. Chim.*, 1898, xix., 1009-1011.)—On treating 500 grammes of essential oil of thyme with aqueous solution of potassium hydroxide, the author obtained 160 grammes of thymol. The substances insoluble in the above solution were washed, dried, and fractionally distilled, the following fractions being obtained: Between 155° and 158° C., about 83 grammes; 165°-169°, about 67 grammes; 174°-177° about 70 grammes; 180°-184°, about 30 grammes; 195°-200°, about 15 grammes; 200°-215°, about 28 grammes.

The portion distilling between 155° and 158° was a hydrocarbon, which from the melting-point of its nitroso-chloride (106·5°) was proved to be distinct from pinene, the presence of which was noted by Schimmel and Co. in thyme oil.

The second fraction (165°-169°) had the same boiling-point as menthene, with which substance it was identified by the melting-point of its nitroso-chloride (113°-113·5°), and by the fact that on oxidation with permanganate it yielded cymene.

The fraction which distilled over between 174° and 177° had the characteristic odour of cymene, and like that substance yielded terephthalic acid on oxidation. The fourth fraction (180°-184° C.) also had the odour of cymene, and yielded the same oxidation products. Hence, the author considered it probable that the third and fourth fractions consisted of a mixture of different cymenes boiling at from 174°-184° C.

The next fraction (195°-200°) was identified as linalol by its odour, and by being converted into geraniol on heating in a sealed tube at 150° C. with an equal volume of acetic anhydride.

In the fraction boiling between 200° and 215° C. borneol was identified by Schimmel and Co's. method of oxidizing it to camphor by means of bichromate. The nature of the residue was not determined.

From the results of his determinations the author gives the following as the percentage composition of oil of thyme: Thymol, 30; hydrocarbon (156°-158°), 17; menthene, 15; cymene, 21; linalol, 5; borneol, 8; residue, 4.

He points out that the valuation of the oil should not, as is customary, be based solely on the proportion of phenols which it contains, since the other compounds, such as linalol and borneol, have also pronounced odours, which contribute to and modify the perfume of the essential oil. C. A. M.

On the Estimation of Glucose. Maquenne. (*Bull. Soc. Chim.*, 1898, xix. 926.)—The author simplifies Lehmann's method of determining glucose by titrating the unreduced copper, and by having a large excess of sulphuric acid in the liquid which obviates the filtration. Ten c.c. of Fehling's solution (Pasteur's formula) are mixed with a quantity of the glucose solution containing less than 50 milligrammes, and water added so that the total volume of the liquid is exactly 30 c.c. The whole is then rapidly heated, boiled for two minutes, cooled, and after the addition of 20 c.c. of dilute sulphuric acid (1 : 1) and 10 c.c. of a 10 per cent. solution of potassium iodide, titrated with 2 per cent. thiosulphate, using starch as indicator.

The difference between the number of c.c. required by the original Fehling's solution and by the liquid after titration gives the amount corresponding to the glucose.

The following table gives the volume of the thiosulphate solution corresponding to known quantities of saccharose inverted by the ordinary method.

Sugar, milligrammes.		Thiosulphate, c.c.	Sugar, milligrammes.		Thiosulphate, c.c.
2·5	...	0·90	30	...	10·95
5	...	1·80	35	...	12·70
10	...	3·75	40	...	14·45
15	...	5·65	45	...	16·15
20	...	7·45	50	...	17·80
25	...	9·20			

C. A. M.

Test for Albumin in Urine. W. C. Alpers. (*Amer. Journ. Pharm.*, 1898, lxx. 449-451.)—The test for albumin consists in acidifying the urine with hydrochloric acid, and adding an equal volume of a 1 per cent. solution of mercury succinimide. In the presence of as little as 1 part of albumin in 150,000, a white cloudiness is obtained. C. A. M.

The Influence of Food Preservatives on Digestive Enzymes. H. Leffmann. (*Journ. Franklin Instit.*, 1899, cxlvii., 97-108.)—The enzymes used in the author's experiments, which had reference principally to the digestion of starch, were: Malt diastase (Merck); pancreatic extract (Parke, Davis and Co.); peptenzyme, a preparation containing all the digestive ferments of the alimentary tract (Read and Carnick);

and papaïn, the enzyme of papaw sold under the name of "caroid." In each experiment 50 c.c. of a freshly-prepared solution of arrowroot-starch (10 grammes per litre) were used.

The following results were obtained in a series of experiments with taka-diastase 11 milligrammes of the enzyme and 50 milligrammes of the preservatives being used in each case, and the solutions diluted to 150 c.c. after the digestion:

1. Salicylic Acid: Showed starch reaction strongly, and only traces of sugar; 133 c.c. of the solution did not reduce 10 c.c. of copper solution (equivalent to 0·046 gramme of dextrose).

2. Sodium Benzoate: No starch present; much sugar formed.

3. Saccharin: Much starch present; traces of sugar.

4. Boric Acid: No starch present; much sugar formed.

With pancreatic extract solution the results were:

	Milligrammes.	Pancreatic Solution, c.c.	
Salicylic acid... ...	50	1	No sugar formed.
Sodium benzoate ...	50	1	Much sugar formed.
Saccharin	50	1	No sugar formed.
Boric acid	50	1	Much sugar formed.
Salicylic acid... ...	50	3	No sugar formed.
Sodium benzoate ...	50	3	Much sugar formed.
Saccharin	50	3	Trace of sugar formed.
Boric acid	50	3	Much sugar formed.

Saccha[illegible] in small quantities (10 milligrammes) interfered with the digestion of starch b[illegible] taka-diastase (10 milligrammes), by papaïn (20 milligrammes), and to a lesser extent by peptenzyme. Formalin (3 c.c.) did not affect taka-diastase (11 milligrammes), but 1 c.c. had an injurious effect on pancreatic extract (1 c.c.).

From the results of these and similar experiments which are given in tabular form, the author has arrived at the following general conclusions: Beta-naphthol is injurious to malt diastase, but does not seriously affect the starch-converting capacity of the taka-diastase or pancreatic extract. Boric acid, borax and boroglyceride, interfere but little with either starch or proteid digestion. Salicylic acid interferes with the action of most of the enzymes, especially those that convert starch, but does not seriously affect proteid digestion. Sodium benzoate has no appreciably injurious influence on any of the enzymes. Sodium fluoride interferes but little with the digestion of starch, but sodium silicofluoride has a considerable influence on pancreatic extract.

In the author's opinion, if the use of any preservative is to be permitted in food, boric acid and sodium benzoate are the least objectionable, since they appear to have less tendency to disturb the digestive functions than the other preservatives commonly employed. C. A. M.

Estimation of Humus in Soil. C. Aschmann and H. Faber. (*Chem. Zeit.*, 1899, xxiii., 61.)—This process depends on dissolving the humic acid in alkali, and titrating the liquid with permanganate. Solutions required: Sodium hydroxide

50 grammes per litre; permanganate, 0·32 gramme of the potassium salt per litre; oxalic acid, 0·63 gramme per litre; 1 : 5 sulphuric acid. To standardize the reagent, the strength of the oxalic acid must first be ascertained in terms of the permanganate. 0·125 gramme of pure humic acid (Merck) is dissolved in 500 c.c. of water with the aid of sodium hydroxide. To 5 c.c. of the solution and 100 c.c. of water permanganate is added until the colour remains constant; after five minutes 10 c.c. of oxalic acid are added, and the end-point of the reaction is determined in the usual manner by titrating the excess with permanganate. In carrying out the actual analysis, 25 grammes of air-dried, finely sieved earth are heated for an hour on the water-bath with 100 c.c. of the sodium hydroxide solution. The solution is removed by decantation and the insoluble matter treated similarly several times. The liquid is finally diluted to 510 c.c. (allowing 10 c.c. for the deposit), and after standing some days to clarify (filtration is to be avoided), is ready for titration, 5 c.c. being manipulated exactly as above. In order to obtain accurate results, the proportion of humic acid present in the extract should not greatly exceed that employed during the standardization of the permanganate, a point which can be settled by comparison of their respective colours, and adjustment of the volume of the solution obtained from the soil.

As examples of the amount of humic acid in various soils, the following may be quoted:

	Per cent.
Good garden mould	1·87
Highly manured hotbed	5·5—11·5
Forest earth, upper layer	0·88
,, ,, subsoil	0·3
Soil from tan-pit, upper layer	1·25
,, ,, under ground	0·44
Field earth, extremes	0·05—1·7
,, ,, average	0·5—0·7

F. H. L.

Combustion of Mixed Gases containing Carbon Monoxide, Methane, and Hydrogen. L. M. Dennis and C. G. Hopkins. (*Zeits. anorg. Chem.*, 1899, xix., 179.)—The authors remark that there are objections to all processes for the analysis of gaseous mixtures which depend on absorption of hydrogen with palladium or of carbon monoxide with cuprous chloride; and they fall back on the old explosion methods, so modified by the aid of suitable apparatus as to avoid liability to excessive pressure, which may cause the formation of oxides of nitrogen, if not actual danger to the operator. The apparatus which they have adopted resembles that of Winkler, and is shown in the accompanying illustrations. The rubber cork *a* (Fig. 1) carries a glass tube *b* open at both ends, in which a copper wire *c*, 3 mm. thick, is held air-tight by a rubber ring. The second copper wire, 1·5 mm. in diameter, is pushed through the cork and twisted round the glass tube till it reaches the top of *c*; and a platinum spiral *d*, of twenty or thirty coils, 2 mm. in diameter, made of wire 0·25 mm. thick, the ends of which are wrapped round the copper conductors, forms the source of heat. The general arrangement of the apparatus is

explained by Fig. 2: *o*, *o* are clips; *k* is a screw clamp. The measuring vessel is an ordinary Hempel burette fitted with a water-jacket. *F* is a means of varying the resistance, so that *d* may be kept at the desired temperature. The sealing liquid is mercury which bears a drop of water on its surface to insure perfect saturation. The volume of gas operated on is selected so that neither it, nor the necessary oxygen, nor the residue after explosion, shall exceed 100 c.c. The pipette is filled with mercury by opening *g* and raising the reservoir, then closing *g* and applying a vacuum pump to *t* till the air in *b* is extracted. A measured quantity of the sample is introduced, and a known excess of oxygen brought into the burette, which are both kept at about atmospheric pressure. *k* is closed, the burette-reservoir is raised to such a position that the mercury shall eventually fill the burette entirely without passing over into the pipette. Electrical connections are then made, the spiral heated to redness, *o*, *o* are opened, and *k* is cautiously unscrewed till the oxygen flows into the pipette at about 10 or 20 c.c. per minute. The exact speed is chosen so that the spiral remains incandescent, and it needs to be increased in inverse proportion to the molecular weight of the material examined. The combustion proceeds quietly without flame or explosion; but if pure hydrogen be under treatment, it is necessary, owing to the excessive contraction, to employ a mixture of oxygen and air, and also to diminish the force of the current as the operation proceeds, lest the platinum melt in the final atmosphere of oxygen and nitrogen.

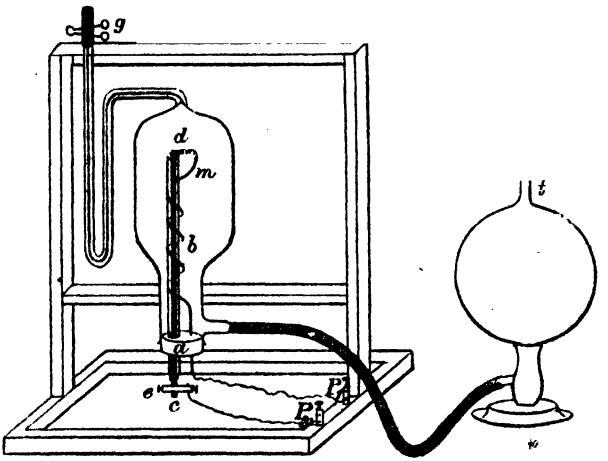

FIGURE 1.

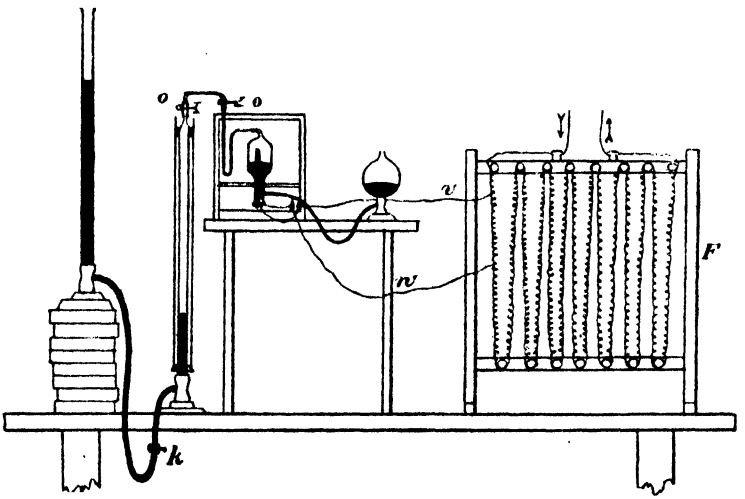

FIGURE 2.

Mixtures of hydrogen, methane, and nitrogen were prepared from ordinary coal-gas by absorbing the heavy hydrocarbons in fuming sulphuric acid, the oxygen in alkaline pyrogallol, and the carbon monoxide by double treatment with cuprous chloride. A known volume (60 to 67 c.c.) of the gas was then burnt with a known amount of oxygen, the residual volume was noted, the carbon dioxide absorbed by potassium hydroxide, and the final residue measured. Five successive tests showed from 56·4 to 56·6 (mean 56·44) per cent. by volume of hydrogen, and 39·9 to 40·0 (mean 39·94) of methane; corresponding experiments with 12 c.c. in a Hempel pipette giving 55·85 of hydrogen and 41·10 methane. Mixtures of hydrogen, carbon monoxide, methane, and nitrogen similarly prepared yielded equally satisfactory results, the greatest variation from the average proportion of hydrogen being 0·37 per cent. when analysing a mixture containing 53·7 per cent.

In the latter case the process is carried out as follows: A measured volume of the gas is burnt with a measured excess of oxygen, the residue is driven over into the burette and measured, the carbon dioxide is removed by potassium hydroxide, and the volume again noted. A known amount of hydrogen is introduced into the pipette, the current is again started, and the remaining mixture of nitrogen and oxygen forced back gradually until all the gas is in the combustion pipette once more. From the amount of contraction which then occurs the excess of oxygen can be calculated, and the difference between this figure and the original quantity of oxygen employed gives the volume of oxygen actually used in the first combustion. By means of these data the composition of the gaseous mixture may be deduced thus: V = the original volume of the sample; K = the contraction during the (first) "explosion"; O = the volume of oxygen required to oxidize V; CO_2 = the volume of carbon dioxide already determined:

1. $H = K - O$.
2. $CO = \frac{4CO_2 + H - 2O}{3}$.
3. $CH_4 = CO_2 - CO$.
4. $N = V - (H + CO + CH_4)$, or,
5. $CO = CO_2 - CH_4$.
6. $CH_4 = \frac{2K - CO_2 - 3H}{3}$.

In the absence of nitrogen, these formulæ may be substituted:

7. $H = V - CO_2$.
8. $CO = \frac{CO_2 + 3V - 2K}{3}$.
9. $CH_4 = \frac{2CO_2 + 2K - 3V}{3}$.

F. H. L.

The Calculation of the Calorific Power of Coal from Analytical Data. D. De Paepe. (*Bull. de l'Ass. belge.*, 1898, xii., 279-302.)—The author has studied the various methods of calculating the calorific power of coal, comparing the results with actual calorimetric determinations. He has obtained good results by Mahler's formula (*Bull. de la Soc. d'encour. pour l'ind.*, 1892, vii., 358):

$$P = 8140C + [34{\cdot}500H - 3000(O+N)],$$

in which P represents the calorific power, and C, H, O and N the respective percentages of carbon, hydrogen, oxygen and nitrogen. This method, however, has the drawback that elementary analysis is too tedious and delicate for ordinary technical analytical work.

E. Goutal (*Rev. de Chim. ind.*, 1896, vii., 65) has proposed the following formula as being more readily applicable:

$$P = 8150C + \frac{AM}{100},$$

in which P represents the calorific power; C, the percentage of fixed carbon (= coke —ash); M, the percentage of volatile matter (= 100—[coke+water]); and A, a co-efficient which varies with the amount of volatile matter: viz., $A = 13{,}000$ for $M = 2$ to 15; $A = 10{,}000$ for $M = 15$ to 30; $A = 9{,}500$ for $M = 30$ to 35; and $A = 9{,}000$ for $M = 35$ to 40.

According to the author's experiments, the results obtained by the use of this formula agree well with those calculated by Mahler's formula, or actually determined, if the following values for A are substituted for those given by Goutal. Where M' is used to represent the amount of volatile matter calculated on the coal supposed to be deprived of its water and ash, $M' = \frac{100M}{(M+C)}$

$A = 14{,}000$ for $M' = 2$ to 12	$A = 9{,}400$ for $M' = 30$ to 35
$= 12{,}000$,, $= 12$ to 17	$= 8{,}000$,, $= 35$ to 38
$= 11{,}000$,, $= 17$ to 24	$= 7{,}900$,, $= 38$ to 40
$= 10{,}200$,, $= 24$ to 30	$= 7{,}600$,, $= 40$ to 50

The accuracy of the calculations with the modified formula is illustrated by a long series of tables, of which the following, giving its application to the analytical results of Noyes, McTaggart and Craver (ANALYST, xxi., 22), may be quoted.

Coal.	Calorific Power calculated by Goutal's modified formula.	Calorific Power determined with Hempel's calorimeter.	Difference.	Percentage Difference.
1. New Pitsburgh, A	6,288	6,175	+113	+1·85
2. New Pitsburgh, B	6,502	6,415	+87	+1·35
3. Lancaster	6,694	6,703	—7	—0·10
4. Brazil	6,721	6,846	—125	—1·90
5. Shelburn	6,492	6,532	—40	—0·60
6. Shop	5,823	5,806	+17	+0·30

C. A. M.

INORGANIC ANALYSIS.

Electrolytic Estimation of Tin in Tin Ores. E. D. Campbell and E. C. Champion. (*Journ. Amer. Chem. Soc.*, 1898, xx., 687-690.)—One gramme of the finely-powdered ore is treated with sodium carbonate and sulphur, in the usual manner. When cold the mass is dissolved in 40 to 50 c.c. of water, and filtered from the insoluble oxides and sulphides. The solution contains nearly all the tin in the form of sodium sulphostannate, and the small quantity left in the residue is fused as before and brought into solution. The united solutions are made weakly acid with hydrochloric acid, and the tin precipitated as tin sulphide. The liquid which contains the stannic sulphide in suspension is then boiled to expel the excess of hydrogen sulphide, and concentrated to about 75 to 80 c.c. Ten c.c. of hydrochloric acid (specific gravity 1·20) are added to the hot solution, and small quantities of sodium peroxide stirred in until the tin sulphide is completely converted into oxide and the solution has become clear. The liquid is boiled two or three minutes, filtered from the sulphur into a large platinum dish, and the residue washed with hot water. Ammonia is added to the solution until a permanent precipitate results, and then 50 c.c. of a 10 per cent. solution of ammonium oxalate, and the clear liquid is electrolyzed over night with a current of N D_{100} = 0·10 A and 4 V. When the tin has been completely precipitated the deposit is washed with water and alcohol and dried at 80 to 90° C., and the dish weighed.

The deposit is finally dissolved off the basin with dilute hydrochloric acid, and the weight of the washed and dried platinum basin determined. C. A. M.

Iodometric Estimation of Gold and Platinum. H. Peterson. (*Zeits. anorg. Chem.*, 1899, xix., 59.)—The De Haen process for the determination of copper (Fresenius, *Quant. Anal.*, i., 335), which depends on the addition of an excess of potassium iodide to a solution of copper free from any substances capable of decomposing the reagent, and titrating the liberated halogen by means of thiosulphate, is equally available in the case of gold and platinum. With the latter, the dark reddish-brown liquid produced when a strong solution of iodide in excess is mixed with the double platinic chloride should be treated with standard thiosulphate (without starch) till the colour changes to a pale lemon yellow; 1 atom of platinum corresponding to 2 molecules of thiosulphate. Gold is similarly treated in the presence of starch; but, as an intermediate reaction takes place between the aurous iodide and part of the reagent yielding the compound $NaAuS_2O_3$, 1 atom of gold corresponds to 3 of thiosulphate. Both methods should be useful where only small amounts of the respective metals have to be estimated; and in many instances cupellation of gold samples may thus be avoided. F. H. L.

Qualitative Separation of the Platinum Metals. F. Mylius and R. Dietz. (*Ber.*, 1898, xxxi., 3191.)—The following process is published as an appendix to an article on the characteristics and purity of the several platinum metals now met

with in commerce; it does not profess to give absolutely complete separations, but is the simplest that can be devised. The amount of material operated upon should contain about one gramme of the platinum metals; and beside gold and mercury, the common metals may be present in the neutral or acid solution as chlorides. Platinum alloys may be run down with lead, which converts iridium and ruthenium into an insoluble form, leaving the others soluble. The solution, mixed with nitric acid, is distilled in a retort and the vapours led into caustic soda. If the liquid becomes yellow, *osmium* may be present, and can be identified by the odour of its tetroxide on addition of hydrochloric acid, or by the production of its brown sulphide when the acid liquor is warmed with thiosulphate. The cold residue from the retort is extracted, three times if necessary, with a little ether. Should this become yellow, *gold* is indicated (chromic acid also gives a colour varying from yellow to blue, and ferric chloride may equally tint the ether), and may be tested for with ferrous sulphate, etc. The residual solution is treated with ammonium acetate, and boiled for several hours with formic acid under an inverted condenser in order to throw down the noble metals. The precipitate is filtered off, washed with acetate solution, dried and ignited in a porcelain boat in a stream of hydrogen. *Mercury* yields the well-known metallic sublimate. The residue is extracted with warm HCl (to remove traces of tin and other heavy metals not reduced by the formic acid), dried, mixed with common salt, heated as before to dull redness in a current of damp chlorine, and the product leached with water. Any insoluble matter must be repeatedly submitted to the same process; should any portion resist the chlorine, it must be further examined for iridium and ruthenium. To the aqueous solution from the ignition in chlorine, saturated ammonium chloride is added as long as a precipitate (B) falls, which should consist of Pt, Ir, and Ru; Rh and Pd remaining theoretically in solution (A). If dark in colour, (B) is dissolved in warm water, treated with hydroxylamine hydrochloride, cooled, and precipitated again with ammonium chloride. The deposit is recrystallized twice, if necessary, and identified as *platinum* under the microscope. The hydroxylamine converts the bichlorides of Ir and Ru into sesquichlorides; their solution is evaporated to dryness, ignited in hydrogen, and fused with nitre and potash in a silver crucible. The melt is attacked with water and separated by decantation into a blue-black residue (C) and a solution (D). (D) is saturated with chlorine, and distilled from a retort as long as the vapours are coloured into weak alcohol containing HCl. A yellowish-brown colour indicates *ruthenium*, which, volatilizing as tetroxide, now exists as chloride. Its presence may be corroborated by rendering the liquid ammoniacal and adding thiosulphate: a strong red-violet colour is produced. (C) is washed, dried, ignited with salt and chlorine, and taken up in water; *iridium* yields a dark-brown solution, from which ammonium chloride precipitates the double salt. (A) is slowly evaporated with excess of ammonia, and the residue crystallized from weak cold ammonia; any insoluble matter, consisting generally of Ru, is removed by filtration. *Rhodium* separates as yellowish crystals of $Rh(NH_3)_5Cl_3$, soluble in hot, strong sulphuric acid with a yellow colour. (It should be noted that ignition with salt and chlorine gives a pink aqueous extract, from which Rh is not thrown down by NH_4Cl in dilute solution, *cf.* A and B above.) The ammoniacal filtrate is acidified with strong HCl

when *palladium* falls as $Pd(NH_3)_2Cl_2$. It is purified by ignition in hydrogen, solution in nitric acid, evaporation, dissolution in water, and precipitation with mercuric cyanide. F. H. L.

Estimation of Manganese by means of Potassium Permanganate. F. W. Daw. (*Chemical News*, vol. lxxix. [2043], p. 25.)—To obviate the sources of error usually present—non-elimination of organic matter, excessive use of zinc oxide, and standardizing the reagent against iron instead of manganese—the author proposes the following method: 0·5 gramme of spiegel or ferro-manganese—together, in the latter case, with 0·4 gramme of pure iron wire—is dissolved in 30 c.c. of hydrochloric acid (the iron being oxidized with a little nitric acid), and 15 c.c. of 50 per cent. sulphuric acid added. After evaporation until a copious disengagement of acid fumes ensues, the sulphates are taken up with water and the solution made up to about 500 c.c. The acid is then partly neutralized with sodium carbonate, and the iron thrown down by a gradual addition of zinc oxide, a large excess being avoided. The whole is boiled up, and, without filtering, titrated with permanganate solution (10 grammes per litre, standardised against ferro-manganese of known composition).

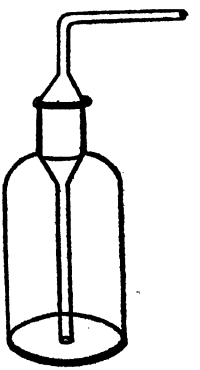
In estimating the manganese in the standard sample, the author precipitates with bromine and ammonia, and weighs as mangano-manganic oxide. Silica and metallic oxides are removed by dissolving in hydrochloric acid, adding ammonium acetate, and passing hydrogen sulphide, the weight of the resulting precipitate, after ignition, being deducted from the result of the first weighing. C. S.

Separation of Cerium from Lanthanum and "Didymium." P. Mengel. (*Zeits. anorg. Chem.*, 1899, xix., 67.)—The author has investigated the reactions of the cerium group of metals singly and in combination, studying their behaviour when ignited in the air, and using specially prepared and purified specimens of cerium salts or artificially made mixtures of cerium oxides with those of lanthanum and "didymium." He finds that of all the oxidizing agents hitherto proposed for the isolation of cerium, sodium peroxide is the most convenient; it is available in all cases, and gives the largest yields. When the various oxalates of this group of metals are strongly ignited together, the whole of the cerium is converted into dioxide. When a mixture of the oxides of lanthanum and didymium is heated to 400° or 500° C., it takes up oxygen and becomes brown in colour; at a white-heat the surplus oxygen is expelled, and the colour changes to gray. But if cerium be present simultaneously, this decolorization does not occur; for a definite brown compound of cerium dioxide and praseodymium peroxide (Pr_4O_7) is produced which is permanent at high temperatures. For this reason processes for the determination of cerium that depend on oxidation followed by ignition are incorrect, and only give approximate results when but little praseodymium occurs in the sample.

F. H. L.

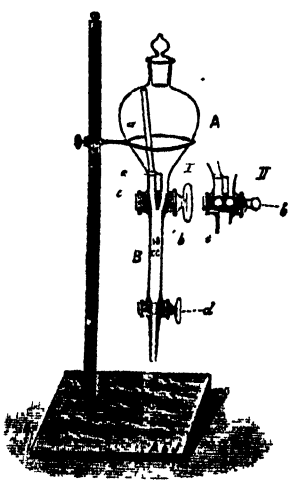
The Separation of Rubidium and Cæsium. A. Lemoine. (*Bull. de l'Ass. belge*, 1898, xii., 344-847.)—A usual method of separating these metals consists in

treating the mixed carbonates with absolute alcohol, which dissolves cæsium carbonate, leaving rubidium carbonate, which is nearly insoluble. Various methods have been proposed for converting the chlorides into carbonates, but the author finds the following the most simple and rapid: The residue of chlorides is warmed for some time on the water-bath, with frequent stirring, with an excess of silver carbonate suspended in water. The liquid is filtered, the precipitate washed with cold water, and the filtrate containing the rubidium and cæsium as carbonates evaporated to dryness and treated with alcohol in the usual manner.



C. A. M.

Copper as a Reagent for Polysulphides in Ammonium Sulphide. T. Chandelon. (*Bull. de l'Ass. belge*, 1898, xii., 277.)—On introducing a strip of bright copper into a solution of ammonium sulphide free from polysulphides, the metal remains bright for several days, whereas if only a minute quantity of a polysulphide be present it becomes black within a few hours. By means of this reaction the author has found that traces of polysulphides are formed when a dilute solution of ammonia is saturated with hydrogen sulphide. He has proved that the blackening of the copper is not due to any excess of hydrogen sulphide in the liquid, a saturated aqueous solution having no action on the metal, at least during the first hours of contact. C. A. M.



Copper as a Reagent for Tetrathionates in Sodium Thiosulphate. T. Chandelon. (*Bull. de l'Ass. belge*, 1898, xii., 277-279.)—On treating metallic copper with a solution of a tetrathionate there is an immediate abundant deposit of copper sulphide, with the formation (probably) of tri- or penta-thionate, or perhaps a mixture of the two. By means of this reaction it is possible to detect traces of tetrathionate in a solution of thiosulphate. From an 8 per cent. aqueous solution of sodium thiosulphate sold as "chemically pure" the author obtained a very adherent deposit on the copper within twenty-four hours. C. A. M.

APPARATUS.

Apparatus for the Employment of Sulphuretted Hydrogen. C. Graebe. (*Ber.*, 1898, xxxi., 2981.)—Attention is called to the advantages, both on the score of purity of the laboratory atmosphere and economy in raw material, accruing from the adoption of closed vessels for the treatment of liquids with this reagent. A convenient form of flask is shown in the annexed sketch; it is constructed of such dimensions that the solution only fills it about half-way. The supernatant air is driven out before the stopper is fully inserted, and then the gas simply passes into the vessel at the rate it is absorbed; the operation may thus be left over night, or can be hastened by periodical agitation. F. H. L.

Apparatus for Distillation in High Vacua. L. T. C. Schey. (*Chem. Zeit.*, 1899, xxiii., 61.)—This apparatus, illustrated in the accompanying sketch, is designed for distillations *in vacuo* with the aid of a water and mercury pump. As will be seen, it has only one rubber connection. The long-necked flask is charged through a tube funnel, and the opening is then sealed; at the end of the distillation a piece of rubber tubing is slipped over the point, which is broken to allow dry air to enter. The flask is heated in an air-bath, the temperature of which alone is noted. The receiver is cooled with an ice-jacket. When the distillate has been collected, the lower bulb is cut off or removed by fusion. By joining a fresh bulb in the same place, the whole apparatus is ready for use again, and can be employed as long as sufficient neck remains to the distilling flask. It is convenient to use two similar apparatus, one being at work while the other is mended and filled. F. H. L.

An Automatic Reservoir Pipette. H. Göckel (*Zeits. angew. Chem.*, 1899, 10.) The construction of this apparatus is shown by the annexed diagram. The stopcock *b* has two parallel holes, and also a groove *c* which serves for the admission of air when the pipette *B* is being emptied. Care must be taken that no liquid (or water when the pipette is washed) passes into *a* otherwise the pipette works quickly and accurately It is made in various sizes by Alt, Eberhardt, and Jager of Ilmenau. F. H. L.

THE ANALYST.

MAY, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, April 12, in the Chemical Society's Rooms, Burlington House, the President, Mr. W. W. Fisher, M.A., occupying the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of the following candidates were read for the second time: Julian L. Baker, F.I.C.; Herbert Edward Burgess; Louis Charles Deverell; Julius Lewkowitsch; F. R. O'Shaughnessy; Arthur Marshall; and Edward T. Shelbourn; and in favour of the following candidates for the first time: Edward Halliwell, F.I.C., Analyst to the West Riding of Yorkshire Rivers Board, Wakefield; Arthur John Starey, assistant to Mr. Lawrence Briant, London; and William Lincolne Sutton, F.I.C., Public Analyst for West Suffolk, East Suffolk, and the boroughs of Norwich, Ipswich, and Bury St. Edmunds.

The following were elected members of the Society: Percy T. Adams, Arthur French Angell, John B. Ashworth, Alfred Joseph Bull, Charles Crocker, John S. Ford, C. A. Hackman, Norman Leonard, J. F. Liverseege, Richard Murray, G. E. Scott-Smith, W. P. Skertchly, Harry Metcalfe Smith, Lionel W. Stansell, and W. Northfield Yarrow.

The PRESIDENT (Mr. Fisher) said that the Council had been considering the Sale of Food and Drugs Bill recently introduced in the House of Commons by Mr. Walter H. Long (President of the Board of Agriculture), the Solicitor-General, and Mr. T. W. Russell, and had thought it advisable to make some representation to the President of the Board of Agriculture, and to bring before him in a definite way the views of the Society of Public Analysts. In the forefront of the interview which Mr. Long had accorded to the representatives of the Council was placed the strong feeling which the Council held that there was a necessity for the establishment of what had been termed a Standing Departmental Committee or Court of Reference. The Bill provided that the Board of Agriculture should, after such inquiry as it might deem fit, issue regulations having relation to certain agricultural products. It was represented to Mr. Long, on behalf of the Council, that they would still desire to see a wider and more comprehensive body established, failing which it was suggested that the Local Government Board should have equal powers with the Board of Agriculture to confer with a strong scientific body in reference to other articles of food and to drugs. Mr. Long did not make any distinct promise on this matter, but it

might fairly be said that he received the Council's representation sympathetically. In addition to the provision which the Bill contained, that the Board of Agriculture should decide what proportions of extraneous matters were to be permitted in certain articles of food, the Council asked that the subject of preservatives should be definitely mentioned. A suggestion was made with the object of rendering clause 8, which dealt with the admixture of butter-fat with margarine, more clear and definite in meaning; and also that there should, if possible, be embodied in the Bill definitions of skimmed and separated milk in terms of the percentages of residual fat which they respectively contained. Other suggestions were offered by the Council respecting the effect of the time limit of twenty-eight days in proceedings against the giver of a warranty; the reference of samples to the Commissioners of Inland Revenue; the form of certificates; and the embodiment in the Bill of some definition by which the word "food" might be made to apply to articles which, although not themselves strictly of the nature of food, were used in the preparation or flavouring of food.

The following papers were read: "On a recent Ginger Case," by E. J. Bevan, Bernard Dyer, D.Sc., and Otto Hehner; "The Composition of Milk and Milk Products," "An Attempt to compute mathematically the most Probable Limits for Milk," and a "Note on the Estimation of Ether and Alcohol when mixed with Petroleum Ether and other Solvents," by H. Droop Richmond; "The Estimation of Fat in Milk, using Petroleum Ether as a Solvent," by H. Droop Richmond and C. H. Rosier; and "Notes on Milk Analysis, including the Molybdate Test for Cane Sugar," by L. de Koningh.

Mr. W. P. Skertchly exhibited a new form of distilling flask for use in water analysis.

A METHOD FOR THE QUANTITATIVE SEPARATION OF ISOVALERIC AND ACETIC ACIDS.

By Alfred C. Chapman, F.I.C.

(*Read at the Meeting on November* 2, 1898.)

The quantitative separation of small quantities of isovaleric and acetic acids is not by any means a simple matter. The method of partial neutralization followed by distillation is in this case practically useless, whilst the ingenious method of Duclaux, although affording an approximate determination of the proportions in which the two acids exist, does not affect their separation. When a solution containing the above two acids free from their homologues has been obtained, they may, of course, be estimated by neutralization with baryta, followed by a determination of the percentage of barium in the mixed salts. This indirect method is open to the objection that any failure to obtain the mixed barium salts in a pure and dry condition (by no means an easy matter) will introduce a very appreciable error into both determinations.

Moreover, it is not, strictly speaking, a method for their separation. Having frequently had occasion to estimate the percentages of these two acids when present together in solution, and if possible to obtain them separately for purposes of further

identification, I was led to make experiments with this object in view. At the outset it seemed likely that a difference of solubility of a metallic acetate and of the corresponding valerate in some solvent might offer the best chances of success.

Sodium valerate dissolves fairly readily in a solution containing 99·5 parts of acetone and 0·5 part of water, whilst sodium acetate is practically insoluble in that menstruum. The 99·5 per cent. acetone is, in fact, an excellent solvent from which to obtain pure sodium valerate in a crystalline condition. If the commercially pure salt is treated with a sufficient quantity of the solvent at its boiling-point and filtered, beautiful crystals having a pearly lustre separate from the filtrate on cooling, which can readily be filtered by the aid of a pump, and dried in a vacuum over sulphuric acid. The salt purified in this manner was used for the experiments described below. A determination of sodium showed it to be perfectly pure:

Found, 18·46 per cent. Na. Calculated, 18·54 per cent. Na.

It was in the first place necessary to determine the best conditions for the application of this method, and to ascertain with what degree of accuracy the separation could be effected. Known weights of dry sodium valerate and anhydrous sodium acetate (both powdered) were transferred to a small flask and thoroughly mixed. The requisite quantity of the 99·5 per cent. acetone was then added, and the mixture heated just to its boiling-point for some minutes, a piece of glass tubing passing through a cork in the flask serving to prevent the loss of any appreciable quantity of the acetone. The liquid was then passed through a small asbestos filter into a second small flask, and the residue in the first flask washed with a further quantity of the acetone in two successive portions. The acetone was then distilled off, the residue washed into a platinum dish, evaporated to dryness, treated with sulphuric acid, and weighed as sodium sulphate. The sodium acetate remaining in the first flask and on the funnel was then dissolved in water, and treated in a similar manner. From the weights of sodium sulphate obtained the amount of acetic and valeric acids can of course be easily calculated.

In the following table some of the results obtained are given:

Taken.			Found.		
Sod. Acetate.	Sod. Valerate.	Total.	Sod. Acetate.	Sod. Valerate.	Total.
0·122 gr.	0·109 gr.	0·231 gr.	0·122 gr.	0·106 gr.	0·228 gr.
0·124 gr.	0·117 gr.	0·241 gr.	0·123 gr.	0·118 gr.	0·241 gr.
0·144 gr.	0·093 gr.	0·237 gr.	0·143 gr.	0·090 gr.	0·233 gr.
0·067 gr.	0·104 gr.	0·171 gr.	0·066 gr.	0·103 gr.	0·169 gr.
0·250 gr.	0·250 gr.	0·500 gr.	0·246 gr.	0·254 gr.	0·500 gr.
0·217 gr.	0·238 gr.	0·455 gr.	0·217 gr.	0·235 gr.	0·452 gr.
0·210 gr.	0·145 gr.	0·355 gr.	0·211 gr.	0·142 gr.	0·353 gr.

Potassium valerate is also soluble in 99·5 per cent. acetone, and can be obtained from it in pearly plates. Although potassium acetate is almost insoluble in that liquid, the potassium salts cannot be used for the purpose of separation by this method, as the valerate abstracts water from the solvent, and the acetate is converted into a pasty mass.

Experiments were next made starting with the acids themselves. Aqueous

solutions of the two acids were prepared, and their strengths determined by titration with standard alkali.

The isovaleric acid used had a constant boiling-point of 176°, and yielded a sodium salt containing the theoretical percentage of the metal. Definite volumes of these solutions were mixed and carefully neutralized with a solution of pure caustic soda. The flask containing the solution of the mixed sodium salts was then connected with a condenser and the water distilled off under reduced pressure. In this way the slight loss of valeric acid which usually occurs when solutions of the metallic valerates are evaporated in contact with the air, was avoided, and the rate of evaporation was of course accelerated. The residue was dried in the air-bath at 100° for a short time, and then extracted with the acetone mixture.

The success of the separation depends to a great extent upon the conditions under which the filtration of the valerate from the undissolved acetate is carried out. After many experiments I have found the following method to give the best results: A funnel is taken with a very long stem, which is passed through a cork in a small inverted bell-jar, filled with hot water for the purpose of keeping the solvent near its boiling-point during the process. A small plug of glass-wool is inserted in the upper part of the stem, and is then covered with a thin layer of fine asbestos, which should allow the solution to pass rapidly through. When the extraction is thought to be complete, it is well to dry the residue in the flask in an air-bath for a few minutes, and to treat it with a further small quantity of the solvent. Owing to the slight solubility of the valerate in the acetone at temperatures much below its boiling-point, it is essential that it should be kept nearly at this temperature throughout the process.

The following results were obtained:

Taken.			Found.		
Acetic Acid.	Valeric Acid.	Total.	Acetic Acid.	Valeric Acid.	Total.
0·102 gr.	0·087 gr.	0·189 gr.	0·104 gr.	0·084 gr.	0·188 gr.
0·102 gr.	0·087 gr.	0·189 gr.	0·105 gr.	0·081 gr.	0·186 gr.
0·102 gr.	0·087 gr.	0·189 gr.	0·103 gr.	0·084 gr.	0·187 gr.
0·157 gr.	0·044 gr.	0·201 gr.	0·159 gr.	0·041 gr.	0·200 gr.
0·153 gr.	0·043 gr.	0·196 gr.	0·155 gr.	0·040 gr.	0·195 gr.

The best "commercially pure" acetone should be purchased, and allowed to stand over a considerable quantity of dry chloride of calcium for one or two days, that portion which boils constantly at 56° being separated and used for the preparation of the acetone solution.

The valeric acid determination is almost invariably a little low, owing to the impossibility of removing the last trace from the acetate by washing. This can always be detected by the odour, when sulphuric acid is subsequently added to the acetate.

My thanks are due to my assistant, Mr. Dick, for the help he has given me in connection with this work.

Discussion.

The President (Dr. Dyer) said the process was one that would possibly be useful in the determination of small quantities of amyl alcohol in spirits. In the

method brought before the Society many years ago by Dr. Dupré, the amyl alcohol was fractionated from the spirit, and obtained ultimately along with some ethyl alcohol. It was oxidized, neutralized with barium carbonate, and, in the barium salt thus formed, the barium was determined, from which the valeric acid was calculated.

Mr. RICHMOND observed that ordinary fusel oil was a mixture of about equal parts of the active amyl alcohol and the iso-amyl alcohol, and would give a corresponding mixture of the two valeric acids on oxidation. It would be interesting to know whether or not the active valeric acid behaved in the same way as the iso-valeric acid. Perhaps the author had made some experiments that would yield information on this point.

Mr. HEHNER said he supposed that, as the molecular weight advanced, the sodium salt would become more and more soluble. He inquired whether, in applying the method to other separations, the author would consider it necessary to use 99·5 per cent. acetone, or whether some weaker strength might be used; and also how a lower acid, such as butyric acid, might be expected to behave under a similar process.

Mr. BEVAN asked how the author managed to hit upon 99·5 per cent. acetone, and whether the fractional percentage of water was essential.

Mr. CHAPMAN said that want of time had prevented his going beyond the immediate object of the investigation, which was simply the separation of acetic and isovaleric acids, so that he could not at present say anything as to the behaviour of active valeric acid, or of any lower acid. He intended, however, to continue the investigation, and to ascertain to what extent the process might be employed in determining fusel oil. Mr. Hehner's suggestion as to the increased solubility of the sodium salt with the rise in molecular weight was doubtless correct. With regard to the solvent, he thought it probable that, in other separations, other strengths of acetone might be employed. It seemed curious that the presence of such a very small quantity of water should have such a marked effect; but sometimes, he thought, insufficient importance was attached in analytical procedure to the influence on solubilities exerted by a small quantity of some third substance.

CAPER TEA.

By JOHN WHITE, F.I.C.

(*Read at the Meeting on March* 1, 1899.)

IN the course of the last two years I have had occasion to examine a considerable number of samples of tea, particularly of that variety distinguished by the name of caper tea, submitted to me under the Sale of Food and Drugs Act. Prior to this time I had always regarded tea of any description as an article which was sufficiently supervised by the provision made for its analysis and inspection in bond before being distributed for sale. The Local Government Board returns evidence the fact that this arrangement has worked well in the past, for although tea, and especially caper

tea, was found to be largely adulterated in the early days of the Food and Drugs Acts, either by the addition of exhausted or foreign leaves, or by the introduction of a comparatively large proportion of extraneous mineral matter, in the year 1897, of 403 samples of tea analysed by the Public Analysts of England and Wales, only one was certified to be adulterated. Further, it was stated in the Local Government Board Report for 1897, that of 4,289 samples of tea analysed under the Act during the ten years ending with 1896, only four were condemned.

In the ANALYST for the present year (vol. xxiv., p. 30) a paper appears by C. Estcourt, in which he emphasizes the fact of the disappearance of adulterated caper tea from the retail market, and quotes a report from the Government laboratory containing the results of analysis of seven samples of caper tea, described as authentic samples out of bond.

The following table gives the results obtained by me from samples of caper tea submitted under the Act between June, 1897, and January, 1899. These samples were not confined to any one particular district, but were collected from various parts of the county of Derby. The estimations were made upon the undried tea, and in nearly every instance the figures given represent the mean of three or four separate determinations. The results are expressed in parts per cent.:

TABLE.

Number of sample.	1.	2.	3.	4.	5.	6.	7.	8.
Total ash	12·20	11·34	11·31	9·90	9·88	13·47	8·80	8·82
Ash soluble in water ...	2·76	2·79	2·84	3·24	2·98	2·80	2·80	3·20
Ash insoluble in water ...	9·44	8·55	8·47	6·66	6·90	10·67	6·00	5·62
Mineral matter insoluble in acid	5·66	4·66	5·10	4·40	3·84	6·26	3·10	3·10

The mineral matter which remained after boiling with dilute hydrochloric acid, with subsequent thorough washing and ignition, consisted in each instance of clean sharp sand mixed with small stones, among which occurred fragments of quartz. The original mineral matter was not in any sample noticeably magnetic.

I do not apprehend any serious difference of opinion as to whether or not these samples are adulterated; it will, I believe, be generally admitted that the extraneous mineral matter shown by these figures is present in too high a proportion to have been "unavoidably mixed in the process of collection and preparation" of these teas. This is certainly obvious in respect of samples 1 to 6, the results of which will possibly justify the chief purpose of this paper, viz., to show that after having lain dormant for many years, the sophistication of caper tea has again become a practicable process, and the sale of the spurious product has apparently become possible.

Proceedings were successfully instituted against the vendors of samples 1, 2, 3, and 4, and are pending in the case of 6; sample 5 will be referred to later. I advised that no action be taken respecting 7 and 8, and also with reference to several other samples containing a total ash of slightly over 8 per cent., as I thought it distinctly undesirable that prosecutions should be undertaken unless the adulteration proved to be of substantial extent.

In addition to the eight samples the results of which are set forth in the above table, I have also found nine other samples yielding a total ash ranging from 8 to 8·4 per cent.; the highest percentage of mineral matter insoluble in acid present in these was 2·7, which occurred in one sample, the next highest being 2·56. Some years ago this Society fixed as a limit 8 per cent. as a maximum of total ash to be permitted in genuine tea, when calculated upon the tea dried at 100° C. Were this figure rigidly adopted, these nine samples must perforce be condemned, but this, in my opinion, is a standard that should be interpreted with very considerable discretion.

Some fifty further samples yielded a percentage of total ash varying from 6·2 as a minimum to 7·9 as a maximum, the average being 7·04, and, what I think is especially important, in no instance did the mineral matter insoluble in acid exceed 2·0 per cent. These results indicate what may fairly be held to represent the composition of genuine caper tea, though both A. H. Allen and Wynter Blyth have expressed the opinion that this variety of tea hardly deserves the description of "genuine," indeed, the former "believes it to be invariably a factitious article." Whether this be so or not, caper tea has come to be recognised as a distinct article of commerce, and one that is in great demand, more especially by the lower classes and by those tea-drinkers who prefer tea with what is known as a "rough" flavour. Caper tea is also believed to be of considerable value for use in mixed teas for the purpose of flavouring the mixture; sample 4 was sold at the high price of 3s. 8d. per pound, and was said by the vendor to be of especially superior quality and character.

The argument has been raised that it is unfair to purchase caper tea under the Act, inasmuch as it is an article which palpably is adulterated by the tea growers abroad, and that the unfortunate vendor who may be prosecuted here is the innocent victim of circumstances outside his control. It is also argued that to buy this special variety of tea appears to be an attempt to entrap the unwary trader. These arguments do not appear to me to be either logical or sound; the Sale of Food and Drugs Acts were passed primarily with the object of protecting the consumer. The process, moreover, by which caper tea is said to be manufactured, viz., by coating the leaves with gum or starch, and subsequently rolling them up into small granules of rounded shape, is in itself highly suspicious. It seems quite possible that this method was adopted for the purpose of allowing the tea to be loaded with mineral matter, the shape of the finished article being favourable to the concealment of it inside the leaves of the tea. Assuming these conclusions to be correct, it is plain that caper tea should not be allowed to compete unduly with the ordinary kinds of tea.

I would suggest that, having regard to the report already referred to from the Government Laboratory, from which it appears that caper tea containing 2·68 per cent. of mineral matter insoluble in acid (I obtain this figure by adding together the sand and the silica less sand) is regarded as genuine, that the presence of 3 per cent. should be considered by Public Analysts to be an adulteration. It is doubtful, however, in view of the result of the appeal Shortt *v.* Robinson, whether a conviction will be obtained until a percentage of 3·5 is exceeded.

Sample 5 was certified by me to contain at least 3·5 per cent. of mineral matter consisting of small stones and sand, and became the subject of the above-mentioned

appeal. At the hearing of the case before the magistrates I gave evidence, and a newspaper report of the certificate from the Government Laboratory, given in respect of Mr. Estcourt's case at Manchester, was produced by the defendant's solicitor, who, however, neither disputed my analysis nor called any rebutting evidence. Our solicitor objected to the production of this document, on the ground that it was not evidence, but it was read. Eventually the Bench dismissed the summons, but granted a case for the decision of the Court of Queen's Bench. The following is the report of the appeal, taken from the *Times* of February 9 last:

QUEEN'S BENCH DIVISION.

(Before Mr. JUSTICE LAWRANCE and Mr. JUSTICE CHANNELL.)

Shortt v. *Robinson.*

This was a case stated by justices of Derbyshire, sitting at Chesterfield, at the hearing of an information against Mark Robinson for selling caper tea adulterated with 3·5 per cent. of mineral matter, consisting of sand, small stones, etc.

Mr. J. H. Etherington Smith appeared for the appellant, the inspector; Mr. Appleton for the respondent, the seller of the tea.

The information, taken out under the Sale of Food and Drugs Act, 1875, was heard on October 22. These facts were proved.—William Marples deposed to purchasing the tea at the shop of the respondent on behalf of the appellant, W. A. Shortt, the Inspector of Weights and Measures for the northern division of the county of Derby. The tea was divided into three parts for the purpose of analysis. The result of the analysis was that it contained 3·5 per cent. of foreign ingredients. At the hearing the County Analyst was called, and swore to the above. In the course of his cross-examination, he was asked whether he had seen in the *Grocer* newspaper a case heard at the Manchester Police-Court on August 16, in which a Somerset House report showed that extraneous matter was necessarily present in caper tea. The analyst admitted that he had seen the report of the case in a paper, not the *Grocer*. The appellant's solicitor objected to this as evidence. The justices allowed the question, though they held that the report was not evidence. The report in the *Grocer*, however, was attached to the case. The analyst in cross-examination stated that, in the course of sixty-five analyses of caper tea, he had found the amount of sand and stones to be not so much as 2 per cent., and that only six specimens contained as much as 3 per cent. It was contended for the appellant that an adulteration of 3·5 per cent. having been proved, there must be a conviction. The justices found that the purchaser asked for caper tea, and that such tea was well known as one manufactured for the purpose of using in small quantities by way of addition to ordinary tea for flavouring it. The justices also found that it was well known that caper, like ordinary tea, was grown under conditions which afforded unusual chances of the introduction of sand and small stones, the tea being grown on friable, sandy soils, and it being a condition of successful growth that rain should be not only very frequent, but copious. They considered that, having regard to these facts, they were not justified in convicting the defendant on so small a percentage as 3·5 of extraneous matter of a nature peculiarly incident to the growth of the article. Moreover, it appeared from the evidence of the analyst himself that there was necessarily some percentage in caper tea of the extraneous matter complained of. They accordingly dismissed the information. The question for the opinion of the Court was whether the justices were justified in considering, on the facts before them, that a presence of extraneous matter to the extent of 3·5 per cent. did not necessarily constitute an adulteration.

Mr. Smith contended that the justices were wrong. They had evidently acted on the report of the Somerset House authorities set out in the case heard in Manchester. That was

not evidence in the case before them. The analyst might have been asked his opinion of the report. If he had affirmed it, then there might have been something for the justices to act on. He was not asked for that, however. His analysis uncontradicted was sufficient to show adulteration under Section 24. He cited Dargie *v.* Dunbar (21 Scottish Law Reports, 536), Regina *v.* Field and others, Justices of Hampshire (64 L. J., M. C., 158). In the Manchester case the defendant gave evidence that the tea when sold was in the same condition as when it was brought out of bond. Section 30 provided for there being an analysis of tea in bond. There was no such evidence in this case.

The Court dismissed the appeal.

Mr. Justice Lawrance said that, in his opinion, the decision of the magistrates ought not to be disturbed. The analyst had stated that there was stone, sand, etc., to the amount of 3·5 per cent. in the sample of tea submitted to him. His attention was then called to the report of the Somerset House authorities supplied in another case dealing with caper tea generally. The analyst admitted that he had seen the report. An objection was taken to the admission of the report as evidence of the facts. It was not stated in the case that the analyst expressed any opinion on the report. In the result, the magistrates apparently brought their own knowledge to bear on the matter, and without calling on the respondent to say whether the tea was in the same state as when it came to him out of bond, dismissed the information, being satisfied that there were always foreign ingredients present in tea.

Mr. Justice Channell concurred. He thought the Court could not interfere in this case. The justices were not wrong in law, unless it were in receiving something as evidence which was not strictly evidence. But the ultimate conclusion at which they had arrived was one to which they were justified in coming. They must have acted on some knowledge of their own. They were entitled to do so, as could be seen by Regina *v.* Field. He thought, in fact, that they had treated the facts about caper tea as well known, partly, at any rate, because they had read in print in the report from Somerset House that there were usually foreign ingredients present in tea. The result of the finding of the justices was right. They thought that the adulterative matter was so near normal in amount as not to justify them in convicting the respondent. The proper course for them to have followed would have been to ask the complainant whether he would insist on going on if they intimated that, supposing the facts set out in the report were properly proved, they would not convict. In all probability the prosecution in such a case would be given up. The magistrates apparently treated this report as evidence. In that they were wrong, but it was only misreception of evidence at the worst, and nowadays, where the misreception of evidence did not affect the result, especially where there had been an acquittal, the Courts would not interfere. The appeal must be dismissed.

The result of this appeal shows once again how far-reaching in its effects a report from the Government Laboratory may be, but the process of reasoning by which the conclusion is arrived at—that because a given sample of authentic caper tea contains 2·68 per cent. of a foreign ingredient, another sample containing 3·5 (or, as I stated in evidence, 3·8 per cent.) is also genuine—does not commend itself to me. I am decidedly of opinion that 3 per cent. as a maximum of foreign mineral matter to be present in caper tea is fair and reasonable, and that if it exceeds that figure the tea should be condemned. There does not appear to me to be any good and sufficient reason why an amount of foreign material that would not for a moment be tolerated in ordinary black or green tea, should be held to be lawful and proper when occurring in caper tea.

ON SOME ANALYSES OF GINGER

By E. G. Clayton.

(*Read at the Meeting, Wednesday, March* 1, 1899.)

Recently I had occasion to examine a considerable number of samples of commercial ginger, and the results of the analyses of these samples are stated in the following table, in which there is a rough classification, according to the origin, condition, and quality of the ginger. It is believed that the series is fairly representative, the samples having been supplied to, or obtained for, me by well-known spice-dealers. Time did not permit me to carry out a fuller investigation; but the analyses for the most part comprise about a dozen estimations: soluble and insoluble ash; the extracts dissolved by cold water, ether, absolute alcohol (after complete extraction with ether), and petroleum spirit; essential oil; alkalinity, calculated as potash, and chlorine, in the soluble ash; and, in some cases, the ash, alkalinity of the ash, and chlorine, in the cold-water extract. Water and silica were also determined in certain instances. All the series of estimations may be regarded as strictly comparable.

The main objects of the inquiry were: (1) To form an opinion whether certain samples submitted to me were, or contained any admixture of, "spent" ginger; (2) to ascertain whether any further information could be amassed as to the effects on the composition of ginger of the operation known as "washing"; (3) to study the influence on the analytical figures of the commercial processes of *grinding*, with removal of the fibre, and *scraping or cutting off the surface* of the rhizome—this latter operation being alleged to be resorted to with the view of giving the ginger a better appearance; (4) to collate analytical data from samples of different geographical origins, and in various conditions, as whole, ground, washed, or otherwise; and (5) to compare the figures yielded by different market qualities (as indicated by the prices) of the same variety of ginger.

In the table (which includes the results of analyses of thirty-seven samples) five principal series are included: (A) Whole gingers, washed and unwashed; (B) commercially-ground gingers; (C) spent gingers; (D) a series of four samples of the same Cochin ginger at different stages of grinding, etc.; and (E) samples of similar ginger, washed, scraped, and cut, as well as some of the cuttings and shavings removed from the surface.

Included in the table are the results of an analysis of green ginger (F), and of a few estimations made in some samples of whole Cochin ginger (G), previously steeped in the laboratory for forty-eight hours in water and in diluted alcohol. The averages and limits observed are also stated.

I desire to express my acknowledgment of the help cheerfully rendered by my assistant, Mr. Henry H. Williams, in the course of these analyses.

The figures obtained, of course, in the main confirm those of other observers, but two or three points may be touched upon.

In the estimations of moisture, it was noticed that after prolonged drying in the water-oven many of the samples began to gain in weight, this being due, I suppose, to oxidation. Hence it was rather difficult to arrive at constant weights, but the lowest of a series of weighings was taken in each instance.

The effect of washing in diminishing the percentages of some of the constituents, such as the ash, soluble ash, cold aqueous extract, etc., is clearly shown; and a similar influence appears to be exerted to a certain extent by grinding, removal of the fibre, and the operation of cutting or scraping the exterior of the rhizome. But the figures have also shown that what I at one time thought possible is not the case; namely, that by the combined effect of all these commercial processes—washing, scraping, cutting, grinding, and separation of fibre—the composition of genuine ground ginger might be so altered or reduced as to approximate to that of spent ginger. Some of the results obtained clearly indicate, at all events as regards Cochin ginger, that even after all these operations have been carried out, the percentage proportions of many, if not most, of the constituents remain sensibly—indeed, considerably—above the corresponding numbers found in spent ginger. I do not know what might prove to be the case with Japan ginger; the figures do not go far enough to show.

The above conclusion is opposed to my earlier anticipations and belief; but some of the later results, notably the figures obtained with the samples constituting series E in the table, have been entirely convincing.

The determinations of the ethereal extract and alcoholic extract (after removal of everything soluble in ether) were effected in a Soxhlet apparatus, the first occupying from two to three days, the second from three to four days. The alcoholic extracts appear to be less than those obtained by other observers; but the last alcohol extraction-fluid was in a number of cases tested, and found to leave practically no residue. Moreover, as it seemed possible that in some instances the extraction with ether had not been carried far enough (in spite of the long time it occupied), and that some matter had been left behind, to be removed by the absolute alcohol, an experiment was made to test this point. Duplicate estimations of the two components were made in one of the samples, absolute alcohol being used *first*, the extract dried to constancy, weighed, and *then* treated with ether. The resulting ethereal extract was dried until constant, and weighed. The numbers obtained were:

Alcoholic extract	0·65 per cent.
Ethereal ,, ...	3·73 ,,

By the other process (using ether first and alcohol last) the same sample (No. 30) had yielded:

Alcoholic extract (after ether extraction) ...	0·75 per cent.
Ethereal extract	3·55 ,,

The fair agreement of the two pairs of estimations would seem to point to the substantial accuracy of the rest of these determinations, and to indicate that the

matter remaining for extraction by absolute alcohol, after ethereal treatment, may be somewhat lower than is supposed, *provided* that there has first been complete extraction with ether.

It will be seen that the fixed extract removed by petroleum spirit was found to be a tolerably constant figure in the genuine samples, and an attempt was made to determine approximately in each case the essential oil of ginger, by a process somewhat akin to that originally described by Dr. Thresh, namely, extracting the ginger with ether, air-drying and weighing the extract, and then drying in the water-oven to constancy; but it was thought possible that the method might be advantageously modified by the substitution for ether of petroleum spirit (by which less of the resinous and other constituents of ginger are extracted than by most other solvents). The figures resulting from this modified process are decidedly lower than those previously obtained, and obviously very variable. Of course, the method is necessarily imperfect.

Chlorine was found to be practically absent from the soluble ashes of the samples of spent ginger; the two exceptions at the end of the series of spent ginger samples I believe to have been, not exhausted ginger only, but to have contained some admixture of unexhausted ginger. Curiously enough, very small quantities of chlorine appeared in most of the ashes of the cold aqueous extracts of the spent ginger samples. Possibly this might be explained by the presence of some soluble organic compound containing chlorine.

The samples Nos. 15*, 16*, 17* and 18*, were different market qualities of the same kind of ginger, namely, Cochin ginger; it is remarkable that the proportions of the principal constituents diminish as the price increases; and the question arises whether the real quality of a sample may not sometimes be sacrificed to mere appearance—whiteness, and so forth.

Discussion.

The President (Mr. Fisher) said it seemed to him that washing ginger till all its valuable constituents disappeared was but little different from mixing it with exhausted ginger, seeing that the result was the same in both cases. It appeared possible, however, that excessive washing was allowed to take place through ignorance on the part of those engaged in the trade.

Mr. Allen desired to ask what figures the author would take as minimum limits in genuine ginger for soluble ash and for cold water extract, the latter determined directly on the ginger, and not after treatment with alcohol and ether. If ginger was exhausted as completely as possible with water, it would still yield an appreciable proportion of soluble ash. He would like to hear if the author had any information as to the limits of silica in exhausted ginger. This constituent was occasionally present in very considerable proportion. He was much interested in the specimens of exhausted ginger free from chlorides. Mr. Stock and other analysts, and he (Mr. Allen) himself to a limited extent, had determined, not the alkalinity, but the actual potash in the soluble ash of ginger and other plant-products, a factor which sometimes yielded valuable information. His practice, he might mention,

was to estimate soluble ash both by difference and by direct determination by evaporation; which latter method generally gave the higher result.

Dr. DYER said that he had recently analysed, in connection with a case in which both he and the author had been interested, a series of samples which he believed were duplicates of many of those referred to in the paper. His conclusions were in agreement with those of the author. The question had been raised at the time by a member of the ginger trade, whether the paring of ginger might not affect the results of its analysis, and particularly the percentage of soluble ash. He (Dr. Dyer) had at the moment not felt prepared to say that it might not, for little was known as to the distribution of the salts contained by the root. The samples which he and the author had both analysed consisted of Cochin ginger of various kinds and in various stages of manufacture — pared and unpared, parings, and fibre separated during grinding. The results of the analyses indicated that any legitimate process to which the ginger might be submitted produced practically no variation in its composition, that is to say, no such variation as could give rise to a suspicion of admixture with spent ginger. One of the samples approximated in composition to what might be regarded as partially exhausted ginger, but that sample had been submitted to a process of excessive washing. There was no evidence that properly-conducted washing resulted in any approach to what might be called exhaustion. It was, however, an undoubted fact that some ginger-washers—for ginger-washing was a trade—steeped the ginger in hydrochloric acid for the purpose of removing lime from its surface; and it was obviously necessary to afterwards steep the ginger in water to get rid of the acid. It seemed to him that no sample so treated could properly be regarded as unexhausted, seeing that such washing largely deprived it of both strength and flavour, and so partially exhausted it. He thought that the discussion at present going on in the trade on this subject would have the effect of altogether stopping the washing of many kinds of ginger that were now quite unnecessarily washed.

Mr. CLAYTON said it seemed rather difficult on the spur of the moment to lay down limits which would carry authority. He thought he might suggest that 1 per cent. would about represent the lowest limit of soluble ash in genuine ginger, but he only made the suggestion tentatively and with diffidence. In a sample which he had been assured was genuine, but which was of unknown origin, he had found 1·43 per cent. of soluble ash. That was the lowest figure for soluble ash that he had actually met with in genuine ginger, apart from one sample of washed Japan ginger. He quite agreed with Mr. Allen as to the difficulty of getting out all the soluble ash by exhaustion. This not only applied to treatment with water, but also with alcohol and ether. He was unable to express any opinion as to silica, not having included this point in his investigations; nor had he determined the actual potash present, as he was aware had been done by Mr. Stock. He might mention that the prices of four of the samples referred to in the paper—viz., Nos. 15, 16, 17, 18—were respectively 90s., 50s., 40s., and 28s. per cwt., and it was curious to note that, as the price rose, the total ash, soluble ash, cold-water extract, and most of the other constituents diminished.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Examination and Characteristics of Commercial Fennel Seed. A. Juckenack and R. Sendtner. (*Zeit. Untersuch. Nahr. Genussm.*, 1899, ii., 69-75.)—The authors have examined a large number of the principal kinds of fennel seed found in the German market, viz., German, Italian, Macedonian, and Galician, with the object of obtaining data for the detection of exhausted and coloured seeds.

The moisture, mineral matter, aqueous extract, alcoholic extract, and the earthy impurities and mineral constituents corresponding with these, were determined on specimens of each variety with the following mean percentage results:

Fennel Seed.	Water.	Total Mineral Matter.		Mineral Matter Deducting Soil.		Aqueous Extract.		Alcoholic Extract.	
		Natural Substance	Dry Substance	Natural Substance	Dry Substance	Natural Substance	Dry Substance	Natural Substance	Dry Substance
German ..	13·85	8·027	9·263	7·966	8·845	22·21	25·66	11·16	13·21
Italian ..	11·74	8·883	10·065	7·987	9·056	23·87	27·05	14·90	16·85
Macedonian	9·88	12·520	13·890	8·010	8·880	26·11	28·96	14·56	16·16
Galician ..	11·59	12·001	14·253	7·844	8·849	21·62	24·46	14·27	15·96

The following table shows the effect of steam extraction on the composition of the seed:

	Water.	Mineral Matter.		Aqueous Extract.		Alcoholic Extract.	
		Natural Substance.	Dry Substance.	Natural Substance.	Dry Substance.	Natural Substance.	Dry Substance.
Saxon fennel ...	12·09	7·445	8·480	21·10	24·00	10·24	13·22
do. extracted	7·74	5·444	5·900	6·40	6·93	4·23	4·58

In order to detect the presence of exhausted seeds, from 3 to 5 c.c. of the fennel are shaken in a reagent-cylinder with from 3 to 4 volumes of 96 per cent. alcohol, and allowed to stand for a short time. The extracted seeds become dark or black, while the genuine seeds retain their original colour. The supernatant alcohol varies from dark green to pale green according to the proportion of extracted seeds in the mixture.

A second test consists in mixing from 2 to 3 grammes of the seed with 20 c.c. of water in a small basin, and allowing the mixture to stand, when the genuine seeds float (on account of their higher percentage of fat, which repels the water) and retain their colour, while the extracted seeds become dark and fall to the bottom.

A difference can also be observed under the miscroscope, the oil-streaks in the genuine fennel being more or less refractive to light, instead of, as in extracted seeds, being dull and black. The ribs of extracted seeds are browner in colour and less sharp in outline than untreated seeds.

The authors conclude from their analyses that the following limits may be taken as the lowest for genuine fennel seed:

	German. Per cent.	Italian. Per cent.	Macedonian. Per cent.	Galician. Per cent.
Moisture	11·5	10·0	9·5	10·0
Mineral matter calculated on the dry substance (excluding earth)	8·0	8·0	8·0	8·0
Aqueous extract (on dry substance)	23·5	24·0	24·0	24·0
Alcoholic extract (on dry substance)	12·0	13·5	13·5	14·5

They also consider that pure undamaged fennel should contain at least 70 to 80 per cent. of grains capable of germinating. Artificial colour is sometimes used to conceal the extraction of the seeds or to improve their appearance. It may be detected by the following tests: (1) When examined under the microscope the ribs of uncoloured seeds are seen to be sharply differentiated from the depressions, which is not the case with coloured seeds. (2) When 5 c.c. of the coloured fennel are shaken for a minute with 25 c.c. of 96 per cent. alcohol, the liquid is at first turbid and green, but on standing the colouring matter is deposited. (3) The colour may be isolated by washing the seeds with water, then shaking them with absolute alcohol, allowing the colouring matter to settle and filtering it off.

The only colouring matter which the authors have met with is ochre. They have not, like Neumann-Wender, detected chrome yellow in any coloured seeds.

C. A. M.

Dionine. L. Hesse. (*Pharm. Central H.*, 1899, xl., 1; through *Chem. Zeit. Rep.*, 1899, 32.)—This new therapeutic agent consists of the hydrochloride of mono-ethylmorphine. The base forms brilliant prisms, having the formula $C_{17}H_{17}NO.OH.OC_2H_5 + H_2O$. The hydrochloride is a white, odourless, bitter, micro-crystalline powder, which melts and decomposes at 123° to 125° C. It is easily soluble in water, giving a neutral solution, and is chemically and physiologically similar to codeine, being exhibited in the same doses. If 5 c.c. of a 10 per cent. solution of codeine hydrochloride are treated with a few drops of 0·910 ammonia, the alkaloid is thrown down; but 1 c.c. of alkali is sufficient to redissolve the precipitate permanently. With dionine, 5 c.c. of ammonia first produce a clear liquid, from which the base gradually separates in crystals. Dionine may be distinguished from morphine by a solution of potassium ferricyanide containing a trace of ferric chloride; when 1 c.c. of a 1 per cent. solution of morphine is added, the liquid becomes dark-blue immediately; dionine only slowly bluish-green.

F. H. L.

The Assay of Liquid Extract of Ipecacuanha. H. Wilson. (*Amer. Journ. Pharm.*, 1899, lxxi., 73-77.)—The author criticises the method of determining the alkaloid in this preparation, as given in the British Pharmacopœia of 1898 (p. 115), asserting that it is complex and tedious, and that a considerable proportion of the alkaloids is lost in the lead precipitate. In its place he recommends the following method: 20 c.c. of the strong liquid extract are diluted with an equal volume of water, and the alcohol removed by evaporating the mixture on a water-bath to less than half its volume. After the addition of 1 c.c. of sulphuric acid, the liquid is transferred to a separating funnel (the dish being washed out with 20 c.c. of water) and extracted three times with 10 c.c. of a mixture of equal volumes of chloroform and

ether, the extracts being rejected each time. The aqueous residue is then rendered alkaline, and again extracted three times with the same quantity of mixed ether and chloroform. The united extracts are evaporated to dryness in a weighed dish, and the residue dried below 80° C. and weighed.

The following table gives the results obtained by this method in comparison with those yielded by the officinal process:

Ipecacuanha Extract.	Officinal Process.			New Process.
	Alkaloids extracted. Gramme.	Alkaloids lost in Lead Precipitate. Gramme.	Total Alkaloids. Gramme.	Alkaloids found. Gramme.
1.	0·386	0·031	0·417	0·417
2.	0·393	0·028	0·421	0·426
Mean	0·389	0·029	0·419	0·421

The author considers that at present the alkaloids of ipecacuanha cannot be accurately determined by titration. For, if it be assumed that the alkaloids consist of emetine with molecular weight 248 and cephaëline (molecular weight 238), in about equal proportions, each c.c. of decinormal acid should correspond with 0·0241 gramme of the mixed alkaloids. But in practice the results obtained by a volumetric estimation using this factor are from 50 to 60 milligrammes lower than the results of the gravimetric methods. This, in the author's opinion, is probably due to the presence of the third alkaloid, which Paul and Cownley believe to have a higher molecular weight that either of the others. C. A. M.

TOXICOLOGICAL ANALYSIS.

The Isolation and Identification of Sulphonal in Forensic Work. C. Kippenberger. (*Zeit. Untersuch. Nahr. Genussm.*, 1899, ii., 75-91.)—I. *Isolation of Sulphonal.*—The usual method of extracting sulphonal from cadaveric remains consists in extracting the substance with hot alcohol, evaporating the extract, dissolving the residue in hot water, filtering, evaporating and purifying the residue by crystallization from boiling alcohol. According to the author, the preparation thus obtained may be so contaminated with organic impurities as to render the identification of sulphonal uncertain.

From his investigations it appears that 100 c.c. of benzene (B.P. 80°-82° C.) dissolve 8·01 grammes of sulphonal, 100 c.c. of petroleum spirit (B.P. 30°-50° C.) 0·06 gramme, and 100 c.c. of chloroform 32·5 grammes. Its solubility in other solvents is: Water, 500 parts; boiling water, 15 parts; ether, 133 parts; alcohol, 65 parts; boiling alcohol, 2 parts. Toluene and acetone dissolve it in considerable quantities, and carbon tetrachloride dissolves it sparingly.

The following method of quantitative isolation is recommended when sulphonal has been detected qualitatively. The dry or only slightly moist material is extracted with chloroform or benzene on the water-bath, and the extract filtered and evaporated. The residue is treated several times with small quantities (2 to 4 c.c.) of petroleum spirit, which removes fat and colouring matter, and leaves the sulphonal as a white mass. If cholesterin was present in the original substance, it is separated from the sulphonal by treatment with water, and extracting the sulphonal from the

aqueous solution with chloroform or benzene. This treatment can also be used to separate sulphonal from the xanthin bodies, which are only sparingly soluble in water. The method of isolation and purification also effects a separation from these bases, owing to their insolubility or sparing solubility in benzene, and their fairly ready solubility in petroleum spirit.

When putrefactive decomposition compounds are simultaneously present, the author's method of extracting alkaloids with glycerin tannic acid solution (ANALYST, xx., 201) often gives satisfactory results. If vegetable alkaloids have been also isolated, they can be readily separated by precipitating them from an acid solution by means of iodine in potassium iodide.

It should not be lost sight of that fatty oils dissolve a considerable proportion of sulphonal on heating, which they only deposit very slowly on cooling, although in the cold they only take up slight traces.

In the method described by Hilger and Tamba (*Arch. d. Pharm.*, 1887, 225, 408) for the separation of ptomaines and alkaloids by means of oxalic acid solution, the sulphonal remains permanently dissolved.

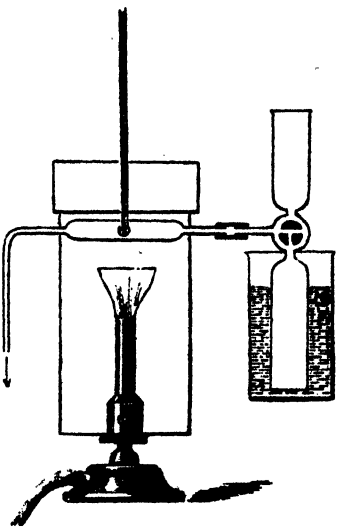
II. *The Identification of Sulphonal.*—Sulphonal, or diethyl-sulpho-dimethyl-methane $(CH_3)_2C(SO_2C_2H_5)_2$, forms odourless crystals, which are neutral in reaction, and to most people tasteless. It is unacted upon by cold concentrated sulphuric acid, by boiling concentrated nitric acid, by bromine, or by boiling solutions of alkaline hydroxides. It melts at 125° to 126° C., and volatilizes at 300° C with slight decomposition.

Several tests for its identification have been based on the formation of strong odours attributed to mercaptan, on treating it with different substances. Thus, Vulpius heats it with twice its weight of potassium cyanide ; Ritsert uses pyrogallol ; Scharz, charcoal ; and Strobel, zinc chloride.

When sulphonal is heated with twenty times the amount of dry sodium acetate, mercaptan and hydrogen sulphide can be detected in the decomposition products.

The author has attempted to estimate the mercaptan in this reaction by absorbing it with a solution of silver nitrate, and collecting the silver mercaptide, but with only partial success.

When sulphonal is heated with magnesium powder, a sublimate is obtained which consists of malodorous sulphides of various composition, with traces of oily thioalcohols which solidify to a crystalline mass on cooling.



On heating a mixture of manganese peroxide and sulphonal, white acid vapours with a penetrating smell are obtained, and the sublimate is a perfectly white substance with no trace of the yellow oil formed in the magnesium powder reaction. A similar reaction is obtained with lead peroxide, barium peroxide, platinum black, and alkaline nitrates, with the formation of oxidation products of the thioacetones derived from the decomposition of the sulphonal (thioacetone oxides).

When a mixture of sulphonal and an alkaline hydroxide is heated in a silver basin until the mass assumes a reddish tint, and then cooled, the residue on extraction with water and filtration furnishes a solution which becomes dark on treatment with ferric chloride, reddish-violet with sodium nitro-prusside, and on acidification deposits sulphur.

C. A. M.

ORGANIC ANALYSIS.

Estimation of Hydrogen and Methane by Fractional Combustion with Copper Oxide. E. Jager. (*J. Gasbeleucht.*, 1898, xli., 764; through *Chem. Zeit. Rep.*, 1898, 335.)—The processes for separating methane from hydrogen by fractional combustion with air suffer from the disadvantage that, owing to the limited size of the burette, only small volumes of the gas can be taken for analysis. The author finds that if a mixture of hydrogen, methane, and nitrogen is passed two or three times over copper oxide heated to 250° C., as indicated by the thermometer, the bulb of which is in contact with the tube, the hydrogen alone is oxidized; and by raising the temperature to a red heat, after removing the thermometer, the methane can afterwards be burnt. Small corrections are necessary for the alterations in volume of the oxide during reduction, and for the amount of atmospheric oxygen in the combustion tube; but these can easily be ascertained. The apparatus required is partly illustrated in the accompanying sketch.

F. H. L.

The Determination of Arsenic in Glycerin. A. C. Langmuir. (*Journ. Amer. Chem. Soc.*, xxi., 133-136.)—In this modification of the Polenske method 15 to 20 grammes of crude soap glycerin, or 15 to 20 grammes of saponification- or C. P. glycerin are diluted to 100 c.c. with hot water, and carefully boiled down with 200 c.c. of concentrated nitric acid and 12 c.c. of concentrated sulphuric acid until sulphuric acid fumes are copiously evolved, the nitric acid being finally expelled by strongly heating. The cooled liquid is diluted to 50 c.c. and run slowly into a Marsh apparatus, drop by drop, the flow being regulated so that not more than two bubbles of gas per second pass the lead nitrate wash-bottle. Any escape of undecomposed hydrogen arsenide can be detected by placing a strip of paper, soaked in mercuric chloride, in the further end of the heated tube. The mirror section of the tube is finally separated from the rest, and weighed before and after the removal of the mirror. The arsenic content in saponification-glycerins averaged 0·00018 to 0·00030 per cent., whilst crude soap-lye glycerins gave 0·00064 to 0·01 per cent.

The Gutzeit method gives fairly good indications for comparison with known quantities when mercuric chloride is employed as the detecting agent, the limit of delicacy being about 0·00010 per cent., but the silver nitrate used by Gutzeit gives very imperfect results. C. S.

The Flash-Point of Dilute Alcohol and other Organic Bodies. P. N. Raikow. (*Chem. Zeit.*, 1899, xxiii., 145.)—The author suggests that a determination of the flash-point of inflammable organic substances in the ordinary Abel apparatus may frequently be of service in judging their degree of concentration or of purity.

For instance, absolute ethylic alcohol flashes at 12° C.; addition of 0·5 per cent. of ether reduces it to 9°; presence of 2 per cent. of ether lowers the flash-point to 2·5° C.; so that even 0·1 per cent. may be recognised and estimated. The introduction of 1 per cent. of benzene to monochlorobenzene causes the flash-point to fall from 27·5° to 24°; so that 0·1 per cent. may also be estimated in this case. The operation is carried out exactly as in testing petroleum, but the water-bath and annular air-jacket of the Abel apparatus should be filled with hot, warm, or ice-cold water, air, snow, etc., according to the height of the flash-point expected. Further experiments are in progress; in the meantime the author submits a curve and table of the flash-points of diluted ethylic alcohol. These show that the rise is not in proportion to the amount of water, that there is no break in the curve at the point where maximum contraction occurs (51·9 v/v spirit), as should happen if a definite hydrate were formed, and that alcohol flashes until it contains 97 v/v of water.

FLASH-POINTS OF AQUEOUS ALCOHOL.

The Separation of Unsaturated Fatty Acids from one another. K. Farnsteiner. (*Zeit. Unters. Nahr. Genussm*, 1899, ii., 1-27.)—(*a*) *Experiments on the Separation of Oleic Acid as Lead Elaidate.*—Various methods of converting oleic acid into elaidic acid were tried, and it was found that the largest yield could be obtained by saturating the fatty acid with nitric oxide, and converting this into nitrogen peroxide by introducing oxygen. The most favourable conditions were with the temperature at 10° to 20° C., and with 20 to 25 c.c. of nitric oxide to each gramme of oleic acid. A special apparatus is described, in which the reaction was carried out in a flask from which the larger proportion of the air was first removed. The acid obtained was hard, dry and crystalline, melted at about 43° C., and contained from 82 to 86 per cent. of pure elaidic acid.

The lead salt of the impure elaidic acid behaved like those of the saturated fatty

acids as regards its solubility in ether and benzene, 100 c.c. of the former dissolving 0·0086 gramme, and 100 c.c. of the latter 0·0040 gramme, at 16° to 20° C.

The author made use of this fact to determine the amount of acid not converted into elaidic acid in his experiments with pure oleic acid, the lead salts being treated with benzene in the method described in his paper on the separation of saturated from unsaturated fatty acids (ANALYST, xxiii., 285). Although so far he has been unable to obtain sufficiently constant results with the elaidic reaction for a quantitative method to be based upon it, he considers that, applied in the method described, it is a valuable qualitative test for the presence of oleic acid, and for determining the purity of that acid.

(*b*) *Experiments on the Estimation of Oleic Acid as a Barium Salt.*—Dry barium oleate is insoluble or dissolves only in traces in hot benzene. On adding absolute alcohol to the benzene and boiling, the salt is only dissolved with great difficulty; but with weaker strengths of alcohol it is readily dissolved, and is deposited as a crystalline powder on cooling. The separation of barium oleate from benzene (containing alcohol) is so complete that it appears suitable for the quantitative separation of oleic acid from other unsaturated fatty acids whose barium salts are soluble in benzene, etc.

The following experiment with olive oil illustrates the general method employed: About 1·3 gramme of olive oil was saponified, and the hot soap solution precipitated with barium chloride. The precipitate was washed with water, and dissolved in 50 c.c. of benzene containing 2·5 c.c. of 95 per cent. alcohol. The next day the precipitate was filtered off, and dissolved in 50 c.c. of benzene containing 10 c.c. of the alcohol, the precipitate from this being recrystallized from 50 c.c. of benzene containing 20 c.c. of alcohol. The filtrates yielded soluble barium salts containing 0·190 gramme of fatty acids, corresponding to 14·9 per cent. of the oil. The fatty acids recovered from the insoluble barium salts were converted into lead salts and separated into saturated fatty acids (9·95 per cent.) and oleic acid (70·9 per cent.) by the author's process (ANALYST, xxiii., 285). The oleic acid yielded a firm elaidic acid, melting at 41° to 42° C. The saturated fatty acids melted at 57° C.

Earthnut oil contained 30·3 per cent. of fatty acids forming soluble barium salts. A lard with an iodine value of 49·0 gave the following results: Solid acids, 42·2; oleic acid, 39·2; and fatty acids forming soluble barium salts, 13·9 per cent. Cocoa-butter was found to contain: Solid acids, 59·7; oleic acid, 31·2; and other acids, 6·3 per cent.

In the case of butter-fat, cotton-seed oil, and sesame oil, the author was unable to separate the oleic acid in an approximately pure condition by this method, a considerable proportion of the barium oleate remaining dissolved in the benzene, while a corresponding amount of the barium salts and other acids were found in the barium oleate precipitate.

By treating the liquid fatty acids of butter-fat with nitrogen peroxide, as in *a*, about 45 per cent. of elaidic acid was obtained, from which result the amount of oleic acid in the fat was calculated to be about 20 per cent.

The barium salts of the fatty acids can be prepared directly from the fats by saponifying them with a solution of barium hydroxide in equal volumes of benzene and methyl alcohol.

(*e*) *The Detection and Quantitative Estimation of Linolic Acid.*—A method of determining linolic acid is based on the insolubility of linolic tetrabromide in cold petroleum spirit, the precipitate being collected and weighed as described by the author in his former paper (ANALYST, xxiii., 286).

The results thus obtained under varying conditions of bromination (temperature − 10° to + 20° C.) with different oils and fats are summarized below.

Cotton-seed oil total fatty acids yielded a tetrabromide melting at 113° to 114° C. (uncorr.), the amount corresponding with (1) 18·9; (2) 18·45, and 18·2 per cent. of linolic acid. The quantity obtained from the liquid fatty acids in two determinations corresponded with 23·0 and 23·9 per cent., or 17·2 per cent. and 18·2 per cent. respectively on the total fatty acids.

Sesame oil (with 12·1 per cent. of solid acids) was found to contain in its total acids (1) 16·4, and (2) 15·2 per cent. of linolic acid. A second sample extracted in the laboratory gave the following results: Solid acids, 14·1; liquid acids, 86·7; and linolic acid, 12·6 per cent.

Earthnut Oil.—As the total fatty acids yielded no insoluble bromide, the more unsaturated fatty acids were concentrated by treatment of the barium salts with benzene, as in *b*, and the acids recovered from the soluble barium salts brominated in petroleum spirit. The insoluble bromide melted at 113·5, and had a molecular weight of 602·5. The unsaturated acids brominated amounted to about 30 per cent. of the weight of the oil, and the linolic acid obtained to about 6 per cent.

Olive Oil.—This was examined in the same way as the earthnut oil, and the acids from the soluble barium salts treated with petroleum spirit. The bromination products did not dissolve completely in the hot solvent, a powdery residue remaining (probably linolenic hexabromide). The solution deposited crystals, melting at 113° C. on cooling.

Rape-seed Oil.—On brominating the total fatty acids, a considerable quantity of an insoluble substance, of which only traces were soluble in petroleum spirit, but which was much more soluble in ether, was obtained. From its melting-point on crystallization from benzene (178° C.), the author regarded this as linolenic hexabromide.

Almond Oil.—The amount of tetrabromide (M.P. 113-114° C.) obtained from the total fatty acids corresponded with 5·97 per cent. of linolic acid.

Mustard-seed oil gave bromides melting at 178° to 179° C. and 111° to 112° C. respectively. The yields corresponded with 4 per cent. of linolenic acid and 4·5 per cent. of linolic acid.

Butter-Fat.—This was prepared in the laboratory from the milk of cows whose fodder for a long time previously had contained cotton-seed meal. The liquid fatty acids yielded an appreciable quantity of an insoluble bromide which had all the characteristics of linolenic hexabromide. The bromide of linolic acid was not found.

Lard.—Five grammes of the fat were separated by the barium method (*b*), and the acids from the soluble barium salts brominated in petroleum spirit. The bromination product dissolved completely in the hot solvent, but on cooling deposited a small quantity of two bromides, one of which was identified as linolic tetrabromide, while the more insoluble, which melted without purification at 165° was probably linolenic hexabromide.

Horse-Fat.—The liquid fatty acids yielded an insoluble bromide corresponding with 9·9 per cent. of linolic acid in the fat.

Ox-Tallow.—This, like lard, was found to contain a small amount of linolic acid and traces of linolenic acid.

As regards the detection of linolic acid by the formation of its oxidation product (sativic acid), the author points out that Hazura, in all his researches prior to 1888, gave the melting-point of sativic acid as 160° to 162° C., but that, in a paper published in that year in conjunction with Grüssner, the melting-point was given as 173° C. On the other hand, Fahrion found the melting-point of his sativic acid to be 152° C. The author is inclined to believe that Hazura's acid melting at 160° to 162° C. was not pure sativic acid, but contained an isomeric substance. C. A. M.

The Constants of Various Train-Oils. W. Fahrion. (*Chem. Zeit.*, 1899, xxiii., 161.)—The constants of various kinds of fish-oils are collected in the following table. To determine the saponification and Hehner numbers, 2 or 3 grammes of the sample were heated on the water-bath with 10 or 15 c.c. of 2N alcoholic alkali, the spirit removed, the soap dissolved in hot water, placed in a separating funnel, acidified with dilute hydrochloric acid, and when cold extracted with 30 or 40 c.c. of petroleum ether (b. p. 75°), allowing the mixture to rest over-night. The aqueous liquor was drawn off from below, the small proportion of oxidized fatty acids in solution being neglected, and the petroleum ether poured off from above; the insoluble acids washed in warm ether, and the whole of the solvent evaporated on the water-bath, weighing the residue to obtain the fatty acids plus the unsaponifiable matter. This was dissolved in 40 or 50 c.c. of alcohol, and titrated with $\frac{N}{2}$ aqueous potash to yield the "inner saponification number." The neutral liquid was extracted with petroleum spirit, the extracts washed with 60 per cent. alcohol, and dried to give the unsaponifiable matter. By calculation the molecular weight of the fatty acids was thus arrived at. The insoluble oxy-acids in the separating funnel were taken up in warm alcohol, evaporated, weighed, and the ash determined; the difference being the oxidized acids themselves. The sum of the fatty acids, oxy-acids, and unsaponifiable matter gave the Hehner number. The iodine value was estimated with the Waller solution, working for twenty-four hours in the dark, and arranging as accurately as possible for an excess of 50 per cent. of the iodine absorbed—uniformity is particularly necessary in this operation.

It should be noted that when the catch of dorse (Baltic cod) is small, brown liver oils appear on the markets which contain 5 per cent. or more of unsaponifiable matter. This does not always point to adulteration, but simply to a sort of fermentation and the use of a high temperature during extraction of the oils. Such products, of course, are of less value, and 3 per cent. should be taken as the limit. With the exception of herring-oil (No. 9) all were completely liquid and translucent at ordinary atmospheric temperatures, which shows that the greater part of the palmitin had already been precipitated by cold. The colours quoted were those given by a layer 2 cm. thick.

F. H. L.

Valuation of Resin. A. Heupel. (*Zeit. angew. Chem.*, 1899, 171.)—The results of more than 1,000 determinations of the acid and saponification numbers of colophony gave an average of 100 for the acid number and 170 for the saponification number, and a similar difference was found between these numbers with other resins. The author agrees with Schick that the determination of constants as a basis for the valuation of colophony is useless. Out of many thousands of casks of resin which he has examined, he has never found two to give the same constants.

H. H. B. S.

Contributions to our Knowledge of Colophony. R. Schick. (*Zeit. angew. Chem.*, 1899, 172.)—The author replies to Dieterich's remarks in the *Zeit. angew. Chem.*, No. 5. He again points out that Dieterich's "acid number," obtained by allowing the resin to stand for two hours in the cold, with excess of alcoholic potash and titrating back can be neither an acid number nor a saponification number, since it is greater than the number obtained by direct titration, and less than that obtained on standing for twelve hours in the cold. He considers that the sharpness of the end-reaction and the regularity of the decomposition which takes place on direct titration point to the correctness of this method of determining the acid number.

Among other reasons for objecting to the direct method of titration, Dieterich states that this method gives numbers below the calculated acid number of abietic

anhydride. The author replies to this by referring to the numbers given by Dieterich himself (155·85 to 170·80 and 168·00 to 183·50), and by pointing out that Perrenoud has already shown (*Chem. Zeit.*, 1885) that colophony does not consist solely of abietic anhydride. Further, Dieterich himself asserts in the same paper that the resins (and therefore presumably colophony) are to be regarded as mixtures of very uncertain composition.

The author does not attach any importance to the iodine number as a means of valuation, the fluctuations (as stated by Dieterich) being too great (*cf.* ANALYST, this vol., 77). H. H. B. S.

A Reaction of Gallic Acid, Tannin, and Pyrogallol. G. Griggi. (*Boll. Chim. farm.*, 1899, xxxviii., 5; through *Chem. Zeit. Rep.*, 1899, 29.)—When a few c.c. of a 1 per cent. solution of gallic acid are shaken with 1 c.c. of a 3·3 per cent. solution of potassium cyanide, a bright ruby-red colour is produced, which disappears on standing, but is re-formed every time the tube is agitated in presence of air. A drop or two of hydrogen peroxide also colours the bleached liquid similarly. A 1 per cent. solution of tannin or pyrogallol gives a yellowish-red colour with potassium cyanide, and the subsequent decolorization is slower. Agitation and hydrogen peroxide reproduce the tint, but an excess of the latter gives a permanent yellowish-brown colour with gallic acid, and a characteristic dirty-white precipitate with tannin. F. H. L.

A New Method of Estimating Tannin. L. Vignon. (*Bull. Soc. Chim.*, 1898, xix., 923-926.)—This is based on the fact that ungummed silk can absorb tannin quantitatively from an aqueous solution, leaving the other substances which usually accompany it (gallic acid, glucose, etc.). The silk is used in large excess of the tannin, which should be in dilute solution, the proportion being about 5 grammes of silk to 0·1 gramme of tannin in 100 c.c. of water. The tannin is absorbed after four or five hours at 50° C., and can then be determined by any of the usual methods; titration of the liquid with permanganate, using indigo as indicator, gave the most exact results.

The silk (ungummed) is prepared by being washed and rinsed in distilled water and dried, and 5 grammes are used for each estimation.

Absorption by silk has the advantage over absorption by violin-strings or hide-powder of being much more rapid, while, unlike hide-powder, it does not yield soluble organic matter to the solution. Finally, the colour of the silk after the absorption enables one to estimate comparatively the degree of coloration of the tannin—an indication which is of value to the dyer and to the tanner. C. A. M.

INORGANIC ANALYSIS.

Gravimetric Estimation of Sulphuric Acid in presence of Iron. The Importance of the Ionic Theory in Analytical Chemistry. F. W. Küster and A. Thiel. (*Zeits. anorg. Chem.*, 1899, xix., 97.)—It is now well known that sulphuric acid cannot safely be thrown down by means of barium chloride from a solution con-

taining dissolved iron; for inasmuch as the impurity in the precipitate takes the form of ferric sulphate, which is decomposed into oxide on ignition, part of the acid is lost, and attempts to purify the barium sulphate by extraction of the iron simply lead to increased deficiency in the yield, because they remove that portion of ferric oxide which, left behind, would partially take the place of the weight of sulphuric anhydride that was not originally combined with barium. The usual method of precipitating the iron first with ammonia and treating the *filtrate* with barium chloride consumes much time, and is also inaccurate, since some of the acid is carried down with the ferric hydrate as a basic sulphate. The authors find, however, that when barium chloride is added to a liquid in the presence of iron, the precipitate falls with absolute purity provided the iron is either (1) in an insoluble form, *i.e.*, a state of suspension; or (2) is in solution combined with a complex ion, *e.g.*, tartaric, or preferably oxalic acid.

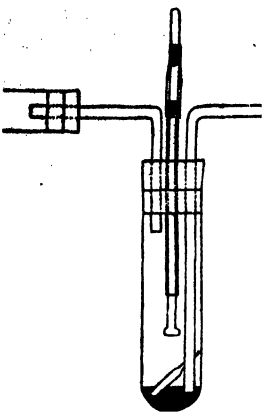
A solution of sulphuric acid and ferric chloride containing 2 atoms of iron to 3 of sulphur (the proportion occurring in pyrites) was prepared of such a strength that 25 c.c. should theoretically yield 0·713 gramme of $BaSO_4$. This volume was diluted with an equal amount of cold water, and an excess of ammonia (20 c.c.) introduced. The whole was heated almost to the boiling-point with constant stirring, and, neglecting the ferric hydrate, 15 c.c. of about 10 per cent. barium chloride solution were dropped in slowly. Eight c.c. of 10 per cent. hydrochloric acid were next added, and the liquid kept warm and well mixed for two hours. It was then set aside to cool for half an hour, the liquid run off through a filter, and the residue treated several times in succession with 2 c.c. of cold HCl and 30 c.c. of boiling water, allowing each extraction to take place for thirty minutes. Finally the barium sulphate was washed three times by decantation with boiling water, brought on to the filter, washed, dried, and weighed. The precipitate was perfectly white, and weighed from 0·7109 to 0·7142 (mean 0·7125) gramme: 0·5 milligramme, or 0·07 per cent., less than that required by theory. In the second process, 25 c.c. of the acid ferric chloride liquor were mixed with 15 c.c. of water and 25 c.c. of a cold saturated solution of ammonium oxalate, heated to the boil, precipitated with 15 c.c. of barium chloride, and acidified with 15 c.c. of HCl. The further treatment was precisely as above: the yield was almost pure white, and weighed 0·7115 or 0·7129 (mean 0·7122) gramme, *i.e.*, 0·8 milligramme, or 0·11 per cent., less than demanded by theory. A tartaric acid solution gave very similar results, and the barium sulphate was ultimately of perfect purity; but the employment of this acid is not to be recommended, for much more iron is first carried down, and the individual yields show wider variations among themselves.

In describing their methods and experiments, the authors express some surprise that the idea of converting the iron into some soluble compound other than sulphate before precipitation does not appear to have occurred to the numerous investigators who have endeavoured to overcome the difficulty of obtaining a barium sulphate uncontaminated with this troublesome and exceedingly common impurity. As Jannasch has conclusively shown that the precipitated iron always takes the shape of ferric sulphate, it is clear that such precipitation cannot occur unless the liquid contains ions both of ferric iron and of sulphuric acid. The latter obviously cannot

be avoided; the former may, either by throwing the metal entirely out of solution, or by combining it with some more complex ion which does not behave in an analogous fashion. The effect of precipitating and removing the iron as hydroxide is not perfectly satisfactory, and even with the greatest care must lead to a loss of some 0·5 per cent. of the sulphuric acid.

F. H. L.

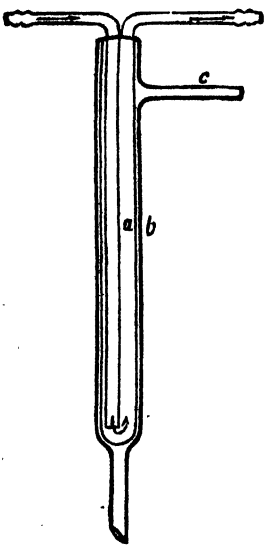
Estimation of Boric Acid. F. A. Gooch and L. C. Jones. (*Zeits. anorg. Chem.*, 1898, xix., 417.)—The process described by Thaddéeff (ANALYST, 1898, xxiii., 165) suffers from two defects: there is no proof that a mixture of potassium hydrogen fluoride and potassium borofluoride can be quantitatively separated by extraction with potassium acetate solution; while, as the present authors have definitely ascertained, when such a mixture is evaporated in presence of hydrofluoric acid, some of the boric acid volatilizes. Thaddéeff's method always gives too high a result, presumably because the former source of error is the more serious; obviously it can only be exact if they happen to neutralize one another.



The modified form of Rosenbladt's process, in which a borate is distilled with methylic alcohol and acid into a solution of a known weight of lime, is reasonably accurate. The acid may be nitric or acetic, and should only be employed in sufficient excess to decolorize phenolphthalein, a few drops more being added occasionally during the distillation. In this way the necessity for having such a large quantity of lime, as recommended by Moissan, is avoided. Particularly when nitric acid is adopted, the dried residue of lime and boric acid requires very cautious heating before the actual ignition; even with acetic acid it should be handled carefully to prevent loss. It is perfectly possible to ignite the original calcium oxide to constant weight, and to weigh it without appreciable error in spite of its hygroscopic nature; but to avoid the troublesome manipulation, the authors suggest sodium tungstate as an absorbent.

This salt is fused with a small excess of tungstic acid (to remove traces of carbonate); a known weight of lime (4 to 7 grammes for 0·2 to 0·3 gramme of boric oxide) is dissolved in water, placed in the receiver of the distilling apparatus, surrounded with ice-cold water, well agitated with the boric acid vapours, allowed to rest half an hour, and then evaporated, melted, and weighed. Using acetic acid, the residue must be ignited till it is perfectly colourless on cooling. Either nitric, acetic, or sulphuric acid can be employed—excess of the latter is objectionable. Various examples are quoted; the results are fair, but tend to be a little too low.

F. H. L.



APPARATUS.

Estimation of Carbon and Hydrogen in Volatile Organic Liquids. F. W. Streatfield and L. Eynon. (*Chemical News*, vol. lxxix. [2045], p. 50.)—The apparatus devised by the authors for this purpose consists of a strong, moderately large test-tube containing a small quantity of mercury and fitted with a triple-bore caoutchouc stopper. The tube from the supply of air

or oxygen dips into the mercury, to prevent backward diffusion; a second tube leads to the combustion tube; and a glass rod with a flattened head passes loosely through a tube fixed in the central bore of the stopper, communication with the external air being prevented by a joint of rubber tubing. The substance is introduced into the test-tube, enclosed in a sealed bulb which is broken by means of the rod, and the vapour is carefully expelled into the combustion tube by a current of air or oxygen entering through the supply tube. If the vapours are capable of attacking the caoutchouc fittings, the apparatus can be inverted, the air-supply tube being in such event bent upon itself so as to dip into the mercury seal. C. S.

A Condenser for Extraction Work. C. G. Hopkins. (*Journ. Amer. Chem. Soc.*, vol. xx. [12], pp. 965, 966.)—This condenser obviates the trouble caused by condensed atmospheric moisture collecting on the outer surface of Liebig or Allihn condensers and running down over the extraction apparatus.

It consists of a closed tube *a* of thin glass, 25 cm. long and 25 mm. external diameter, into the top of which are sealed two glass tubes about 6 mm. in diameter, as water inlet and outlet, one of them extending nearly to the bottom of *a*. The whole is enclosed, by sealing, in a stronger glass tube *b*, 30 mm. in internal diameter, drawn out below, for a length of 8 mm., to 10 mm., and ground off obliquely at the end. A lateral tube *c*, 5 cm. long and 12 mm. wide inside, is sealed on to *b*, about 3 cm. from the top, to facilitate connection with a drying tube.

The vapour being distributed in a thin layer over a large cooling surface, greater efficiency is obtained; the risk of breakage, through unequal expansion below and above the water-line, is nil; and the outer surface of the condenser is too warm to condense atmospheric moisture. C. S.

MISCELLANEOUS.

Antiseptics in Food.—A paper on the subject of preservatives or antiseptics in food was read by Dr. Alfred Hill, the Medical Officer of Health and Public Analyst for the City of Birmingham, at a recent meeting of the Incorporated Society of Medical Officers of Health. A discussion ensued, in which a number of medical officers of health and public analysts took part, and ultimately the following resolutions were adopted: (1) That the Incorporated Society of Medical Officers of Health strongly disapproves of the practice of adding preservative chemicals to milk and other foods. (2) That if preservative chemicals are added to any food, a full disclosure as to the nature and amount thereof should be made to the purchaser.

THE ANALYST.

JUNE, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, May 3, in the Chemical Society's Rooms, Burlington House, the President (Mr. W. W. Fisher, M.A.) occupying the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of the following candidates were read for the second time: Edward Halliwell, F.I.C.; Arthur John Starey; and William Lincolne Sutton, F.I.C.; and in favour of the following candidates for the first time: Thomas Waterworth Glass, B.Sc. (Lond.), Analyst, London; Henry Dixon Hewitt, assistant to Mr. Thomas A. Pooley, B.Sc., London; Daniel Lewis Thomas, Public Analyst for the Limehouse District, London; and Samuel Allinson Woodhead, B.Sc., Public Analyst for East Sussex, Uckfield.

Messrs. Julian L. Baker, F.I.C., Herbert E. Burgess, L. C. Deverell, Julius Lewkowitsch, Ph.D., F.I.C., F. R. O'Shaughnessy, Assoc. R.C.S., Arthur Marshall, A.I.C., and Edward T. Shelbourn, A.I.C., were elected members of the Society.

The following papers were read: "The Assay of Belladonna, B.P.," by F. C. J. Bird; "On the Use of Boric Acid and Formaldehyde as Milk Preservatives," by S. Rideal, D.Sc., and A. G. R. Foulerton, F.R.C.S., and "The Value of the Estimation of Pentosans in Food Materials," by Otto Hehner and W. P. Skertchly.

NOTE ON BORIC ACID IN MILK SAMPLES.

BY E. G. CLAYTON.

(*Read at the Meeting, March* 1, 1899.)

BORIC ACID was tested for qualitatively in 403 samples of milk received by me for analysis during the years 1893-98, and the following is a record of the results:

Total number of samples, 403; of these 164, or 40·6 per cent., contained boric acid. Thus:

In 1893, of	45	samples,	28	contained boric acid, or 62·2 per cent.
1894, ,,	28	,,	17	60·7
1895, ,,	92	,,	43	46·7
1896, ,,	62	,,	29	46·7
1897, ,,	108	,,	37	34·2
1898, ,,	68	,,	10	14·7
	403		164	

In the table on the opposite page the samples are classified according to quality, and the relative amounts of boric acid added. The numbers of adulterated, doubtful (that is, poor or inferior, or *probably* adulterated), and genuine samples are also shown. Watered milks and samples with the fat abstracted are indicated respectively by the letters w and s; both sophistications together are shown by w/s. The figures demonstrate a gradual diminution in the use of boric acid, possibly owing to the introduction of formaldehyde, which, however, was not tested for in any of these samples.

DISCUSSION.

The PRESIDENT desired to ask by what method the author had tested for boric acid. He himself had latterly found that the most expeditious way was one which had been described several years previously in the ANALYST (xvi., 180), viz., to heat 0·5 c.c. of the milk in a dish with a little weak and slightly acid tincture of turmeric. The reaction was thus obtained more readily than by any other method that he had tried.

Mr. CLAYTON said that he had tested the ash after acidification by hydrochloric acid with turmeric paper, confirming the test by applying alkali to the turmeric paper after drying. The alkali used was generally potash, but sometimes ammonia.

NOTES ON MILK ANALYSIS.

BY L. DE KONINGH, F.I.C.

(*Read at the Meeting, April* 12, 1899.)

Analysis of Sour Milks.—An attempt to analyse sour milks by the specific gravity process has already been successfully made by Weibull (*Chem. Zeit.*, 1895), the process being briefly as follows: The milk is mixed with a definite volume of ammonia of known specific gravity to the extent of about 25 per cent., the whole is well shaken until the milk solids have redissolved, and the volume is then carefully measured, the exact quantity of milk used thus being found; the specific gravity of the mixture is taken, and that of the milk found by calculation.

The process, I am informed, is accurate, but the result greatly depends on the skill of the operator; it also renders the estimation of the fat by the Leffmann-Beam process less accurate. The process which I now wish to bring to your notice is much more simple and less dependent on analytical skill, and, therefore, more suited for a commercial laboratory.

The whole, or at least the greater portion, of the well-mixed sample is emptied into a measure; an improvised one, having a mark 95 c.c., and also two other marks, 100 and 105 c.c. respectively, will generally be found to answer the purpose. After pouring in the milk up to the mark 95, solution of caustic soda is added up to 100 c.c., the whole is emptied into a dry flask and gently shaken for five minutes. The solution of the soda is made by partially filling a large cylinder with water at nearly 60° F., and then gradually adding strong aqueous soda until the specific gravity is exactly 1,030 (water = 1000) at 60° F. This gravity being the same as that of

average milk, a c.c. more or less of the alkali does not affect the experiment. The alkaline milk is now emptied into the ordinary test-glass, and its specific gravity taken at 60° F. with a delicate milk-hydrometer; if the temperature should differ from 60° F., then correct by means of Richmond's sliding rule. If the action of the soda has not been successful, empty the milk into the measure and add another 5 c.c. of soda; in one obstinate case 15 c.c. was required, but if the sample is not too stale 5 c.c. will always be sufficient. The specific gravity found may be assumed to be correct if the mixture has a density not greatly varying from 30; but if this is much higher or lower, the following correction should be applied: If 5 c.c. of alkali have been used, then deduct from the gravity found 1·5 and divide the difference by 0·95; if 10 or 15 c.c. have been used, substitute 3 or 4·5 for 1·5 and divide by 0·90 or 0·85 respectively.

When trying the accuracy of the process with samples, the specific gravity and fat of which were carefully taken when quite fresh, it was found that the specific gravities as found by the soda process were rather lower than might be accounted for by decomposition of the samples. The remarkable fact was now disclosed that when treating fresh milk with from 5 to 15 per cent. of the soda solution the gravity is instantly lowered, the hydrometer moving not quite so fast, although very regularly. I am at a loss to account for this phenomenon, but think it not improbable that it may be, partially at least, caused by the precipitation of the calcium triphosphate. The loss in specific gravity is, however, as far as my experiments go, fairly constant, and I therefore propose adding 0·8° in order to get the true gravity of the sour sample, and fancy that the result will be the same as that of the original milk minus the loss in specific gravity caused by decomposition.

To prevent disappointment, I wish to state particularly that I have no idea how the process will work with samples which are in an advanced state of decomposition, and deserve the name of "putrid." But I think the process will be found useful to those analysts who get their samples from a distance, or who are unavoidably prevented from touching them the very day they are brought in, and then find them unsuitable for the gravity process next morning.

The alkaline liquid may now be advantageously used for the estimation of the fat by the invaluable Leffmann-Beam process. If 5 c.c. of soda solution have been used, then add an extra c.c. to save the trouble of correcting for dilution.

Detection of Cane-Sugar.—It cannot be denied that the ordinary non-fatty-solids process is not alone conclusive, and that it is a very easy matter for intelligent milk-vendors to defeat the authorities by adding to their milk a solution of sugar, or highly dilute sweetened condensed milk. This, if much overdone, may be readily detected by the taste, but I quite agree with an experienced private inspector, who himself carried out some experiments, that although one may swear to the presence of 15 per cent. of sugar-water of 8 per cent. strength (this sugar solution has a density of 1030·8, and consequently defeats the gravity test), less than 10 per cent. is likely to be overlooked. Until recently it was not possible to certify the presence of sugar without making a regular chemical analysis coupled with polarimetric observations, and if the proportion of cane-sugar is below 1 per cent., I am somewhat doubtful as to the results so obtained. Moreover, the process is too complicated and takes too much time to be

of any use, either in a public or private laboratory, where the analyst is often required to give in his result the same day. Fortunately a test has recently been published (ANALYST, 1898, 37) which is based on the reduction of molybdic acid by cane-sugar, a fact already used for detecting simple syrup in commercial glycerin. Cotton, noticing that lactose has no reducing action, proposed the following test: 0·5 gramme of powdered ammonium molybdate is dissolved in 10 c.c. of milk, 10 c.c. of dilute hydrochloric acid (1 : 10) is added and the mixture heated slowly to 80° C., when the presence of cane-sugar will betray itself by a blue coloration, even when its amount does not exceed a few tenths of a per cent.; pure milk is said to be unaffected.

I have tried the process, and it certainly will detect 0·4 per cent. of cane-sugar. In practice I find it more convenient to keep a saturated solution of the reagent ready for use in a narrow graduated measure, 2 c.c. sufficing for one test; 8 c.c. of acid (1 : 8) is then added. The mixture first turns yellow owing to the formation of phospho-molybdate, but this precipitates along with the curd. The test-tube is now placed in water, which is then gradually heated to 80° C., and then kept for five minutes at that temperature, which should not on any account be exceeded. Those practising the process for the first time should make a blank experiment side by side with pure milk, so as to accustom the eyes to the slight but differently shaded colour always given by a genuine sample. With a little practice the process will be found to be a valuable one, and will enable the operator to state within fifteen minutes whether there is sufficient cane-sugar to unduly increase the non-fatty solids; the approximate amount may be judged by trying side-by-side a sample purposely mixed with, say, 10 per cent. of sugar solution. I tried whether decomposed milk gives any reduction, but find this is not the case; on the other hand, milk containing 5 per cent. of sugar-water and kept for fourteen days only gave a very unsatisfactory test, but another sample containing 10 per cent. still gave a decided reaction. It was also tried whether the presence of "colouring" might deceive the analyst. Annatto, the dye almost universally used in London, when added to milk in such quantity as to render the article unsaleable, does give a slight reduction, but the amount used in practice is so small that it does not interfere with the test.

Detection of Boric Acid.—It is well known that the incineration of a large quantity of fatty organic matter causes a loss of acid; the rapid evaporation of a large quantity of milk and the burning of its residue is also a very unpleasant operation. A good deal of inconvenience is avoided by adopting the following plan: 100 c.c. of milk are put into a large beaker covered with a light basin containing some cold water. The milk is now rapidly heated to boiling, the flame is at once removed, and 8 c.c. of very weak nitric acid (1 in 50) are poured in from a small test-tube. When cold the liquid is filtered, and an actual experiment has proved that this volume of acid just compensates for the volume occupied by the curd from good average milk; when dealing with separated milk 6 c.c. are sufficient. As there is no need to have an absolutely clear filtrate, the milk may be rapidly filtered through muslin and 80 c.c. collected. One eighth of a gramme of sodium carbonate is now added, and the whole is rapidly boiled down in a spacious platinum dish and finally burnt to a gray ash; the nitrate greatly assists in the burning, without, however, causing the least deflagration. The water-soluble portion of the ash is then tested for

boric acid either qualitatively or quantitatively by one of the now numerous methods. If done by the fluoride process it is preferable to use potassium instead of sodium carbonate. I have found that the aqueous solution of the ash can be obtained practically free from phosphoric acid in the following manner: Before adding the soda, add to the hot solution 2 drops of a saturated solution of calcium chloride and then a little ammonia. When cold filter off the calcium phosphate, which, however, in this case is not precipitated so completely as might be expected, distinct traces being afterwards found in the insoluble ash. As the filtration of the calcium phosphate is often a little slow, the filter-pump should be used.

NOTE ON A POSSIBLE SOURCE OF ERROR IN MODIFICATIONS OF THE LEFFMANN-BEAM METHOD FOR ESTIMATION OF FAT IN MILK.

By H. Droop Richmond and F. R. O'Shaughnessy.

(*Read at the Meeting, March* 1, 1899.)

Leffmann and Beam recommended the use of amyl alcohol mixed with an equal bulk of hydrochloric acid for their centrifugal method of fat estimation; one effect of the mixture was that the amyl alcohol was well distributed throughout the milk by the curdling effect of the hydrochloric acid before the sulphuric acid was added.

The modification of Gerber, in which the hydrochloric acid is omitted, has come into general use; his instructions were to add first the sulphuric acid, next the amyl alcohol, and finally the milk. He drew attention to the fact that the sulphuric acid and amyl alcohol could not be left long in contact without vitiating the results, and as an alternative recommended that the acid be added first, next the milk, and finally the amyl alcohol.

During the summer of 1897, it was found that when the acid and amyl alcohol were accidentally shaken up together (Gerber's original instructions being followed) before adding the milk, the fat obtained on centrifugalizing was frequently highly coloured, and the resulting estimation was invariably higher than when the acid and amyl-alcohol were not allowed to mix. The difference sometimes reached 0·5 per cent. We found that this effect was much more pronounced on very hot days, and in cold weather practically disappeared.

The following experiments will show that when amyl alcohol and strong sulphuric acid are mixed an action takes place resulting in the formation of a liquid compound which is insoluble in a more dilute acid, while a mixture of sulphuric acid, water, and amyl alcohol results in the formation of no such compound. The action between sulphuric acid and amyl alcohol increases at higher temperatures:

I. A milk giving 3·63 per cent. of fat by gravimetric estimation was taken and examined in the following way. The reagents were added in the following order:

a.	Sulphuric acid	10 c.c.	*b.*	Sulphuric acid	10 c.c.	*c.*	Amyl alcohol	1 c.c.
	Milk	11 ,,		Amyl alcohol	1 ,,		Sulphuric acid	10 ,,
	Amyl alcohol	1 ,,		Milk	11 ,,		Milk	11 ,,

One series of experiments was made at 14° C., and another at 29° C., which represent the temperatures of a laboratory in winter and summer.

The following mean results were obtained:

Temperature	...	...	14° C.	...	...	...	29° C.
a.	...	...	3·66 per cent. fat	...	...		3·63 per cent. fat.
b.	...	...	3·67 ,,	...	...		3·65 ,,
c.	...	...	3·76 ,,	...	...		4·11 ,,

The fat of *c* at 29° C. was darker than the others, and an odour was noted in this, but not in the others, which resembled that obtained on warming sulphuric acid and amyl alcohol. This experiment was several times repeated, with similar results.

II. To exaggerate the action and to see the effect of temperature, mixtures were made containing:

a.	Sulphuric acid	10 c.c.	*b.*	Sulphuric acid	15 c.c.
	Amyl alcohol	1 ,,		Amyl alcohol	1·5 ,,

One series was cooled during mixture and kept at 14° C. for fourteen hours, and the other series was not cooled and was left at 37° C. for fourteen hours; water was then added to make up to 30 c.c., and the separated layer measured. The results were:

Temperature	...	...	...	14° C.	...	...	...	37° C.
a.	...	...	...	0·295 c.c.	...	...	...	0·590 c.c.
b.	...	...	...	0·424 ,,	...	...	...	0·800 ,,

The layers at 14° C. were nearly transparent, while at 37° C. they were deeply coloured.

III. Ten c.c. sulphuric acid, 11 c.c. of water, and 1 c.c. amyl alcohol (all at 29° C.) were mixed; no separation occurred in centrifugalizing, and the solution only became light brown. One c.c. amyl alcohol, 10 c.c. sulphuric acid, and 11 c.c. water (all at 29° C.) were mixed and centrifugalized, a liquid layer equivalent to about 0·2 per cent. fat was obtained, and the liquid became violet.

IV. A series of experiments were made on the rate of heating of sulphuric acid, amyl alcohol, and mixtures of these two bodies in various proportions. The liquid to be heated was placed in a tube, contained in a second tube, which latter was immersed in boiling water. The difference in temperature between the liquid and water was taken, and the logarithms of a series of numbers so obtained were plotted against their corresponding times. The resulting curves, in the case of amyl alcohol which had been previously heated and of sulphuric acid, were straight lines. In the case of the mixtures in various proportions of these two bodies the curves all showed an increasing rate of rise, indicating that continued chemical change was taking place. Amyl alcohol which had not been previously heated showed an abnormal rate of rise, indicating a change on heating which is not continuous.

From our experiments we conclude:

1. To obtain correct results with the Gerber method it is advisable to always employ the alternative method, *i.e.*, to add first sulphuric acid, next milk, and finally amyl alcohol.

2. The modification of the method according to which amyl alcohol is added

first has a tendency to give high results, and at high temperatures (in hot weather) the error may assume serious proportions.

3. Gerber's original method gives good results in the hands of a careful operator, but may at times give rise to error.

We would point out that the order of adding reagents does not appear to be considered an essential part of the method, and there is no reason against Gerber's alternative order of adding reagents being always followed.

DISCUSSION.

The PRESIDENT having invited discussion,

Dr. DYER said that when he first used the Gerber apparatus, working by the original directions, he had often found charring to occur when the milk was put into the acid. When the milk was put in first, the fusel oil next, and the acid last, good results were obtained.

Mr. O'SHAUGHNESSY said that, according to their experience, it was more difficult to make a satisfactory mixture when the milk was put in first, owing to the curdling of the milk by the initial action of the acid.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Influence of Distillery Refuse on Cow's Milk. A. Petermann. (*Bull. de l'Ass. belge*, 1899, xiii., 148.)—The author has examined samples of milk taken at intervals of three months from a dairy of fifteen cows fed on maize wash from a distillery in Namur, but no trace of alcohol could be detected in 1 litre of milk.

The author's experience in this respect differs from that of Weller (ANALYST, xxii., 264). C. A. M.

Proportion of Water in Butter. B. Martiny. (*Landw. Jahrb.*, 1898, xxvii., 773; through *Chem. Zeit. Rep.*, 1899, 46.) As the result of more than 20,000 separate tests of different specimens of butter, the author finds the following average figures:

Country.	No. of Samples examined.	Water Per cent.
Germany, fresh	523	13·96
,, salt	1,107	13·01
Denmark	9,847	13·99
Sweden	4,423	13·66
Finland	438	11·18
England	334	12·08
France	225	13·40

F. H. L.

The Alteration of Milk-Fat in the Ripening of Cheese. H. Weigmann. (*Zeit. Untersuch. Nahr. Genussm.*, 1899, ii., 31, 32.)—Referring to Kirsten's recent communication (ANALYST, xxiv., 34), the author states that in his opinion the evidence there brought forward is insufficient to disprove the conclusions arrived at by Backe and himself (*Landw. Vers. Stat.*, 1898, li., 1-14), and also by Windisch and by Duclaux. He considers that all that Kirsten has proved is that the fat obtained by Devarda's method from the ripe cheese has the same composition as the fat from the same cheese before ripening. But, inasmuch as the treatment with potassium hydroxide solution removes all the free fatty acids as well as the decomposition products of the milk-sugar, he contends that Kirsten's experiments only show that Devarda's process is an excellent method for extracting from the cheese that part of the fat which has not undergone any change. C. A. M.

Detection of Cotton-Oil Stearin ("Vegetal") in Lard by means of the Phytosterin Test. Notes on the Bömer Process. F. Wirthle. (*Chem. Zeit.*, 1899, xxiii., 250.)—It has recently been suggested in the *Chem. Zeit. Rep.* that a certain proportion of cotton-oil stearin might be present in American lard without being capable of detection by Bömer's phytosterin test (*cf.*, however, ANALYST, 1898, xxiii., 283). The author has accordingly examined a lard adulterated with 10 per cent. of "vegetal," and has obtained the kind of crystals characteristic of a mixture of cholesterin with phytosterin (*i.e.*, short, compact, telescope-like needles).

As regards Bömer's process, Wirthle considers the Kreis and Wolf modification (ANALYST, 1898, xxiii., 294) more complicated than the original, and prefers to work as Bömer prescribed, using, however, only 25 grammes of fat. It is also advisable to add a larger volume of water to the alcoholic soap solution, viz., 130 instead of the 100 c.c. ($=\frac{200}{2}$), recommended by Bömer. The separation may be carried out successfully, and the cholesterin and phytosterin recovered pure, even from rancid fats, if the alcoholic residue after the second saponification is treated with animal charcoal before being crystallized from absolute alcohol; but from utterly putrid samples, some years old, no crystalline matter could be obtained.

"Vegetal" is a yellow substance, semi-solid at ordinary temperatures, which remains liquid a long time after it has once been melted. Its iodine number is 89·24, its saponification number 196·1, and its refractometer number, at 25° C., 63·3. It gives the Becchi and Welmans reactions powerfully. "Vegetal" is not pure cotton-oil stearin, but is partly composed thereof. F. H. L.

Estimation of Sugar in Molasses. O. Foerster. (*Chem. Zeit.*, 1899, xxiii., 196.)—Processes for the determination of sugar in molasses which are based on dissolving the substance in water and making up the liquid to a definite volume are inaccurate, owing to the uncertainty respecting the amount and composition of the insoluble residue; it is better, therefore, to recover the sugar by means of absolute alcohol. A multiple (n) of 13·024 grammes of the sample is rubbed down with spirit, placed in a Sickel extractor over a fine platinum gauze, and allowed to extract for

twelve hours. The spirit is driven off, the mass diluted to n times 75 c.c. with water, 75 c.c. are inverted, 50 c.c. are made up to half a litre, and 25 c.c. of the product (equal to 0·3256 gramme of molasses) are treated with copper, halving the figures given in Herzfeld's tables. As an alternative, the sugar may be determined optically.

F. H. L.

The Composition of Banana Flour. **A. Petermann.** (*Bull. de l'Ass. belge*, 1899, xiii., 147-48.)—Flour obtained from the banana is widely used in Central America. The starch which is extracted from it is known in Europe as "arrowroot of British Guiana." The starch granules are large and ovoid, and of characteristic form.

The author has made a chemical examination of the flour prepared by himself from the fruit of the *Musa paradisiaca* with the following results:

	Per cent.
Water	5·60
Fatty substances	1·73
Albuminous substances	3·13
Carbohydrates, etc.	82·39
Cellulose	1·22
Mineral matter	5·93
	100·00
Glucose	7·19
Dextrins	3·34
Starch	45·76

C. A. M.

The Detection of Maize Starch in Wheat Meal. **K. Baumann.** (*Zeit. f. Unters. Nahr. u. Genussm.*, 1899, ii., 27-29.)—It is claimed that as little as 1 or 2 per cent. of maize can be detected in wheat flour by the following method: About 0·1 gramme of the meal under examination is mixed with 10 c.c. of a 1·8 per cent. solution of potassium hydroxide, and the test-tube is shaken at intervals during two minutes. Four or five drops of hydrochloric acid (strength about 25 per cent.) are then added, and the tube is again shaken. The liquid must still remain alkaline, since the proteid substances which are precipitated in an acid solution interfere with the regular distribution of the liquid for microscopical examination. When a drop is placed on a glass slip and examined under the microscope, the wheat starch granules will be found completely ruptured, while the maize starch remains unaltered.

For a quantitative estimation, mixtures are prepared containing known quantities of the two starches, which are treated with the reagents, and drops of the liquid are compared with those of equal size from the sample in question. This method is equally applicable to the detection of maize starch in rye meal, the starch granules of which are ruptured by the potassium hydroxide even more rapidly than wheat starch. The advantages claimed for potassium hydroxide as a reagent over chloral hydrate are that the disintegrating action can be arrested at any given moment by the addition of acid, and that the wheat or rye starch granules are completely

ruptured without the maize being attacked, whereas with chloral hydrate a considerable proportion of the maize granules are burst, while a third or a quarter of the wheat starch still remains intact. C. A. M.

A Contribution to our Knowledge of Wine Vinegar. K. Farnsteiner. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, 198.)—The author has studied the changes which take place during the acetous fermentation of wine. Three different kinds of wine were experimented with, and the principal results obtained embodied in the following tables:

Grammes in 100 c.c.	I.			II.			III.

In the course of the investigation the author discovered the presence of a body of an aldehydic nature, which does not appear to be acetaldehyde. H. H. B. S.

Detection of Formaldehyde in Food Stuffs. F. Jean. (*Rev. Chim. Ind.*, 1899, x., 33; through *Chem. Zeit. Rep.*, 1899, 63.)—As formaldehyde yields insoluble compounds with albuminous substances, and as the methods hitherto advocated for its recognition also show other aldehydes, formalin is not easily detected in articles of food. The following process is recommended: 100 c.c. of the sample (milk, for instance) are heated to 70° C. with 4 or 5 drops of sulphuric acid, dry powdered sodium sulphate is added, the mass is distilled, and the first 50 c.c. of the distillate examined. In presence of formaldehyde this gives (1) a red colour with magenta, bleached by sulphurous acid, and turned violet or reddish by hydrochloric acid; (2) a turbidity with aniline water; (3) a yellow precipitate with Nessler's reagent, changing to red or brown on standing; (4) a turbidity with phenylhydrazine hydrochloride, the solution becoming blue on addition of sodium nitroprusside and sodium hydroxide. Conclusive evidence may be obtained by the blue colour produced with dimethylaniline, according to Trillat's suggestion. F. H. L.

Detection of Saccharin in Articles of Food and Drink. A. Hasterlik. (*Chem. Zeit.*, 1899, xxiii., 267.)—In Spaeth's process 50 c.c. of beer are evaporated with a few crystals of copper nitrate to remove hop-bitter principles, mixed with coarse, clean sand and phosphoric acid, extracted with ether and petroleum spirit, the liquid dried, and the residue dissolved in a little weak sodium carbonate. This solution is then tested in various ways. The sweet taste is very characteristic, and will detect 0·001 per cent. of saccharin; but if many samples have to be tried in succession, the tongue becomes fatigued with the secondary bitter taste of the material, and assistance should be obtained in judging the flavour. The alkaline solution may also be evaporated, the solid matter gradually introduced into fused potassium nitrate, the melt extracted with water, acidified with hydrochloric acid, concentrated if necessary, and sulphuric acid sought for with barium chloride: this process serves equally well for the quantitative estimation of saccharin. In the absence of salicylic acid and tannin, the ether residue may be fused for half an hour at 220° or 250° C. with sodium (not potassium) hydroxide, and the resulting salicylic acid tested for in the acidified aqueous solution with ferric chloride. As Abraham has quite recently shown, however (*Rev. intern. falsif.*, 1899, xii., 17), the iron is apt to give doubtful indications, and especially in the case of pastry, liqueurs, etc., the reaction must be received with caution. Börnstein's fluoresceïn test (*Ber.*, 1888, xxi., 3,396) with resorcinol and sulphuric acid is not only useless for beer, as was pointed out by Gantter, but is utterly without value in the examination of any fermented liquid. [The original article includes a table showing the results of this test as applied to various beers, wines, lemonades, syrups, etc., from which it appears that a green (sometimes a red) fluorescence is produced in the majority of instances, even when the ethereal extract has a sour or indifferent taste and when the salicylic acid reaction is absent.] F. H. L.

Solanine in Potatoes, and a Sensitive Reaction for its Detection. Bauer. (*Zeit. angew. Chem.*, 1899, 99.)—The author examined potatoes for solanine, according to the directions of G. Meyer (*Archiv. für experiment. Pathol. und Pharmacol.*, xxiii., 119, 361). The results were as follows:

Potatoes grown in 1897	...	...	0·02 gramme per kilo.
,, ,, 1898	...	...	0·026 ,, ,,

A solution of telluric acid in moderately dilute sulphuric acid is a very reliable reagent for the detection of minute quantities of solanine, producing an intense red coloration on warming. The reaction does not take place with atropine, morphine, quinine, and other alkaloids. H. H. B. S.

Gomberg's Method for Estimating Caffeine compared with other Methods. E. F. Ladd. (*Amer. Chem. Journ.*, vol. xx. [10], pp. 866-869.)—For this the following three solutions are required: The first contains 18 grammes of potassium iodide and 12·65 grammes of iodine per litre, the second 24·8 grammes of sodium thiosulphate per litre, and the third 4·913 grammes of potassium chromate per litre). The thiosulphate solution is standardized against the chromate solution, and the iodine potassium

iodide against the thiosulphate. A weighed quantity of tea, coffee, or other substance, is boiled with water, made up to a known volume, and filtered. An aliquot part of this is treated with basic lead acetate, until a precipitate ceases to form. After settling, the precipitate is filtered off, and the lead removed from the filtrate with hydrogen sulphide. The liquid, after being boiled to remove dissolved gas, is divided into two equal parts, one of these being acidulated with either sulphuric or hydrochloric acid. To both of these are added a definite quantity of the iodine potassium iodide solution, and, after settling for ten minutes, each is filtered off and titrated with $\frac{N}{10}$ thiosulphate solution. The acidulated portion serves to show if there is any substance present capable of being precipitated by Wagner's reagent; if there is, the corresponding correction is made. One c.c. of $\frac{N}{10}$ sodium thiosulphate solution corresponds to 0·00485 caffeine.

In the case of Vité's method, when working on pure caffeine, there was a loss of 10 per cent., and with tea the results came out as low as 42 per cent. below those yielded by Gomberg's method. Apparently the caffetannate in tea and coffee is not wholly broken up by the lead oxide.

Gomberg's method gave the best results, 99·9 and 100·5 per cent. of caffeine being recovered when working with 0·1 and 0·2 gramme respectively of the pure substance; and higher values than yielded by the other methods were obtained from teas.

For pure caffeine, Peligot's method proved about equal to Gomberg's, but with teas a loss of caffeine results from the use of an excess of lead and prolonged treatment with hydrogen sulphide.

Crosschoff's method gave good results with pure caffeine, but with teas the values came out from 0·355 to 0·786 per cent. below those yielded by the Gomberg method, which is, moreover, simple, and the most suitable one for rapid work.

C. S.

Estimation of Sinapine. **F. Bek.** (*Farmaz. J.*, 1899, xxi., 118; through *Chem. Zeit. Rep.*, 1899, 99.)—The author finds that by using the double thiocyanate of potassium and platinum (Guareschi's reagent for alkaloids) in place of the simple potassium salt, a higher yield of sinapine is obtained from mustard, and also that *Sinapis nigra* does contain some alkaloid, Huseman's statement to the contrary notwithstanding. In carrying out an analysis, 100 grammes of mustard flour are repeatedly extracted with 96 per cent. alcohol, the solvent is evaporated, the residue taken up in water, filtered from fat, mixed with the double thiocyanate, allowed to rest for a week, and the precipitate washed with ether. Calculated as sinapine thiocyanate, the comparative results of the processes are:

	Potassium Salt.	Guareschi's Double Salt.
Sinapis alba	0·509 per cent. ...	0·738 per cent.
,, ...	0·410 ,, ...	0·888 ,,
Sinapis nigra	— ,, ...	0·198 ,,

F. H. L.

On the Ash of Certain Descriptions of Cinnamon. G. Rupp. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, 209.)—A new article of commerce has recently been introduced in Germany under the title "cinnamon powder." It is said to be prepared from broken cinnamon. As the ash and sand of this preparation were found to exceed the limits of genuine cinnamon (5 per cent. of ash with 1 per cent. of sand), the author, at the request of the Chamber of Commerce (Karlsruhe), examined reliable specimens of broken cinnamon, as imported from China and Ceylon. The highest proportions of ash and sand found in these samples were:

	Ash.		Sand.
In the Chinese	6·08 per cent.	...	3·20 per cent.
„ „ Ceylon	6·50 „	...	2·48 „

On cleaning the specimens by picking out the larger stone particles and sifting out the sand, the proportions of ash and sand were much reduced.

As a result of the inquiry, the Government of the Grand Duchy of Baden, pending action by the Imperial Government, has fixed the maximum ash and sand permissible at 6 per cent. and 3 per cent. respectively. H. H. B. S.

Estimation of Alcohol in Tinctura Lobeliæ [Ætherea]. E. Dowzard. (*Pharm. Jour.*, 1899, lxii., 170; through *Chem. Zeit. Rep.*, 1899, 66.)—This operation being complicated owing to the presence of ether, the author makes use of the fact that alcohol combines with calcium chloride. Fifty grammes of the tincture are mixed with 25 grammes of anhydrous sodium sulphate, a large excess of calcium chloride is introduced, the whole allowed to rest for ten minutes, and the ether driven off by heating to 40° C.; water is then added, and the spirit determined as usual.

F. H. L.

ORGANIC ANALYSIS.

Solubility of Methane and Ethane in Fuming Sulphuric Acid. R. A. Worstall. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 245.)—In spite of the fact that the insolubility of the saturated hydrocarbons in fuming sulphuric acid forms one of the fundamental principles of ordinary gas analysis, the author finds that both methane and ethane are actually dissolved on standing over the acid for any length of time. One sample of methane prepared from methylic iodide lost, roughly, 4 per cent. of its volume per day during eleven days, and another from natural gas lost about 1·4 per cent. per day in much cooler weather. Ethane dissolved at the daily rate of 4·7 per cent. Further experiments to determine the absorption of each gas in short intervals of time showed that methane lost about 0·1 c.c. per hour, the corresponding figure with ethane being on an average 0·25 c.c. per hour. In technical gas analysis, therefore, assuming the absence of ethane, the gas may be allowed to rest over fuming sulphuric acid for an hour, if necessary, without serious error; but in presence of ethane fifteen minutes is the maximum; and in all cases the time of contact should be shortened as much as possible. F. H. L.

Detection of Acetone in Urine. R. van Melckebeke. (*Ann. Pharm.*, 1899, v., 49; through *Chem. Zeit. Rep.*, 1899, 84.)—The author considers Penzoldt's process the best: in presence of acetone a freshly-prepared solution of orthonitrobenzaldehyde gives a blue colour in a few minutes' time. It is better to apply the test to a distillate rather than to the urine itself. F. H. L.

Constitution of Oil of Orange Flowers (Neroli). Schimmel and Co.'s April Report. (*Chem. Zeit.*, 1899, xxiii., 330.)—Oil of orange flowers contains a nitrogenous constituent which is intimately connected with its peculiar odour, and which can be extracted by acid. On investigation this body has proved to be the methyl ester of anthranilic acid, distilling at 9 mm. pressure between 124° and 125° C., solidifying on standing, and melting at 25·5° C. Its solutions have a blue fluorescence, and by hydrolysis it yields anthranilic acid melting at 144° to 145°. The substance recovered from the natural oil is thus identical in every respect with the methyl ester synthetically prepared from anthranilic acid. Further details are promised.

F. H. L.

The Composition of Oil of Lemon Grass. H. Labbé. (*Bull. Soc. Chim.*), 1899, xxi., 77-79.)—According to the analysis of F. Tiemann (*Bull. Soc. Chim.* xx. [23], 1) this oil contains only one aldehyde (citral), which forms from 84 to 85 per cent. of the total constituents. As the author's experiments have led him to a different conclusion, he has again examined the oil, using the method of separating citral and citronellal previously described by him (ANALYST, this vol., p. 99).

One hundred grammes of the oil were shaken for two or three hours with an equal volume of a freshly-prepared saturated solution of sodium bisulphite, containing a small quantity of ether to facilitate the crystallization. The crystals were dissolved in water, the solution washed with ether, and a concentrated solution of barium chloride added. The precipitate (18 grammes) was washed with water, alcohol, and ether, and treated with alcoholic potassium hydroxide (5 per cent.) which decomposed it. On extraction with ether, about 6 grammes of an oil with the characteristics of citronellal were obtained. Theoretically at least 8·5 grammes of aldehyde should have been obtained by saponification, but the author states that he has not yet been able to recover the citronellal quantitatively from its barium compound.

The aqueous solution which had been treated with the potassium hydroxide yielded a considerable proportion of citral, and a further quantity which had escaped combination in the first treatment was obtained by again treating the original filtrate with bisulphite. The total amount of citral found was 76 to 77 per cent., or about 7 or 8 per cent. lower than that found by Tiemann. The citral obtained by the second treatment with bisulphite was practically free from citronellal, the bisulphite compound of which is more readily formed than that of citral.

The residue of 24 grammes was found to contain about 4 grammes of geraniol, the presence of which was also mentioned as probable by Tiemann; about 4 grammes of a liquid with an odour of citral (B. P. 200-220° C.); 3 to 4 grammes of a liquid

boiling at 170°-180° C., and judged by its odour and properties to be methyl-heptenone; and a residual portion of 8 to 9 grammes not yet investigated.

C. A. M.

The Composition of Essence of Petit-Grain. E. Charabot and L. Pillet. (*Bull. Soc. Chim.*, 1899, xxi., 74-77.)—The essential oil of petit-grain has usually been described as a slightly dextro-rotatory liquid, and the authors have found the oil from Paraguay to have this property and to be less soluble in 80 per cent. alcohol than the various lævo-rotatory specimens distilled by themselves in Cannes (ANALYST, this vol., p. 100).

The various French samples mixed together gave a product with a rotation of −5·34° at 15° C. and containing 61 per cent. of esters.

This oil saponified and distilled under normal pressure yielded the following fractions:

		°C.	Grammes.	Rotation in 100 millimetre tube.
1	before	185	20	− 9·40°
2	between	185-195	31	−12·45
3	,,	195-197	14	−13·00
4		197-200	110	−13·30
5		200-210	55	− 9·40
6		210-220	24	− 6·48
7		220-232	20	+ 0·20
8	residue and loss		36	

After several fractionations the first fraction was reduced to 11 grammes boiling below 185° C. with a rotation of −6·56°, from which the authors concluded that their native essence did not contain any appreciable quantity of limonene. This terpene was found by Tiemann and Semmler among the constituents of petit-grain, and has also been found by the authors in an American essence, the rotation of which was +0·12°, and which after a single fractionation gave a portion distilling below 190° C. with a rotation of +7·40°. They consider that the presence of the larger proportion of limonene explains the difference in character between the French and American oils, and suggest that this is probably due to French oil being obtained by the distillation of the leaves only, whilst in the preparation of American essences both leaves and oranges are employed.

All the fractions distilling below 197° contained linalol in considerable proportion, and the products boiling between 197° and 200° C. consisted of nearly pure linalol. The fraction boiling between 220° and 232° C. was composed almost exclusively of geraniol, which could be isolated by treatment with calcium chloride and converted into citral by oxidation.

The fractions boiling between 200° and 220° C. were mixtures of linalol and geraniol, the fifth fraction containing 70 per cent. of the former and 30 per cent. of the latter, and the sixth fraction about equal proportions of each, as indicated by the respective rotations.

The authors calculate that essence of petit-grain distilled from the leaves

alone contains after saponification 70 to 75 per cent. of lævo-rotatory linalol ($(\alpha)_D = -15{\cdot}72°$), and 15 to 10 per cent. of geraniol.

The residue yielded a solid substance crystallizing from petroleum spirit, and a liquid giving the reactions of sesquiterpenes. C. A. M.

Formation of Furfural from Starch and its Derivatives. F. Sestini. (*L'Orosi*, 1898, xx., 325; through *Chem. Zeit. Rep.*, 1899, 74.)—If 10 or 15 grammes of crust of bread are heated to 110° or 115° C. in an oven, furfural is given off, and may be recognised by the bright red colour produced on a piece of paper moistened with a solution of aniline acetate and exposed to aqueous vapour. Crumb of bread only shows a similar reaction after it has been dried and baked at a temperature of 140° or 160° till it assumes a hazel-nut tint. Distilled in a current of steam, crust yields no furfural, so that the substance does not exist as such in bread. Commercial or acid-free starch gives the same reaction if it is heated to 185° or 200°; and after moistening with sulphuric or hydrochloric acid yields furfural at 100°. Washed starch, in which the absence of pentosans was proved by means of phloroglucinol and hydrochloric acid, evolved notable quantities (0·44 to 1·16 per cent.) of furfural on boiling with hydrochloric acid (specific gravity, 1·06). Under similar conditions, pentosans themselves exhibit the same property. These experiments indicate that Tollens' process for estimating pentosans in hay is incorrect unless all sugar-forming substances (starch, dextrocellulose, etc.) are removed before treatment with acid.

F. H. L.

Estimation of Pentoses in Presence of Saccharose. Andrlik. (*Böhm. Zeits. Zuckerind.*, 1899, xxiii., 314; through *Chem. Zeit., Rep.*, 1899, 84.)—When pentoses are estimated by the phloroglucinol method, as the amount of sugar rises, increasing errors are produced, until 0·6 to 0·9 per cent. too much pentose is returned. The author has prepared a curve, by means of which the figures obtained on analysing mixtures of 9 grammes of saccharose with up to 3 per cent. of arabinose can be corrected. Per 100 parts of sugar, the diffusion syrup contains 0·20, the concentrated syrup 0·13, the first crystals 0·03 of pentoses; the remainder passing into the sludge and the molasses. F. H. L.

Influence of Temperature on the Optical Determination of Sugar. — Herzfeld. (*Zeits. Zuckerind.*, 1899, xlix., 1; through *Chem. Zeit. Rep.*, 1899, 65.) — Polarimetric observations ought to be made in a room where the temperature has remained constant for three hours; and in every laboratory a definite working temperature should be adopted, at which the value of the quartz plates should be checked on the normal weight of pure sugar. Correct results can thus be afterwards obtained with a half-shadow apparatus, even if the temperature of the test differs from the standard; but to be strictly accurate a correction of 0·00036 for every degree of variation from the 100-point and from the normal temperature should be made when working on crude sugars if the divergence in temperature is serious.

A simple setting of the zero point in good polarimeters insures the accuracy of the scale at the temperature of correction (17·5° or 20°); at other temperatures the value of the graduations changes. A normal sugar solution prepared at 20° and examined between 22° and 35° shows losses in rotatory power up to 0·6 per cent., and similar differences occur even if the tubes are not at the proper temperature.

F. H. L.

Methods for Distinguishing between Raw Linseed and Boiled Oil. F. Evers. (*Chem. Zeit.*, 1899, xxiii., 334.)—Linseed oil which has been boiled in presence of a drier is usually browner in colour, different in odour, and quicker in drying than the original material; but these tests are not certain, and are not available for the identification of mixtures of raw and boiled linseed oil. The author finds a process employed by the German Customs authorities quite satisfactory: 5 c.c. of a solution of 100 grammes of crystallized lead acetate in 150 c.c. of water are mixed with 1 c.c. of 20 per cent. of ammonia and 32 grammes of anhydrous glycerin; 12 c.c. of the oil are agitated with 6 c.c. of this reagent, and heated on the water-bath for three minutes. Raw linseed oil yields two distinct layers of liquid, the lower of which is perfectly clear; boiled oil containing a drier gives an emulsion. The metallic driers can also be extracted from a boiled oil by agitation with boiling dilute nitric acid, and the aqueous liquid can be examined as usual.

Linseed-oil "varnish"—*i.e.*, an oil boiled at a high temperature, or treated at a lower temperature with oxygen, without any addition of driers [*e.g.*, "lithographic varnish"]—does not respond to these tests, but naturally behaves like raw linseed. Morpurgo's process, however, is trustworthy. It depends on the fact that the soaps of raw linseed oil can be completely salted out of their aqueous solution, whereas those from a lithographic varnish remain partly in the liquid. The soap solution is prepared by the ordinary method of alcoholic saponification, the spirit is driven off, and the clear dilute liquid is treated with common salt as long as a precipitate falls. The mass is filtered, and acetic acid added in large excess: turbidity indicates an oil boiled without driers.

F. H. L.

[It may be remarked that linseed oil is seldom boiled without driers, except to such an extent as to raise considerably the specific gravity, redden the colour, cause a green fluorescence, and (mostly) to increase the viscosity to the eye. "Oxygenated" oils are not generally fluorescent, nor appreciably different in shade. In all cases, however, the iodine absorption is greatly diminished, falling some thirty to fifty points during the earliest stages of the boiling or blowing process. Oxygenated oils have a more disagreeable odour, especially on warming, than such as are prepared by fire heat; their specific gravity is higher; and they tend to dry rather more rapidly. However manufactured, the less viscid descriptions of lithographic varnish do not dry at all quicker than raw oil; while as the boiling progresses, the drying power (actually or apparently) falls off. *Cf. J. Soc. Chem. Ind.*, 1894, p. 203.—Abs.]

Examination of Oils and Varnish with the Refractometer. M. Weger. (*Zeits. angew. Chem.*, 1899, 297 and 330.)—In 1895 Hefelmann and Mann stated

that the purity of an oil or oil-varnish could be ascertained by examining the products in Zeiss's refractometer, and that the extreme limits were 80·6° to 84·2° for genuine varnishes uncontaminated with rosin, rosin oil, or mineral oil. Further experiments have shown that, although this is true in the majority of cases, there are numerous exceptions and irregularities, so that the optical method is not trustworthy unless it is checked by a chemical investigation—*e.g.*, determination of the saponification value and the amount of unsaponifiable matter.

As regards pure linseed oil, the refractometer number at 25° in sodium light ranges between 80·2° and 82·2°, one English specimen, which possessed an unusually high iodine number and a great capacity for absorbing oxygen, giving 85·1°. After "boiling," blowing with air, or the natural absorption of oxygen on keeping, linseed oil has a higher refractometer number; but the several products cannot be distinguished one from another by this means. The quantity of oxygen that a pure linseed oil or varnish is capable of absorbing rises with an increasing iodine number, but the refractive power does not invariably rise in the same manner—at least, such parallelism is only characteristic of new, raw oils. Among the boiled and oxidized oils and linseed varnishes the oxygen absorption and iodine values stand in inverse proportion to the refractometer number. The general effect on the refraction of linseed oil of treating it in various ways is shown in the annexed table; and similar results obtain with the non-drying oils, raw rape showing 69·2°, blown or thickened rape, 74·7° and 78·2°.

Sample No.	Material.	Refractometer No.
1	Raw Indian linseed oil	80·2
2	No. 1 + 1 per cent. of mangano-lead resinate, prepared cold ...	81·6
3	,, + 2 ,, ,, ,, ...	82·8
4	,, + 3 ,, ,, ,, ...	83·6
5	,, + 5 ,, ,, ,, ...	85·8
6	No. 6 heated to 150° C. for 1 hour	86·7
7	No. 1 + 1 per cent. of manganese linoleate dissolved at 50° ...	81·1
8	No. 7 heated to 150° C. for 2 hours	82·2
9	No. 1 + 0·5 per cent. of litharge and 0·3 per cent. manganese hydroxide heated to 230° C. for 2 hours	85·5
10	Commercial "Elektrofirniss," free from driers	89·8
11	English "ozonized" varnish containing 2 per cent. mangano-lead resinate	87·3

The refractometer numbers given by different mineral oils vary from 67·1° to over 105°; rosin and rosin oil also exhibit figures higher than 105°; fresh American oil of turpentine shows 65·5°, and, after exposure to air and partial evaporation, 77·0°. Therefore the refractometer cannot ensure the absence of these substances; and if they be not present, a high optical number does not point to adulteration, but may even be evidence of good qualities. The most that can safely be said is that an oil giving figures lying between Hefelmann's limits must be genuine. Weger's article includes sundry tables recording the refraction, oxygen-absorbing power, speed of drying, etc., of oils, boiled oils, drying oils, and linseed varnishes, made by different processes, and examined fresh or after being stored for various intervals of time.

F. H. L.

Analysis of Dégras, or Sod-Oil. E. Hopkins, D. L. Coburn, and E. Spiller. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 291.)—Dégras proper is defined as the oil obtained from skins in the manufacture of chamois leather, as distinguished from sod-oil, which is the oil obtained from ordinary leather. In its preparation cheap fish-oils are mostly used—*e.g.*, menhaden and cod oils; but even olive-oil and certain greases are occasionally employed, which give the "constants" an exceedingly wide range. The chief features of dégras are the presence of the so-called "dégras former," hide fragments, and a high proportion of ash, and it is claimed that the value of the material rises with the amount of "former" and diminishes with that of mineral acid; but the price of the product does not appear to be governed by these factors. Dégras former, a comparatively uninvestigated substance, is described as being of a resinous nature (not a resin), melting at 65° to 67° C., and showing certain degrees of solubility in various solvents.

To estimate the moisture, the authors prefer to absorb the oil in a roll of ashless paper, enclosed in a folded filter (like a paper capsule), placed between two wads of cotton in a short test-tube, with a hole at the base. This is dried to constant weight at 100° C. while a current of air is aspirated through it. The dried sample is extracted in a small Soxhlet with petroleum ether (boiling-point 40° C.) to give the soluble matter, then with alcohol to recover the soap, while the residue is ignited to yield the ash and (by difference) the hide fragments. As both soap and oil contain inorganic matter, the total ash should be determined on another sample. The dégras former is estimated by a modification of the Jean process: The oil is saponified (determining unsaponifiable matter at the same time), the solvents evaporated, the soaps dissolved in hot water and salted out, the liquid filtered, cooled, and hydrochloric acid added; the former is collected on a filter (simple decantation leads to loss), washed with water till free from salt, etc., and with petroleum spirit till free from oil, then dissolved in absolute alcohol, evaporated, and weighed. It should melt at 65° to 67° C. As it exists in sod-oil, dégras former can be extracted by petroleum spirit, but in the pure state it is insoluble in this reagent. When titrating dégras soaps with acid in presence of phenolphthalein to ascertain the saponification value, etc., the interference of the dark liquid may be avoided by shaking the flask and watching the appearance of the foam.

The paper also includes copious tables of the results obtained on analysing some twelve different specimens of dégras; but in view of their very irregular and divergent character, the figures are scarcely capable of useful reproduction or condensation. The proportion of dégras former ranges between 0·65 and 21·41 per cent.; of hide fragments between 0·15 and 3 per cent.; of mineral acid in terms of milligrammes of potassium hydroxide per gramme of oil, between 0·96 and 90·5 per cent.; and of total ash between 0·05 and 1·05 per cent.—all calculated on the original wet material.

F. H. L.

Estimation of Tannins, and the Influence of Gallic Acid on the Process. A. Heinemann. (*Zeits. angew. Chem.*, 1899, 245.)—This article consists of a comparative study of the von Schröder-Löwenthal volumetric and the Simand-Weiss gravimetric methods of estimating tannins, as well as an investigation into the effect

produced on the results by the presence of varying proportions of gallic acid. The paper is scarcely capable of systematic abstraction; but the following points are brought out in the course of the work. No processes except those mentioned above are of the least use in valuing materials containing tannin; Vignon's idea of employing silk instead of hide-powder may perhaps be equally practicable; no process whatever can lay claim to real accuracy. The two chief sources of error in the hide-powder methods are (*a*) the undesirable precipitation of various substances (colouring matters, gallic acid) which were previously held in solution by the tannins, but which are no longer soluble after the tannin-hide reaction has taken place, and (*b*) the absorbing power of the hide-powder for non-tannins. As the solutions used in the volumetric process are less concentrated than those in the gravimetric, *a* is not so serious in the former case; on the contrary, for the same reason, and on account of the larger excess of hide-powder (30 : 1, as against 3 : 1), *b* is the chief defect of the volumetric method. This may partly be avoided by conducting the tannin absorption in stronger liquids (1 : 100), and diluting to 1 : 500 before titration. When the two processes yield different results, the gravimetric one is always lower, and probably more correct. The difference can only be explained by the absorption of bodies other than tannin which reduce permanganate powerfully. The difference, also, is roughly proportional to the amount of gallic acid present.

Mixtures of tannins with gallic acid cannot be valued by the volumetric process, for 1 gramme of the dry acid reacts with the same quantity of permanganate as 1·505 gramme of dry tannin. Provided the solution does not contain more than 5 or 10 per cent. of gallic acid, the gravimetric process is fairly trustworthy, each 1 per cent. of gallic acid up to 15 per cent. increasing the yield of tannin by 0·19 per cent., and from 15 to 30 per cent. by 0·17 per cent. A large excess of hide-powder in a dilute liquid absorbs almost all the gallic acid; 3 grammes per 1 gramme of tannin in 100 c.c. is sufficient.

The Weiss-Eitner-Simand process (*Zeits. Anal. Chem.*, xxviii. 110) is not satisfactory; and it must be remembered that the effect of adding 1 gramme of hide-powder three times in succession, and filtering between each, as done by Weiss, is widely different from that of introducing 3 grammes at once. The former plan leads to increased absorption of gallic acid. Gravimetrically, Vignon's method requires enormous weights of silk (11 : 1); apart from this, the modification is fairly good. Volumetrically it exhibits all the defects of the von Schröder-Löwenthal process, except that it absorbs far less gallic acid.

On the whole, the following seems to be the best method of conducting the operation: The hide-powder is agitated with twenty times its weight of water, allowed to settle, and filtered through linen; this is repeated six or eight times, and finally it is extracted with alcohol, filtered, and dried at 100° C. The tannin solution should contain from 1 to 1·5 gramme per 100 c.c.; it is treated with 3 grammes of hide-powder, and allowed to react for fourteen or sixteen hours, with occasional agitation. The mass is filtered through paper, the filtrate tested for tannin with a 1 per cent. solution of gelatin containing (as a preservative) a trace of phenol, and, if thought necessary, with a solution of pure tannin for dissolved hide-powder. If neither is present, an aliquot portion is evaporated to obtain the non-tannins and the tannins by difference.

The author complains that hitherto analysts have always approached this problem from the leather manufacturer's point of view, whereas the value of a particular "tannin" is by no means the same to the tanner, the dyer, and the writing-ink maker. Gallic acid is simply an impurity in the two former businesses, but it is very serviceable in the preparation of an iron ink. The article concludes with sundry speculations as to the theoretical constitution of the tannins.

F. H. L.

Separation and Identification of Coumarin and Vanillin. W. H. Hess and A. B. Prescott. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 256.)—Twenty-five to 100 grammes of the commercial extract are evaporated at 80° C., with periodical additions of water to keep the volume of liquid constant till the alcohol has volatilized. Normal lead acetate is dropped in with agitation as long as a precipitate falls; the mass is filtered under pressure through asbestos, and the precipitate washed with a few c.c. of hot water. The cool filtrate is extracted three or four times with ether, or preferably chloroform, till all soluble matter is recovered; and the solution is treated in a separating funnel several times with 2 c.c. of 1 : 2 ammonia as long as the aqueous liquid becomes yellow. The ether is washed with 2 c.c. of water (the washings being mixed with the ammonia), then allowed to evaporate spontaneously or over sulphuric acid *in vacuo*, using a sealed capillary tube with its open end beneath the solution to prevent bumping. When free from moisture, or after drying at a temperature not exceeding 45° C., the ethereal residue is dissolved in a little cold petroleum spirit (boiling point 30° to 40° C.), the solvent is driven off *in vacuo* over paraffin, the coumarin dried at or below 45° and weighed. Its melting-point (67°) should be determined, and, coupled with the odour, is sufficient for identification. The ammoniacal liquid containing the vanillin is rendered faintly acid with 10 per cent. hydrochloric acid, then shaken out with ether, the solvent removed, and the residue dried *in vacuo* over sulphuric acid, or at a temperature not exceeding 55° C. The mass is extracted with boiling petroleum spirit, the solution decanted into a tared dish, evaporated at 55° and weighed. The yield should be pure vanillin melting at 80° to 81° C. After weighing, its colour reactions may be tested; but it should be noted that some vanillin extracts contain phenol-like bodies that give colours with iron salts, therefore such tests are only trustworthy after purification. Experiments on artificially prepared mixtures gave yields of 96 to 98 per cent. of the coumarin taken. The process is quicker and easier to work than the bisulphite method, and the separation of the vanillin is more complete.

F. H. L.

The Hæmatin of the Blood of Different Animals. P. Cazeneuve and P. Breteau. (*Journ. Pharm. Chim.*, 1899, ix., 321-23.)—The authors find that hæmatin prepared in the following rapid manner is a chemically pure substance, and varies in composition with the species of animal from whose blood it was derived.

The defibrinated blood is heated to the boiling point with its own weight of sodium sulphate. The precipitate is collected, washed with boiling water, slightly drained, and extracted at 50° C. in a mortar with successive small portions of 93 per

cent. alcohol, containing 10 grammes of oxalic acid per litre. About 2 litres of solvent are required to extract the precipitate from 1 litre of blood. Strong ammonium hydroxide solution is added drop by drop to the filtered alcoholic extracts, care being taken that the liquid still remains acid. The gelatinous precipitate of hæmatin is collected on a filter, washed with cold alcohol, redissolved in dilute ammonium hydroxide (5 per cent.), and reprecipitated with acetic acid. Finally it is washed successively with cold water, alcohol (93 per cent.), and ether, and dried first at the ordinary temperature, and then for twenty-four hours at 135° C. The yield amounts to about 1 gramme of hæmatin from a litre of blood.

According to the authors' analyses, the hæmatin thus obtained from the blood of the ox, horse, and sheep has the following elementary composition:

	Ox.	Horse.	Sheep.
Carbon	64·68	64·37	64·24
Hydrogen	5·33	5·38	5·32
Nitrogen	9·02	10·11	9·41
Iron	8·81	9·38	10·65
Oxygen...	12·16	10·76	10·38
	100·00	100·00	100·00

An analysis of the hæmatin of ox-blood by Hoppe-Seyler is given for the purpose of comparison: Carbon, 64·30; hydrogen, 5·50; nitrogen, 9·20; iron, 8·83.

Note on the Estimation of Hydrocyanic Acid by Liebig's Method. **Lextreit.** (*Journ. Pharm. Chim.*, 1899, ix., 323-25.)—Liebig's method of determining hydrocyanic acid consists in first neutralizing the acid with potassium hydroxide, and then titrating the liquid with a standard solution of silver nitrate. A very soluble double cyanide of silver and potassium is produced, and the end of the titration is shown by the formation of the insoluble silver cyanide. The author points out that there are two objections to this method. If any free hydrocyanic acid is left in the liquid it does not react with the silver nitrate. And on the other hand, if too large an excess of potassium hydroxide be added the formation of silver cyanide is interfered with. Moreover, alkaline cyanides themselves have a distinctly alkaline reaction towards ordinary indicators, such as turmeric and phenol-phthalein, and it is therefore difficult to determine the exact point of neutralization.

This difficulty is obviated by using as indicator the blue C4B, which is not acted upon by alkaline cyanides or hydrocyanic acid, but is changed to red by alkaline hydroxides.

Having determined the amount of alkali required to neutralize the acid in the liquid, this quantity is added to a similar portion, and the titration with silver nitrate carried out in the usual manner.

Medicinal hydrocyanic acid is frequently prepared by decomposing potassium cyanide with tartaric acid. Liebig's method is unsuitable for the valuation of such preparations, since silver tartrate is formed and disappears too slowly, especially towards the end of the reaction, so that the final reading is not sharp. C. A. M.

Estimation of Uric Acid. E. Mallet. (*Rep. Pharm.*, 1899, lv., 100; through *Chem. Zeit. Rep.*, 1899, 93.)—This is essentially a combination of the Denigès and the Hopkins processes. One hundred c.c. of urine are treated with 10 c.c. of a 16 per cent. solution of anhydrous sodium carbonate to remove the phosphates. The filtrate is mixed with 5 c.c. of a 4 per cent. solution of copper sulphate and 20 c.c. of a reagent prepared as follows: sodium thiosulphate (cryst.) 100 grammes, Rochelle salt 100 grammes, water 1 litre. The precipitate is well washed, suspended in 500 c.c. of water, decomposed with 5 c.c, of sulphuric acid, and the uric acid titrated with permanganate. The results agree well with those obtained by the methods referred to above. F. H. L.

Reactions between Iron Salts and Pyrogallol. A. Hirsh. (*Pharm. Zeit.*, 1899, xliv., 205; through *Chem. Zeit. Rep.*, 1899, 99.)—When a few c.c. of a 1 per cent. solution of pyrogallol are mixed with 2 drops of dilute ferric chloride, an amethyst blue colour is produced, which very quickly changes to reddish-brown. One c.c. of 0·1 per cent. sodium hydroxide solution alters the colour to dark blue, and a trace of mineral acid restores the brown. The brown tint is, therefore, due essentially to the inorganic acid; for on adding ferric acetate to the pyrogallol, a blue colour is formed, which is also changed to red-brown by a mineral acid. With ferrous salts the white turbidity mentioned by Beilstein does not appear if the solutions are very weak, and an intense blue coloration is given on the addition of a minute amount of caustic soda. F. H. L.

INORGANIC ANALYSIS.

Estimation of Sulphuric Acid in Presence of Iron. Determination of Pyrrhotite in Pyrites. O. Herting. *Zeits. angew. Chem.*, 1899, 274.)—Provided the instructions are carefully followed, Herting has always found Lunge's process quite accurate; and comparative experiments with Küster and Thiel's methods (ANALYST, this vol., p. 137) show that the latter are less rapid and convenient.

The author also calls attention to the frequent presence of pyrrhotite in American pyrites, which is not completely burnt in the usual furnaces, and refers to Cone's process (ANALYST, 1893, xxi., 223) for its estimation. F. H. L.

Estimation of Sulphuric Acid in Presence of Iron. G. Lunge. (*Zeits. anorg. Chem.*, 1898, xix., 454.)—This is a protest against the inference contained in Küster and Thiel's article (ANALYST, this vol., p. 137) that Lunge's process is tedious and inaccurate. It can be carried out completely in two or three hours; whereas the very removal of the iron in the methods suggested by the former authors occupies four hours. As regards accuracy, Jannasch himself has admitted that the Lunge process is trustworthy (*J. pr. Chem.* [2], xl., 236). F. H. L.

Determination of Tungsten in Steel. G. Auchy. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 239.)—In the estimation of tungsten in steel the amount of acid in

the liquid from which the tungstic acid and silica are filtered should be as small as possible; and the preceding evaporation to dryness to render them insoluble should take place in hydrochloric (not nitric) acid solution. Evaporation of a nitric acid solution does not lead to a complete separation of the tungsten; but in presence of hydrochloric acid, provided an excess be not employed, only one evaporation to total dryness is necessary. The best method of procedure is to dissolve 4 grammes* of the steel in dilute nitric acid, evaporating until a scum appears on the surface, adding 30 or 40 c.c. of strong HCl, evaporating to dryness and heating on the hot plate, dissolving in 40 c.c. of strong HCl, evaporating again until a scum forms, taking up in 5 c.c. of HCl and 15 c.c. of water, heating, diluting with 25 or 30 c.c. of hot water and filtering.

At least in the case of steels low in phosphorus, the tungstic acid need not be removed before estimating the former; but the yellow molybdate precipitate must not be allowed to stand more than 2 or 2½ hours. When neutralizing with ammonia, excess must be avoided, or tungstic acid will be thrown down and remain undissolved in the nitric acid subsequently introduced. The usual method of getting ferro-tungsten into solution depends on a preliminary roasting; the author has obtained unsatisfactory results when operating in this manner. He prefers to attack the alloy by heating it with strong nitric acid, adding strong hydrochloric acid by degrees, and then following the above scheme. A metallic residue is left consisting apparently of almost pure tungsten; but this is readily oxidized by ignition after it has been removed by filtration. F. H. L.

Some Reactions of Chloric, Bromic, and Iodic Acids. D. Vitali. (*Giorn. Farm. Trieste*, 1899, iv., 39; through *Chem. Zeit. Rep.*, 1899, 99.)—When a solution of manganous sulphate acidified with sulphuric acid is treated with a bromate, a fine violet colour is produced, which is due to a mixture of basic manganese sulphate and free bromine. The salts of chloric and iodic acids yield no colours. This reaction may be used as a means of determining manganese; for if the violet liquid is boiled for some time, the metal is finally precipitated as dioxide.

Salts of iodic acid are decomposed in the cold by hydroxylamine sulphate, iodine being liberated; bromates only behave similarly on warming; chlorates remain unreduced. An analogous reaction occurs with compounds of phenylhydrazine, but the iodine, instead of being set free, combines with the phenyl group, producing a red precipitate which presumably consists of triiodophenol.

Hypophosphorous acid decomposes iodates in the cold, liberating iodine at first and yielding finally a mixture of a phosphate and hydriodic acid; bromates are attacked on warming; chlorates not at all. F. H. L.

Titration of Persulphates. M. le Blanc and M. Eckardt. (*Zeits. Elektrochem.*, 1899, v., 355; through *Chem. Zeit. Rep.*, 1899, 62.)—Processes for determining the active oxygen in solutions of persulphates which depend on addition of

* If 3·9655 grammes be weighed out, the yield of WO_3 multiplied by 20 gives directly the percentage of tungsten in the steel.

ferrous ammonium sulphate, followed by titration with permanganate, are apt to give too low results, unless the temperature during the operation be raised. The employment of a large excess of iron salt serves the same purpose, but warming is simpler and more accurate. F. H. L.

A New Indicator for Acidimetry. E. Riegler. (*Bulet. Soc. de Sciinte din Bucuresci*, 1899, vii., 453.)—This body consists of the diazo colour which is prepared by treating an alkaline solution of guaiacol with diazoparanitraniline. It is a brown substance, insoluble in water, and soluble in alcohol. 0·20 gramme dissolved in 100 c.c. of spirit forms an indicator exceeding phenolphthalein in sensitiveness, bright red in alkaline liquids, greenish-yellow with acids. F. H. L.

REVIEWS.

CHEMICAL AND BIOLOGICAL ANALYSIS OF WATER. T. H. PEARMAIN and C. G. MOOR, M.A. Cantab. (Baillière, Tindall and Cox. Price 5s.)

In the 168 pages the authors have given a résumé of the subject which, if not sufficiently detailed for the practitioner, will undoubtedly be of service to the lay reader. The work is mainly a reprint from articles in the *Sanitary Record*, and presents a selection of processes which the authors have found convenient. Forty-seven pages are devoted to bacteriology and a chapter on aerated table-waters completes the volume. S. R.

THE MICROSCOPY OF DRINKING WATER. GEO. CHANDLER WHIPPLE, of the Brooklyn Department of Water Supply. (Wiley and Sons, New York; and Chapman and Hall, London. Price 3.50 dollars.)

So much exclusive attention is at present allotted to the Schizomycetes that the larger organisms in most text-books are passed over in a few paragraphs with rare and often incorrect illustrations, with the result that information has to be laboriously gathered from large and expensive monographs like those of M. C. Cooke and others. This book, then, with its delicately-executed plates, succinct descriptions, completed by a brief but sufficient glossary, and useful bibliography and tables, will be welcomed by the "water analyst and waterworks engineer," for whom it is intended. The latter is often painfully cognizant of the objectionable taste, odours, or appearances that many of the macro-organisms communicate to a supply. In Chapter XII. instances are given of the obstructions and difficulties that at recent dates these growths have occasioned in pipes and aqueducts, and "systematic and thorough flushing" is enjoined. The sections on distribution of minute life are exceedingly interesting, and seem exact; on p. 123 quantitative experiments are detailed, comparing the number of these organisms with definite amounts of various odorous chemicals. It is found that "in some cases the odoriferous substances from the organisms pass through the filter, and the disintegration of the organisms gives the filtered water an increased odour over the unfiltered." Though the work is modestly said to be "elementary

in character," and to have been prepared "during the leisure moments of a busy year," it is a valuable contribution to a somewhat neglected section of "Limnology" —the study of lakes and ponds. If any fault can be found, it is that while the Sedgwick-Rafter sand-plug and the "plankton net" of Hensen are fully described, the Dibdin micro-filter, which would appear for many reasons to be preferable, is not mentioned, and the Italian and German researches on the pathogenic action of some Protozoa should also have had some notice. The lesson of the book is summarized in the opening sentence of Chapter X.: "To obtain a permanently safe and satisfactory surface water supply without filtration, the rainfall must be collected quickly from a clean watershed and stored in a clean reservoir"—ideal conditions which are not always attainable in populous countries. S. R.

COMMERCIAL ORGANIC ANALYSIS. By ALFRED H. ALLEN. Third edition. Vol. II., Part I.: Oils, Fats, Waxes, Glycerol, Nitroglycerin, and Nitroglycerin Explosives. Revised and Edited by DR. HENRY LEFFMANN, Philadelphia. (London: J. and A. Churchill, 1899.) Price 14s.

Mr. Allen's great work on "Commercial Organic Analysis" is a text-book which has been found indispensable in every practical laboratory, and which is so well known that it needs no extended notice whenever a new edition of one or other of the volumes appears. We cannot refrain from congratulating the author that new editions are called for, for they give him the opportunity of bringing his work up to date, the more so as the literature on the technical subjects which are treated of by Mr. Allen is growing by leaps and bounds.

The labour of keeping a work of the magnitude of Mr. Allen's up to date is so enormous that one need not experience any surprise that the author has found it necessary to call in the aid of a collaborateur on the present occasion, although it is at the same time to be regretted that Mr. Allen has not been able personally to conduct the work comprised in the present volume, referring as it does to a branch of knowledge in which he is an acknowledged authority, and to which he has contributed so much original information. The aid of an American collaborateur has been felt necessary on account of the threatened appearance of an unauthorized and piratical American reprint, and the present volume therefore appears simultaneously in England and America.

The new edition contains many additions of new matter which has appeared during the last few years—bromine thermal methods, methods for the determination of glycerol, acetyl numbers, various tests for oxidation of oils, composition of and methods for the examination of dynamites and smokeless powders, dégras, cloth oils, and so forth.

Some of these additions are indicated by a different type from that used in the text of the book, while others appear as an appendix to the volume.

There is no class of organic substances of such immense technical importance in the investigation of which so much remains to be done as in that of oils and fats. Some advance in our knowledge has been made during the last ten or fifteen years, but the progress has been far from being in proportion to the importance of the subject.

The research chemist, who naturally prefers to work with compounds which admit of ready isolation and study, has deliberately kept his hands from unpromising and uncrystallizable unsaturated fatty matters. Almost everything which has of late years been accomplished in the elucidation of this theme has had to be done by practical chemists, upon whom the need for differentiating the multitude of oils occurring in commerce has daily pressed. Happily the empirical knowledge which was formerly deemed sufficient is slowly making place for more scientific views.

If we have any fault to find with the volume before us, it is perhaps that sufficient prominence has not been given to the *real* chemistry of oils, little as we know of it. If the problem of their constitution—a most complex and difficult one in any case—is to be solved as satisfactorily as that of sugars and other carbohydrates has been in recent years, it is obvious that new paths of investigation will have to be adopted, and the ripe experience of Mr. Allen in indicating such new paths would have been of great value to investigators.

As yet even the constitution of a body apparently so simple as oleic acid can hardly be regarded as definitely settled; we know nothing of the constitution of the less saturated acids, like linolenic acid; we are still in ignorance as to the constitutional difference between any two oils possessing approximately similar iodine absorptions but of widely different properties; and since we do not know whether these differences are due to constitutional differences in the fatty acids, or whether we have to do with different mixed glycerides, it is obvious that a vast field for research is still left practically untouched.

Since the appearance of the first edition of Mr. Allen's volume on fats and oils, the literature on the subject has increased rapidly. A vast amount of material has been collected which deals mainly with constants—admirable aids to the practical man, though only of moderate theoretical value. In comparing the present volume with the most comprehensive work on "Fats" by another author, it must not be forgotten that Mr. Allen's volume is a portion—only a small portion—of a great and comprehensive work travelling over a vast field of which fatty bodies form but a small part. Just as little as one would expect to find in a general text-book on chemistry a full account of all the modern knowledge, for instance, of the sugars, so Mr. Allen's work should be considered mainly from the point of view on which the whole work was undertaken—the detection and determination of the impurities, adulterations, and products of decomposition of the materials referred to in the work.

As a practical guide, Mr. Allen's third edition is of the same high standard of excellence as were the previous ones, and anyone who has to analyse fatty substances will find in it the fullest and most trustworthy practical information. O. H.

THE ANALYST.

JULY, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, June 7, in the rooms of the Chemical Society, Burlington House. In the unavoidable absence of the President the chair was taken by Mr. Alfred H. Allen (Vice-President).

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of the following candidates were read for the second time: Thomas Waterworth Glass, B.Sc. (Lond.); Henry Dixon Hewitt; Daniel Lewis Thomas; and Samuel Allinson Woodhead, B.Sc.; and in favour of the following candidates for the first time: Frederick Davis, Analyst, 51, Imperial Buildings, Ludgate Circus, London; William Francis, Chief Analyst to the Condensed Milk Company of Ireland, Limited, Limerick; and Edward Russell, B.Sc. (Lond.), F.I.C., Demonstrator of State Medicine, King's College, London.

The CHAIRMAN (Mr. Allen) said that he had recently paid a short visit to the United States, and wished to express to the Society his sense of the cordial and friendly feeling entertained by American chemists towards the Society of Public Analysts as a society, and towards its members individually—a feeling which he was sure would be heartily reciprocated.

The following papers were then read: "On some Comparative Analyses of, and Digestive Experiments with, White and Wholemeal Breads," by Otto Rosenheim, Ph.D., and P. Schidrowitz, Ph.D.; "Note on Coffee Extracts," by C. G. Moor, M.A., and Martin Priest; "On the Determination of the Iodine Value," by J. Lewkowitsch, Ph.D.; and "On the Influence of Ammonium Salts on the Precipitation of Nickel by Ammonia," by Arthur Marshall.

ON A RECENT GINGER CASE.

By E. J. BEVAN, BERNARD DYER, AND OTTO HEHNER.

(Read at the Meeting, April 12, 1899.)

IN a recent case heard at Barnsley, Mr. Allen certified that a certain sample of ginger consisted of 50 per cent. of genuine ginger and 50 per cent. of ginger deprived of its pungent principles. The case was referred to the Government analysts, whose certificate upon the sample was as follows:

"Government Laboratory, Clement's Inn Passage, Strand, London, W.C.

"The sample of ground ginger marked No. 421, and referred to in your letter of

the 23rd ult., was received here on the following day, securely sealed. We hereby certify that we have analysed the ginger, and declare the results of our analysis to be as follows:

Soluble in 90 per cent. alcohol	4·56 per cent.
Soluble in ether (volatile oil)	0·43 ,,
Fixed oil and resin	4·43 ,,
Soluble in alcohol after ether	1·08 ,,
Soluble in water after alcohol and ether	3·70 ,,
Total ash	2·33 ,,
Ash soluble in water	1·03 ,,
Loss on drying sample (at 212° F.)	12·70 ,,

The microscopic and physical characters of the sample indicate that it belongs to one of the lower-grade descriptions of commercial ginger. The amounts soluble in alcohol and ether respectively are equal to that found in genuine ginger of this class, and afford no evidence that the sample has been exhausted with alcohol. The proportions of matter soluble in water, and of ash soluble in water, are lower than we have found in unwashed ginger; but as these amounts are easily reduced by the ordinary washing of the ginger, which usually occurs before grinding, they do not, in our opinion, afford evidence that the sample in question is a mixture of genuine ground ginger and ginger exhausted of its pungent principles. The microscopic and analytical results are consistent with the conclusion that the sample in question is a 'washed' Japan, or similar low-grade ginger. As witness our hands this eleventh day of February, 1899.

(Signed) "G. LEWIN, H. W. DAVIS."

It is quite possible that the supposition that this was a washed ginger may be correct; but if so, it had been washed in no "ordinary" fashion, but in such an exhaustive and drastic way that the matter soluble in water after alcohol and ether was reduced to 3·7 per cent. Of course, some of the matter soluble in alcohol after ether would be also soluble in water, but the total matter soluble in water was rather less than 5 per cent.

Even samples of ginger that have been washed more than is usual sometimes contain 9 or 10 per cent. of matter soluble in water, and no ginger that has been properly washed should contain less than 9 or 10 per cent. of matter soluble in cold water. It is perfectly clear that at least half the total matter soluble in water in this ginger had been removed.

The magistrates felt obliged to dismiss the case, for it was, of course, admitted, both by Mr. Allen and by ourselves (who gave corroborative evidence as to the exhaustion), that it was not possible to say whether the sample was a mixture, as literally described in the certificate, containing one-half of its weight of exhausted ginger, or whether it consisted entirely of half-exhausted ginger. If the certificate had been to the effect that half of the principles of the ginger had been exhausted, there would probably have been a conviction. Although the magistrates dismissed the summons, they stated, through their chairman, that the case was a perfectly

proper one to have been brought forward and proceeded with, and they refused to allow any costs to the defendant.

The main point of interest in the case to Public Analysts is the finding of the Government chemists, and the way in which it is expressed. It was clearly admitted in this certificate that washing to some extent removed the soluble matter, but there was no indication in the certificate that the washing (if the cause of the abnormality) had been in this case of an unusually drastic or exhaustive character, and no statement to the effect that the result of whatever had happened to this sample was precisely the same as if the sample had consisted of a mixture of exhausted and unexhausted ginger. Furthermore, the Government chemists appear to assume that exhausted ginger means ginger exhausted with alcohol, forgetful of the fact that fermentation ginger-beer is made by the water-exhaustion of ginger.

We have ourselves met with many samples of badly-washed ginger, but never with a case carried so far as this, assuming the exhaustion to have been produced as the Government chemists suggest. Ginger can be quite properly washed without any appreciable exhaustion; but it is washed by persons called in the trade "ginger-washers," who in their operations sometimes use hydrochloric acid and bleaching-powder, which have to be washed out; and if the washers steep the ginger for two or three days, it is obvious that they may turn out exhausted ginger.

From what we hear in the spice trade, we think there is some hope that the process of washing may be abandoned altogether, on account of the excessive extent to which it has sometimes been carried. Obviously it matters nothing to the ultimate consumer of the ginger how or by whom or for what purpose the exhaustion is produced.

Discussion.

The President (Mr. Fisher) said it was very unsatisfactory that an article like the sample referred to—which obviously must be regarded as exhausted ginger, by whatever means the exhaustion had been arrived at—should be passed by a certificate describing it as nothing worse than a low-grade ginger. That, he thought, was rather an unhappy expression, and it did not seem from the report that the authorities who issued it were particularly anxious to put down this tampering with ginger. Whether the exhaustion was wilful, or whether it arose through negligence or ignorance, could not be established; but it was regrettable that such a certificate should come from the principal analytical laboratory in the country.

Mr. Moor referred again to the question whether the British Pharmacopœia could be taken as laying down a standard in the case of ginger. The Pharmacopœia did not recognise washing at all, and he thought it was doubtful how far such trade customs ought to be regarded as being any excuse for abnormal samples.

Mr. Chattaway agreed with the authors that the probable result of the action which from time to time had been taken in this matter would be the use of unwashed ginger for grinding. He had gone into the matter pretty closely from a trade point of view, and had reason to think that there was very little ground ginger being made at present except from ginger that had only been washed at the port of export. On the other hand, almost all ginger that was sold whole was still washed at least once in this country, and probably also abroad before exportation.

THE ESTIMATION OF FAT IN MILK, USING PETROLEUM ETHER AS A SOLVENT.

By H. Droop Richmond and C. H. Rosier.

(*Read at the Meeting, April* 12, 1899.)

The almost universally used solvent for fat in milk analysis is ether, and the form usually employed in this country is methylated ether. This solvent has certain undesirable qualities, as it is composed largely of methyl-ethoxide, which, being very volatile, causes a considerable loss of solvent.

Petroleum ether is free from these drawbacks, and has the further advantage of being an excellent solvent for fats, and not dissolving many other substances. Another property in which petroleum ether differs from ether is its insolubility in water, a property which has been considered as an advantage, but which is the one property to which many failures to successfully employ this solvent is due.

In order to see plainly the conditions under which petroleum ether can be used to extract fat from milk, it is necessary to consider slightly the theoretical bearings of the subject.

Milk may be considered for this purpose as an emulsion of small fat globules in a somewhat viscous liquid; the relation between the surface energy of the fat and the liquid is such that a layer is condensed around the fat-globules, which prevents its being touched by anything except the liquid, unless special forces are brought into play. It would therefore be quite hopeless to expect to extract fat from milk by petroleum ether or any solvent which does not dissolve in the liquid portion.

By so modifying the relation between the surface energy of the fat and the liquid that the layer becomes a semi-permeable membrane, a solvent such as petroleum ether would extract fat from this liquid, provided the solvent could be brought into contact with each globule. A solvent like ether soluble in the liquid would be very much more efficient in this respect, as it would dissolve in the liquid, and distribute itself between liquid and fat in proportion to its solubility in each; as ether is very soluble in (liquid) fat, and fairly so in aqueous liquids, the fat globules would soon take up large amounts of ether, and become practically solutions of fat in ether; from their large size and low density they would rapidly rise to the surface, and coalesce to form a liquid layer, and the fat would without difficulty become evenly distributed throughout the ether on shaking.

To attain the same end with petroleum ether, the mixture must be so perfect that every fat globule is brought into contact with petroleum ether. This state of things can only be attained in practice when a sufficient length of time is allowed for the fat globules to rise to the surface, which would prolong the time necessary for an estimation of fat to many hours. Under these circumstances the use of petroleum ether would be a disadvantage.

The employment of amyl-alcohol to expedite the time taken for the fat to rise to the surface, devised by Leffmann and Beam, and elaborated by Gerber, appeared to be a condition likely to insure the extraction of fat by petroleum ether in a short time. We had no fear that amyl-alcohol would be extracted with the fat, as we were

convinced by previous experiment that it combined with the sulphuric acid used to make the milk suitable for extraction, and formed a compound very soluble in water.

The mode of procedure described below was devised entirely from theoretical considerations, though we hoped at first to be able to omit the washing with water. The fact that the process founded on theory worked well in practice incidentally affords evidence of the correctness of the views set forth above.

The following experiments illustrate the slowness with which petroleum ether extracts fat from milk boiled with hydrochloric acid, when nothing is present to hasten the separation of the fat. Three samples of milk were treated by the Werner-Schmid process, petroleum ether being substituted for ether.

	I.	II.	III.
Percentage of fat (Storch)	3·95	3·74	3·84
Fat deduced from the evaporation of an aliquot portion of petroleum ether	—	2·28	—
Fat in three extractions with petroleum ether ...	2·59	3·20	2·83
Fat in a second three extractions with petroleum ether	2·84	3·31	2·94

We next substituted sulphuric acid for the hydrochloric acid, and added amyl-alcohol—in fact, we used the Gerber method as far as mixing was concerned, but instead of placing in a centrifugal machine we cooled and added petroleum ether. This was allowed to separate, re-mixed, allowed to separate again, re-mixed a second time, and finally allowed to separate; an aliquot portion was evaporated. It was observed that the petroleum ether, after the first separation, was not homogeneous, a more highly-refracting layer being easily seen at the bottom. This was expected, and the re-mixing was adopted to guard against this. We found that the layer of petroleum ether containing fat always occupied a volume greater than the petroleum ether added, and the excess was practically equal to the volume of the fat. It was found also that petroleum ether extracted from a mixture of sulphuric acid, water, and amyl-alcohol, a small amount of substance having an ethereal smell.

The table below gives the results of our preliminary experiments:

	I.	II.	III.
Percentage of fat (Storch)... ...	3·34	3·88	3·88
Percentage of fat deduced from an aliquot portion, neglecting volume of fat...	3·38	3·91 3·88 3·87	3·91 3·88
Percentage of fat deduced from an aliquot portion, correcting for volume of fat	3·43	3·97 3·96 3·95	3·97 3·96
Percentage of fat deduced from an aliquot portion, correcting for volume of fat, and for blank ...	3·33	3·87 3·87 3·86	3·87 3·87
Percentage of fat deduced from complete extraction	3·52		
Ditto corrected for blank	3·32		
Percentage of fat deduced from complete extraction and washing the petroleum ether once with water...	—	3·90	3·86

In all experiments where the petroleum ether was not washed the fat darkened on drying, and an odour resembling that of amyl butyrate was developed; this we attribute to the extraction of a little amyl-hydrogen sulphate.

We found that when the petroleum ether was washed the fat was nearly white and odourless.

The following mode of procedure is now adopted: Nine c.c. of sulphuric acid (90-91 per cent. H_2SO_4) are measured into a tube holding about 50 c.c., and constricted just above the point where 20 c.c. reach; 10 grammes of milk are weighed into this tube, care being taken to prevent the milk and acid mixing; 0·9 c.c of amyl alcohol is added, the tube corked, and well shaken; after cooling to about 25° C., 20 c.c. of petroleum ether are added, and the tube well shaken. When separation is complete, the contents of the tube are again well mixed, and allowed to separate; a second re-mixture and separation is given, and the petroleum ether blown off into a tube containing 20 c.c. of water, with which it is shaken and allowed to separate. After separation from the water, the petroleum ether is blown off into a tared flask. Further portions of petroleum ether are added to the tube containing the acid liquid, blown off into the tube containing the water, and transferred to the flask.

We are in the habit of whirling the tubes in a Leffmann-Beam centrifugal machine to reduce the time necessary for separation.

The following additional results will show that this method compares well with others.

Petroleum Ether.	Other Methods.	Methods Used.
3·76	3·75	Storch
3·62	3·62	,,
3·04	3·00	Ritthausen
3·63	3·59	Storch
3·64	3·60	,,
3·67	3·66	,,
4·00	4·00	,,
64·72	64·70	Amyl alcohol extraction

We use this method chiefly because the employment of ether is avoided.

Discussion.

Dr Dyer thought that it was rather to the credit of petroleum ether that it did not give, in the Werner-Schmid process, the same good results which were obtained with ordinary ether. The Werner-Schmid method, although it gave excellent results, only did so in virtue of its errors being balanced in different directions. Scientifically speaking, in spite of its good results, it was a slipshod process. It was assumed that all the fat was obtained in the supernatant ether, but as a matter of fact a tangible proportion of fat remained in association with the ether that still remained in the acid fluid. However, the residue of the supernatant ether, which was called fat, contained, besides fat, nondescript substances, formed probably by the action of the acid on the milk sugar and curd. These impurities, by some happy natural provision, balanced the fat that was not dissolved in the supernatant ether, so that fairly accurate results were obtained. Petroleum ether apparently did not dissolve these substances, though after prolonged shaking higher results were obtained. The

Werner-Schmid process gave admirable results if it was carried out in a separator, the acid liquor being run off and washed with ether a second time, the total ether washings being then washed with a small quantity of water. In the ordinary way, if the ethereal residue were re-dissolved in ether after it was dry, there was a considerable quantity of material which did not dissolve. The errors, perhaps, were not very great, and balanced one another pretty closely in the case of ordinary milk, but in the case of separated milk the percentage error, having regard to the small proportion of fat, was often very large in the Werner-Schmid process as generally used.

Mr. CHAPMAN remarked that petroleum ether was somewhat variable in character, and inquired whether the particular kind of petroleum ether employed affected the results.

Mr. RICHMOND said that Mr. Rosier and he had only employed one kind of petroleum spirit, which was obtained by careful fractionation, and boiled below 80° C. As low a boiling-point as possible was chosen in order that the petroleum spirit might be readily driven off from the fat by drying in a water-bath. He might mention that the fat extracted by petroleum spirit was obtained perfectly white and free from odour if the spirit containing the fat were washed with water. If this were not done, a small quantity of acid was dissolved out, probably in the form of acid ethereal sulphate.

THE ASSAY OF BELLADONNA PLASTER.

By F. C. J. BIRD.

(Read at the Meeting, May 3, 1899.)

THE determination of the alkaloidal value of samples of the belladonna plaster of the Pharmacopœia is an operation which has presented some difficulty on account of the interference of the soap, resin, and other ingredients which enter into its composition. Belladonna plaster (B.P.) should contain 0·5 per cent. of the alkaloids of belladonna root (atropine and hyoscyamine), and there are present in addition lead plaster, resin, and hard soap, together with the evaporated residue of the liquid extract, consisting of fatty and resinous bodies, colouring and extractive matters. During the process of manufacture a certain amount of evaporation takes place, so that the alkaloidal content of the plaster should really be a trifle over 0·5 per cent.

Solvents such as petroleum spirit, chloroform, etc., were at first tried, but they failed to completely dissolve the plaster, and the attempt to wash out the alkaloids merely resulted in hopeless emulsification. Finally a mixture of glacial acetic acid and chloroform was found to be the most satisfactory solvent, only a small and negligiable quantity of colouring and extractive matter remaining undissolved. On addition of dilute sulphuric acid the lead oleate, stearate and soap are decomposed, lead sulphate being precipitated, and the liberated fatty acids and resin going into solution in the chloroform. The alkaloids as sulphates are taken up by the aqueous liquid, and if the whole be thrown on a Buchner's vacuum filter the lead sulphate can be removed as a solid cake, whilst the chloroform and aqueous layer pass through in a clear and easily separable condition.

The following is the process in detail:

Belladonna plaster (B.P.)	15 grammes.
Chloroform	35 c.c.
Glacial acetic acid	5 c.c.

Warm gently to dissolve, and add

Water	40 c.c.
Dilute sulphuric acid (1 in 12)	35 c.c.

Again warm and pour on a 4-inch Buchner's filter connected with a vacuum of 8 to 10 inches of mercury. Remove the nearly dry cake of lead sulphate, break it up, and warm with

Chloroform	10 c.c.
Dilute sulphuric acid	5 c.c.
Water	10 c.c.

Again filter, and transfer the mixed filtrates to a separator. Run off the chloroform (aiding its separation, if necessary, by warming), wash twice with

Dilute sulphuric acid	1 c.c.
Hot water	4 c.c.

and return the washings to the aqueous portion.

To the mixed aqueous liquids add

Chloroform	20 c.c.
Solution of ammonia	A decided excess.

Warm gently, and agitate. Continue the process according to the directions given in the Pharmacopœia, as follows, assisting the separation of the chloroformic layer, whenever necessary, by the application of a gentle heat: "Separate the chloroformic solution, and twice repeat the agitation with 10 c.c. of chloroform and the separation. Shake the mixed chloroformic solutions with 5 c.c. of diluted sulphuric acid (1 in 12), mixed with twice its volume of warm water; separate the chloroformic liquid, and repeat the agitation with acidulated water. Wash the mixed acid liquids with 3 c.c. of chloroform; then agitate with 10 c.c. of chloroform and an excess of solution of ammonia. Separate the chloroformic solution; twice repeat the agitation with chloroform and the separation; wash the mixed chloroformic solutions with 5 c.c. of water containing one drop of solution of ammonia; draw off the chloroformic layer into a counterpoised dish, evaporate on a water-bath, dry the residue below 100° C., and weigh. Dissolve the residue in 10 c.c. of a decinormal solution of hydrochloric acid, and add centinormal solution of soda, free from carbonate, until the liquid is neutral, using tincture of cochineal as indicator. Deduct the measure of the soda solution thus required from 100 c.c., and multiply the remainder by 0·00287; the product will be the weight in grammes of alkaloids present in the 15 grammes of plaster operated upon." The figures obtained by weighing and by titration should agree within about 5 milligrammes.

This method has been in use, with satisfactory results, during the past three months, and its accuracy has been verified by the analysis of samples of known composition.

DISCUSSION.

Dr. RIDEAL said that a considerable number of analyses of belladonna plaster had recently been made in the United States and Canada, where the subject was being much discussed. In America belladonna plasters were made with a rubber base instead of resin plaster, and the process of extracting the alkaloids from them was of necessity different from that required in the case of B.P. plaster. In the last edition of the British Pharmacopœia, under the heading "Emplastrum Belladonnæ," directions were given for preparing the plaster with a certain proportion of the standardized extract of belladonna, containing 0·75 per cent. of alkaloids, it being stated in addition that the plaster so made should contain 0·5 per cent. of alkaloids. Now, the alkaloids of belladonna were extremely unstable, and it was quite conceivable that the method of manufacture laid down in the Pharmacopœia might involve some loss of alkaloids. Since the publication of the new edition of the Pharmacopœia, the efforts of manufacturers have been directed towards the production of a plaster showing on analysis 0·5 per cent. of alkaloids, and he believed that considerable difficulty had been experienced in producing a 0·5 plaster from the 0·75 extract. Some manufacturers had, he believed, actually departed from the instructions, and used an extract stronger than that prescribed by the Pharmacopœia. He had had the opportunity of comparing Mr. Bird's process with some other processes, and had obtained some interesting results, examining for the purpose two specimens of plaster, respectively prepared by Mr. Bird's firm and by another firm according to the Pharmacopœia directions. In the first place he had estimated the alkaloid obtained by titration with Mayer's reagent, a process which was very generally used in the United States for the final valuation of belladonna plasters made with rubber. There was some difficulty in deciding upon the proper factor to be used with this reagent in the case of B.P. plaster, but he had eventually adopted that recommended by Dr. Muter, viz., 0·0049 for $\frac{N}{10}$ Mayer's reagent, which he believed was Dragendorff's original figure. This test gave 0·473 per cent. of alkaloids in the case of the plaster made by Mr. Bird's firm, while Mr. Bird's process (the separated alkaloids being weighed) gave 0·62 and 0·596 in duplicate determinations. In the latter cases, however, the alkaloids were probably not quite thoroughly dry. Titration with soda, according to the British Pharmacopœia, gave 0·512 or 0·518; and an American method, known as Smith's method, gave 0·454 per cent., a result which was obviously too low. The other sample gave 0·48 and 0·43 by Mr. Bird's process, 0·43 by the B.P. method, and 0·398 and 0·372 by Smith's process, the latter giving in this case also a result obviously too low. There was considerable advantage in a modification originally suggested by Smith. After the alkaloids had been obtained in a dry state, there was a little difficulty in getting them thoroughly dissolved in the acid before titrating; this difficulty was completely overcome by adding about 1 c.c. of chloroform to the solid alkaloids, so as to effect their solution before adding the acid. He thought hæmatoxylin, which was recommended by Smith as an indicator, was a little more satisfactory than the tincture of cochineal which was the official indicator in the B.P.

Mr. BIRD said it seemed only right to mention that about March last an

American journal published a process by Frank X. Moerk which was substantially the same in principle as that referred to in this paper, except that the plaster without previous solution was treated directly with aqueous sulphuric acid. This, however, was open to some objection, as it presented certain difficulties in working. He (Mr. Bird) had experimented with plasters of American origin, using glacial acetic acid and chloroform as a solvent, and had found that after about three minutes' immersion the whole of the rubber and belladonna was removed from the cloth. On treating the solution with sulphuric acid, there was very little difficulty in filtering it and getting a solution which responded very clearly to the tests for belladonna alkaloids; the method would therefore probably prove useful in the analysis of plasters with rubber bases. The process of manufacture might involve loss of alkaloids if proper precautions were not taken; but if the liquid extract were evaporated at as low a temperature as possible, and mixed with the resin plaster at a low temperature, there would be practically no loss. The first sample referred to by Dr. Rideal had rather an interesting history. It was made in strict accordance with the Pharmacopœia directions from a carefully assayed liquid extract of belladonna, with the view of ascertaining if loss of alkaloid was a necessary accompaniment of the B.P. process of manufacture, and when finally assayed showed 0·51 per cent. of alkaloids, a result almost in suspicious agreement with that obtained by Dr. Rideal in his analysis of the same sample by this process. The use of chloroform in taking up the alkaloids (as mentioned by Dr. Rideal) was sometimes absolutely necessary, for the alkaloids appeared to carry with them a film of grease, which greatly impeded the action of the acid. He had long since discarded cochineal, on account of the fact that in delicate determinations it was seriously affected by carbonic acid, and now only used methyl-orange as an indicator.

THE ESTIMATION OF PENTOSANS AND ITS APPLICATION TO THE ANALYSIS OF FOODS.

By Otto Hehner, F.I.C., and W. P. Skertchly, F.I.C.

(*Read at the Meeting, May* 3, 1899.)

It is well known, mainly owing to the researches of Tollens and his collaborators, De Chalmot, Stift, Stone, Cross, Bevan, and others, that many vegetable substances yield furfural on distillation with hydrochloric acid.

It is not our intention in this paper to discuss the origin of the furfural. This is attributed by Tollens and the majority of continental investigators to the decomposition of pentosans (anhydrides of penta-glucoses which yield xylose and arabinose on hydrolysis). Messrs. Cross and Bevan have, however, brought forward strong evidence that the production of furfural does not necessarily indicate the presence of the C_5 molecule, but is in many cases due to oxy-cellulose.

The carbohydrates of the C_6 type, or multiples of this, yield on hydrolysis with hydrochloric acid only insignificant amounts of furfural.

Without entering into the controversy as to the origin of the furfural, we have

followed the precedent of Tollens in the results given below, and have calculated the furfural into "pentosan."

Many determinations of furfural, and, by calculation from this, of the furfural-yielding pentosan, have been published during the last few years, mainly in feeding-stuffs intended for cattle, such as straw, hay, lupines, clover, and also in various kinds of wood in various stages of development. A good deal of evidence has also been accumulated which serves to show that the carbohydrates of the C_5 class either pass through the body without being assimilated, or at least are assimilated to a very much less degree than the hexoses and their multiples. From this it follows that it is a matter of considerable importance to distinguish between the C_5 and the C_6 types of carbohydrates in food substances, and that it is no longer permissible to take by difference "starch, sugar, and digestible fibre," as has been the practice for so many years.

But while a good deal of work has been done in food materials intended for animals, we can find but few data in literature to show that the determination of furfural-yielding bodies may also usefully be applied to articles of human consumption. Stone (*Journ. Amer. Chem. Soc.*, vol. xix., p. 195) gives a few determinations in whole wheats, bread, and various kinds of wheaten flour, which show that while whole wheat yields to 1 per cent. hydrochloric acid about 4·5 per cent. of pentosan, wheat flour (presumably free from bran) yields nothing. Stift (*Oest. Ung. Zeitsch. Zuckerind*, xxiv., 290) gives the percentage of pentosan in various articles as follows: Crushed barley, 7·96 per cent.; rice-meal, 5·73; broad beans, 3·43; turnips, 1·13; spinach, 1·02, etc.

The results of analyses which we bring forward in this paper tend to show that the determination of pentosan may in some cases be of considerable use to the analyst.

It is well known that the formation of furfural-yielding substances takes place mainly when lignification in the plant goes on. Hence in the case of seeds it might be expected that the husk would be rich and the kernel-substance poor in furfuroids.

The method of determination of furfural which we have followed is that of Councler; it depends upon the condensation of furfural with phloroglucinol, while the mode of splitting off the furfural is that of Tollens and Krüger (*Zeitsch. Rübenz. Ind.*, D.R., vol. xlvi., p. 480). The combined method, as described by König (*Untersuchung. landwirtschaftlich und gewerblich wichtiger Stoffe*, 1898, p. 225), is as follows:

From 3 to 4 grammes of the substance are placed in a Wurtz flask of about 250 c.c. capacity along with 100 c.c. dilute hydrochloric acid, of specific gravity 1·06, corresponding with 12 per cent. of real hydrochloric acid. The flask is connected with a condenser, and the contents are distilled on a sand-bath. When 30 c.c. of distillate have been collected, a further 30 c.c. are added to the distilling-flask through a tap-funnel, and this is repeated until 400 c.c. have distilled over. As the distillation proceeds, drops of the distillate are taken from the end of the condenser on filter-paper and tested for the presence of furfural by touching the drop on the paper with a dilute solution of aniline acetate containing sodium acetate. When a pink coloration no longer appears the distillation is stopped, and the distillate made up to 400 c.c. with the 1·06 hydrochloric acid; otherwise the distillation is carried on till

400 c.c. have been obtained. It will mostly be found necessary to distil over from 300 to 400 c.c. before the reaction reaches its end. A solution of pure phloroglucinol in dilute hydrochloric acid is now added to the distillate, and the mixture allowed to stand overnight. Next morning the black precipitate which forms is filtered off through a dried and weighed filter, and washed with 150 c.c. of cold water. The filter is laid upon a piece of blotting-paper, which absorbs superfluous water, is then opened out, dried in the water-oven for three and a half to four hours and weighed. The weight of the precipitate of furfural-phloroglucide divided by 1·82 gives the amount of furfural. Following the data given by Tollens, this furfural may be calculated into pentosan by subtracting 0·0104, and multiplying the remainder by 1·88. The percentage of the pentosan is calculated from the weight thus obtained.

This method has been tested by several observers, and found to afford an accurate determination of furfural if the phloroglucinol employed is pure. We have also made some experiments in this direction, with the following results: 1·1680 gramme of furfural was dissolved to 100 c.c. of water; 10 c.c. of this solution yielded 0·2112, and 0·2114 gramme of the phloroglucide, corresponding to 99·31 and 99·40 per cent. of the furfural taken.

In most of the analyses which follow the crude fibre has been estimated as well as the pentosan. As the determination of the fibre yields results largely dependent upon the strength of the acid and alkali employed, it should be stated that 5 per cent. hydrochloric acid and 5 per cent. sodium hydroxide solutions were used, the boiling with each solution lasting one hour.

Mustard.

	Pentosan.	Crude Fibre.
Flour of brown mustard ...	3·03 per cent.	2·94 per cent.
Flour of white mustard ...	3·33 ,,	3·83 ,,
Husk of white mustard seed ...	7·30 ,,	7·01 ,,
Mustard bran	9·52 ,,	10·95 ,,

The following are samples containing varying proportions of the brown and white seed:

Pentosan.	Crude Fibre.
2·92 per cent. ...	3·88 per cent.
2·77 ,, ...	1·92 ,,
0·76	2·77
0·89	3·26
2·63	2·77
3·59	2·76

Three samples mixed with wheat flour yielded results as under:

Pentosan.	Crude Fibre.
1·23 per cent. ...	3·18 per cent.
2·66 ,, ...	2·32 ,,
3·47 ,, ...	1·75 ,,

Coffee.

	Pentosan.	Crude Fibre.
Raw coffee	2·86 per cent. ...	—
Genuine roasted coffee ...	2·50 ,, ...	7·36 per cent.
Coffee containing 32 % chicory	2·71 ,, ...	—

Chicory.

These samples of chicory are all of one kind, but the samples were taken from the roaster after being roasted for different lengths of time. The results obtained from the above were as follows :

	Moisture.	Pentosan.	Crude Fibre.
Best high-dried Belgian root ...	5·51 per cent.	5·14 per cent.	5·47 per cent.
The same after 5 min. roasting ...	6·17 ,,	5·55 ,,	6·57 ,,
,, ,, 10 min. ,, ...	3·95 ,,	5·16 ,,	6·87 ,,
,, ,, 15 min. ,, ...	3·73 ,,	4·80 ,,	8·67 ,,
,, ,, 23 min. roasting, finished for grinding	3·28 ,,	5·56 ,,	11·50 ,,

Here it will be seen that "fibre" increases as the roasting proceeds, carbonized material being included with the fibre.

Pepper.

	Pentosan.	Crude Fibre.
Pepper husk	10·24 per cent. ...	14·68 per cent.
Black pepper	4·58 ,, ...	9·91 ,,
Genuine white pepper ...	1·68 ,, ...	5·54 ,,

Cocoa.

	Pentosan.	Crude Fibre.
Van Houten's cocoa ...	2·00 per cent. ...	6·00 per cent.
Cadbury's cocoa	1·82 ,, ...	7·15 ,,
Cocoa shell powder ...	8·98 ,, . .	not determined
,, ,, ...	8·03 ,, ...	11·95 ,,

The results of the analyses of the following samples of cocoa powders are given in full as the origin of the samples was not known :

Cold Water Soluble.	Total Nitrogen.	Fat.	Ash.	Alkalinity of Ash as K_2CO_3.	Pentosan.
Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
18·60	3·23	28·82	8·18	4·15	2·18
18·08	3·15	29·74	8·12	4·08	2·31
18·56	3·06	28·57	8·38	3·79	2·35
18·08	3·29	28·24	9·03	3·79	1·69
18·08	3·20	28·21	8·84	3·75	1·84
18·48	3·24	27·51	9·30	4·08	1·89
19·00	3·32	28·19	8·61	4·08	2·08
17·44	3·07	26·82	7·18	2·77	2·81

These cocoas show no indications of added husk.

Of the several samples of chocolate powders given below, some were free from husk, whilst in the case of others the "cocoa" they contained consisted wholly of husk or cocoa-shell powder.

Cold Water Soluble.	Total Nitrogen.	Fat.	Ash.	Pentosan.	Fibre.
Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
67·20	0·76	23·76	2·17	1·27	—
66·88	0·80	23·12	1·98	0·83	1·18
65·04	0·70	23·59	2·16	0·81	1·33
42·96	0·60	4·20	—	1·88	2·95
37·52	0·57	4·21	—	1·81	2·71

The two latter samples contained about 25 per cent. "cocoa" which was almost entirely husk.

We have had three samples of cocoa made up, the composition of which was not imparted to us until after the samples had been analysed and an opinion given on the same. The following were the analytical results:

Cold Water Soluble.	Total Nitrogen.	Fat.	Ash.	Pentosan.	Fibre.
Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
31·11	1·14	21·93	1·66	1·39	3·01
41·90	0·72	6·07	2·90	1·55	1·67
15·88	3·09	31·91	4·66	2·45	7·01

From these figures the composition of the samples was calculated to be as follows:

	No. 1.	No. 2.	No. 3.
Cocoa	50	13	Contained about 5 per cent. husk, the rest being pressed cocoa powder.
Sugar	26	40	
Starch	24	34	
Husk	Not more than 1 per cent.	13	

The actual composition was:

	No. 1.	No. 2.	No. 3.
Cocoa	48	18	Contained 9 per cent. husk, the rest being pressed cocoa powder.
Sugar	24	38	
Starch	28	35	
Husk	None	9	

Feeding-Cakes.

	Moisture.	Oil.	Pentosan.	Fibre.
Linseed cake	11·90	8·08	3·38	6·76
Decorticated cotton-cake ...	7·70	10·20	7·22	5·02

	Pentosan.	Fibre.
Agar-agar	25·92 ...	0·28

Arrowroot (genuine St. Vincent).

Pentosan.
0·51 per cent.

In the case of mustard it will be seen that whilst the husk of mustard contains

a considerable quantity of furfuroid, and about an equal amount of crude fibre, the flour of mustard, which has been freed as completely as possible from husk, contains a very small quantity of pentosan, less than 1 per cent., whilst it does not appear to be possible to reduce the amount of fibre to less than 2 or 3 per cent. The determination of the pentosan, therefore, in the case of mustard, affords a surer guide for the estimation of the amount of husk it contains than does the determination of the crude fibre.

In pepper the pentosan estimation likewise appears to be a better guide in arriving at the percentage of husk than that of the fibre. While, in the two samples of pepper examined by us, the proportion of fibre was not quite twice as high in the black as compared with the white, the pentosan in the black was nearly three times that of the white.

In the case of cocoa, the advantage is still more on the side of the pentosan estimation. The best kinds of pressed cocoa contain as much as 6 to 7 per cent. of crude fibre, and cocoa-shell powder about 12 per cent.; while the amount of pentosan in pressed cocoa is only about 2 per cent., against 8 to 9 per cent. in the shell. While, therefore, the estimation of fibre is a very untrustworthy guide for the detection and determination of husk, the pentosans are capable of yielding a far more trustworthy indication.

How near it is possible to determine the relative proportions of cocoa, husk, sugar, and starch (the latter by difference), will be seen from the analyses of the three samples kindly made up for us by a well-known manufacturer.

The difference in the percentage of pentosan in coffee and chicory, although not very large, is yet sufficient to prove of assistance in the analysis of mixtures, whilst the determination of fibre quite fails, coffee and chicory in the roasted condition yielding similar quantities of fibre. During the roasting of coffee and chicory more or less of the substance is carbonized, and the carbon is estimated along with the crude fibre, whilst, as will be seen from the analyses of the five samples of chicory roasted for different lengths of time, the proportion of pentosan is not affected.

Discussion.

Mr. Bevan said that the method employed by Mr. Cross and himself was to determine furfural by precipitation with a solution of phenyl-hydrazine in acetic acid. The precipitate thus obtained was rather more than twice the weight of the furfural to be estimated, so that the error of manipulation was small.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Estimation of the Nitrogenous Constituents of Malt, Wort, and Beer. B. V. Laszczynski. (*Zeit. f. a. gess. Brau.*, 1899, 140.)—The author finds that the albumin of wort and beer is completely precipitated by boiling for an hour under a pressure of one and a half atmospheres; that phosphotungstic acid and cupric hydroxide are not reliable reagents for separating nitrogenous bodies, since the former, though it precipitates the albumin, albumoses, and xanthine bodies completely, carries down an indefinite amount of the amide bodies; the latter precipitates the albumin completely, but also partly precipitates the albumoses and the amides. Krüger's process for the estimation of the xanthine bodies in animal fluids was found applicable to the determination of these bodies in wort and beer. He proposes the following scheme of analysis: The amount of water and of nitrogen are first determined in the sample of malt; 100 grammes of it are then finely powdered and mixed with 500 grammes of water in a tared beaker, and allowed to stand for two hours at the ordinary temperature under constant stirring with a machine. The mixture is then made up to its original weight, and filtered off. Of the filtrate, 25 c.c. are taken for the estimation of the nitrogen; this equals the total soluble nitrogen. Another 100 c.c. of the filtrate are placed in a flask and boiled in an autoclave for an hour at a pressure of one and a half atmospheres; the liquid is then filtered off hot, the coagulum washed with hot water, dried, and the nitrogen estimated in it; this equals the albumin nitrogen. The filtrate from this is evaporated down to 20 c.c., 2 drops of sulphuric acid added, saturated with zinc sulphate, and the albumose nitrogen estimated in the usual manner. The filtrate from the albumoses is heated to boiling with 10 c.c. of a saturated solution of sodium bisulphite, 10 c.c. of a 13 per cent. copper sulphate solution, and 5 c.c. of a 10 per cent. solution of barium chloride, allowed to cool, the precipitate filtered off, washed five times with hot water, dried, and the nitrogen it contains determined; this gives the nitrogen of the xanthine bodies. The amide nitrogen is calculated by deducting the nitrogen of these various bodies from the total soluble nitrogen. In the case of wort or beer 100 c.c. are taken directly. All the nitrogen determinations are made by the Kjeldahl process.

Oil of Cognac. Schimmel and Co.'s April Report. (*Chem. Zeit.*, 1899, xxiii., 329.)—Various analytical data given by different specimens of oil of cognac are collected in the annexed table, from which it appears that although this product has hardly yet been sufficiently studied to enable its genuineness to be deduced from the constants, a low specific gravity and a high ester number point to the presence of the artificial oil. The first two samples from the Rhine and from Forst in Lusatia were specially prepared and purified for comparison with the others.

Description.	Sp. gr. at 15°.	Rotatory power at 20°.	Acid number.	Ester number.	Minimum strength and volume of alcohol to dissolve.
Rhenish oil, crude ...	0·878	−0° 3′	55·2	207·3	2 vol. of 80%.

ORGANIC ANALYSIS.

The Characteristics of Oleo-distearin. R. Henriques and H. Kühne. (*Berichte*, 1899, xxxii., 387-394.)—Heise (*Arbeit. a. d. Kaiserl. Gesundheitsamt.*, 1896, 540) found that Mkani fat, which is derived from the seeds of the East African tallow-tree (*Stearodendron Stuhlmanni*), consisted essentially of a mixed glyceride containing two stearic acid radicles and one oleic acid radicle. As doubt has since been thrown on the correctness of Heise's conclusions, the authors have made a number of experiments on the subject.

By crystallizing a large quantity of the fat five times from a mixture of ether and alcohol they obtained a substance melting at 44·5° to 45·5° C., but which, having once been melted, had a melting-point of 38·5° to 39·5° C. As no further alteration could be brought about by continued crystallizations from absolute alcohol and from glacial acetic acid, the conclusion was arrived at that Heise's oleo-distearin was a definite chemical substance notwithstanding the fluctuations in its melting-point. Its iodine value was 28·6, and its molecular equivalent 295·2, the theoretical values for oleo-distearin being 28·6 and 296·0 respectively.

On treating the glyceride with Waller's iodine solution, or by dissolving it in ether and adding an alcoholic solution of iodine chloride, the chlor-iodo addition compound crystallized out almost quantitatively. This had the same appearance and almost the same solubility in various solvents as the oleo-distearin. It melted at 44·5° to 45·5° C., and after having once been melted and again solidified, had a melting-point of 41·5° to 42·5° C. It was very stable, and retained about two-thirds of its chlorine after repeated boiling with alcoholic potassium hydroxide. Boiling with quinoline or aniline, however, was found to remove the whole of the halogens.

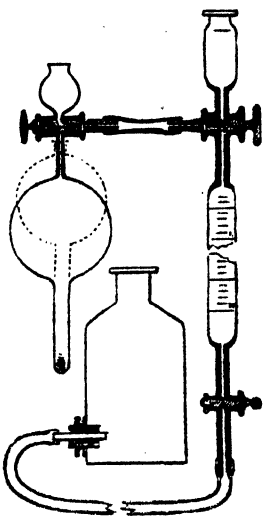
Oleo-distearin yielded an elaidin, but with less readiness than olein. This had only one melting-point (61° C.). It readily formed a chloro-iodide, which melted at 57° to 58° C., and, like the elaido-distearin, did not change its melting-point after fusion.

The authors consider that it may be possible to isolate similar mixed glycerides from other fats and oils in the form of their chloro-iodides, and have already obtained crystalline compounds in this way from butter and from linseed oil, which appear to have properties similar to the substance described above (*cf.* Hehner and Mitchell, ANALYST, xxiii., 317). C. A. M.

On the Saponification Value of Fish-Oils. W. Fahrion. (*Chem. Rev. Fett-u. Harz-Ind.*, vol. vi., pp. 25-29.)—The following values were obtained by the author in a new series of investigations:

	Iodine Value.	Henriques' Cold Saponification Method.		Hot Saponification Method. Henriques' Reagent.	Saponification according to Becker.	Inner Saponification Value by the Fahrion Method.
		24 hours.	2-8 days.			
Sardine-oil	191·7	189·5-195·9	192·5-216·8	190·9-193·8	196·2-200·3	185·2-186·4
Stickleback-oil ...	162·0	183·2-190·7	184·5-209·9	186·6-189·9	190·6-192·6	181·1-181·5
Seal-oil	146·2	186·0-190·4	186·7-197·4	190·7-192·9	189·8-193·5	184·4-186·0
Haddock-oil	166·2	182·3-183·3	183·5-185·5	182·5-183·0	187·8-188·3	181·6-181·9
Japan fish-oil	108·5	186·0-186·8	186·1-189·2	186·6-186·8	189·3-191·4	180·0-180·9
Whale-oil	106·1	184·0-185·1	184·5-188·0	184·5-185·5	191·2-193·5	174·8-175·7
Linseed-oil	172·0	187·0-187·7	187·0-188·6	187·6-189·1	188·8-192·3	186·8-187·9

The abnormally high values furnished by the first three oils in the longer period cold method are due to the formation of low molecular volatile fatty acids under the prolonged influence of alkali on these oils. That oxy-fatty acids, insoluble in petroleum spirit, are also formed has now been ascertained by the author, who obtained from 10 grammes of sardine-oil 0·0413 gramme of liquid and 0·0079 gramme of solid oxy-acids, together with 0·0448 gramme of volatile fatty acids (m.w. 73·9), and also succeeded in isolating oxy-acids from saponified stickleback-oil; and it is to this partial oxidation of the fatty acids that he ascribes the irregularities in the saponification value of these fish-oils, though the temperature of the reaction directly affects the results. The conditions causing these irregularities disappear for the most part when the test is performed without any excess of alkali, as is the case in determining the inner saponification value. The evaporation of the fatty-acid solution in petroleum spirit or alcohol should, however, be effected on the water-bath, and not in a drying-oven, at 100° C., since under the latter conditions the acids undergo a modification which falsifies the results.



In the hot method of saponification the proportion of water in the alkali has an influence on the results, Becker's reagent, with about 16 per cent. of water, giving higher values and requiring longer time to react than that of Henriques, which contains only 3 to 4 per cent. The author recommends the latter, as giving results more in accordance with the cold method, and he agrees with Henriques as to the advisability of dissolving the alkali direct in 96 per cent. alcohol in place of the usual procedure. C. S.

On the Reduction of Chromic Acid by Acetic Acid, and its Effect in Anthracene Testing. H. Bassett. (*Chem. News*, vol. lxxix., p. 157.)—Owing to certain irregularities in the results obtained during a series of experimental tests on anthracene, the acetic acid employed (crystallizing at 56° F.) was subjected to examination and compared with the best acid, crystallizing at 62° F., the solutions being prepared exactly as in the ordinary test for anthracene (with chromic acid of 98 per cent.). It was found that after twenty-four days the loss of chromic acid by reduction amounted to 0·87 gramme (out of 15 grammes taken) in the case of the

inferior acetic acid, and to 0·16 gramme in the other, owing to the presence of aldehyde, acetone, etc., in the former. Under the usual conditions of the anthracene test, a blank experiment gave, after four hours' boiling, a loss of 6·45 and 4·44 grammes respectively. The reduction, however, fell to almost *nil* when equal volumes of acid and water were used.

The use of inferior acid leads to results higher than the truth, the difference in the present instance being equal to about 0·4 per cent. of anthracene; and a similar error (of about 0·3 per cent.) arises from the use of a reagent that has been stored for about a month. It is therefore advisable to employ pure acetic acid, and an oxidizing mixture not more than fifteen days' old. C. S.

Analysis of Illuminating Gas. O. Pfeiffer. (*J. Gasbeleucht.*, 1899, xlii., 209; through *Chem. Zeit. Rep.*, 1899, 129.)—The author has abandoned absorption methods except for the carbon dioxide and the heavy hydrocarbons; he prefers processes of gradual combustion. His absorption apparatus is figured herewith; and for the explosions he uses a burette, which holds 110 c.c., fitted with stoppers at both ends. After explosion and removal of carbon dioxide, the excess of oxygen is absorbed with phosphorus, thus leaving the nitrogen of the original sample. A complete analysis of coal-gas can be carried out in forty-five minutes, the formulæ employed being the same as those quoted by Dennis and Hopkins (ANALYST, vol. xxiv., p. 106, Nos. 7, 8, and 9). F. H. L.

The Use of Silico-tungstic Acid as a Reagent for Alkaloids. G. Bertrand. (*Bull. Soc. Chim.*, 1899, xxi., 434-439.) — Silicotungstic acid ($12WO_3.SiO_2.2H_2O$) and its alkaline salts give precipitates with alkaloids in sufficiently concentrated solution, which can be readily collected on a filter. The precipitates are white, pale yellow, buff, or salmon coloured. They are insoluble, or nearly so, in cold water, but are somewhat soluble in boiling water. When dried at 30° C. to constant weight they retain a certain proportion of their combined water, the amount varying with the alkaloid A further part, at least, of this water is liberated at 120° C.

These neutral alkaloidal silicotungstates generally contain four equivalents of alkaloid to one of silico-tungstic acid:

$$12WO_3.SiO_2.2H_2O.4Alk + nH_2O.$$

They resist the action of concentrated mineral and organic acids, and on calcination leave a fixed residue of silicic and tungstic acids.

The pyridine salt ($12WO_3.SiO_2.2H_2O.4C_5H_5N + H_2O$) is a white crystalline powder, which becomes anhydrous at 120° C. It is slightly soluble in boiling water, from which it crystallizes on cooling in small colourless prisms.

Morphine silicotungstate ($12WO_3.SiO_2.2H_2O.4C_{17}H_{19}NO_3+9H_2O$) forms an amorphous salmon-coloured mass, which retains two molecules of water at 120° C.

The strychnine salt ($12WO_3.SiO_2.2H_2O.4C_{21}H_{22}N_2O_2+8H_2O$) resembles the morphine compound, but is of a buff colour, and only retains one molecule of water at 120° C.

On heating an alkaloidal silicotungstate in the liquid in which it was precipitated, it immediately loses a portion of its water. This body is also obtained in the form of a fine precipitate, which is not readily filtered, by adding the reagent to a hot solution of the alkaloid.

The silicotungstates of morphine and strychnine thus obtained have the following composition when dried at 30° C.:

Morphine silicotungstate ∴ $12WO_3.SiO_2\ 2H_2O\ 4C_{17}H_{19}NO_3+8H_2O$.
Strychnine silicotungstate ... $12WO_3.SiO_2.2H_2O.4C_{21}H_{22}N_2O_2+7H_2O$.

When testing a solution qualitatively for an alkaloid, it is preferable to attempt to form the salts containing the smaller amount of water, since these are often more perceptible than the salts precipitated from cold solutions. Thus, if 1 or 2 drops of the reagent be added to 5 c.c. of a solution of aconitine sulphate (1 : 50000), there is only a very slight opalescence; but on warming the liquid to the boiling-point, it becomes clear, and then on cooling a fine powdery precipitate appears. This difference is still more pronounced in the case of veratrine, it being possible to detect one part in 130,000 by warming the solution after the addition of the reagent.

The author has determined the limits of sensibility of this reaction with the principal alkaloids, and finds that they can be classified into two groups, viz., those whose silicotungstates are equally perceptible in hot and cold liquids, and those whose silicotungstates become more visible on warming the solution to 100° C. and then cooling.

I.	One part in :	II.	One part in :
Pyridine	3,000	Aconitine	80,000
Coniine	8,000	Veratrine	130,000
Morphine	16,000	Brucine	150,000
Theobromine	18,000	Strychnine, Narcotine	200,000
Nicotine	20,000	Quinine, Quinidine, Cinchonine, Cinchonidine ...	500,000
Quinoline, Narceine	30,000		
Codeine	40,000		
Atropine, Caffeine	50,000		
Cocaine	200,000		

Caffeine and theobromine are exceptional in requiring the addition of a sufficient quantity of free acid (*e.g.*, 3 to 4 per cent. of hydrochloric acid) if their full limit of sensibility to the reaction is to be reached. The caffeine silicotungstate formed under these conditions has the formula:

$$12WO_3.SiO_2.2H_2O.3C_8H_{10}N_4O_2+6H_2O.$$

Notwithstanding their stability, the silicotungstates of alkaloids are attacked by

certain reagents, noticeably by oxidizing bodies. It is thus possible in certain cases to obtain the characteristic colour reaction of the alkaloid directly with the precipitate—as, for example, in the case of strychnine with sulphuric acid and bichromate, and of morphine with Fröhde's reagent.

The alkaloids can be recovered from the precipitates by treating the latter with an alkali, which instantly decomposes them, and the alkaloid can then be extracted from the liquid by the usual methods.

The author has also made experiments to determine the action of silicotungstic acid on a number of glucosides, such as arbutin, coniferin, digitalin, ouabain, salicin, etc.; on certain bitter principles, such as picrotoxin, santonin, and quassin; on amides, such as urea, asparagine, leucine, and tyrosine; and on tannin, gum arabic, and other bodies which are often found accompanying alkaloids in plants. With the exception of albuminous substances, however, no precipitate was obtained with any of them, either in neutral or in acid solution. C. A. M.

A Modification of Denigés Method of Estimating Uric Acid. (*Ann. de Chim. Anal.*, 1899, iv., 82, 83.)—The method described below combines the methods of Denigés and of Hopkins. The phosphates are first removed by adding to 100 c.c. of the urine 10 c.c. of a solution of 160 grammes of anhydrous sodium carbonate in a litre of water; 82 c.c. of the filtrate are taken, and the uric acid rendered insoluble either by the addition of 30 c.c. of a mixture of 10 c.c. of Fehling's solution with 20 c.c. of sodium bisulphite solution (36° to 40° Bé), as proposed by Kluger; or, as described by Denigés, by the addition of 5 c.c. of a solution of copper sulphate (40 grammes per litre) and 20 c.c. of a solution containing sodium thiosulphate, 100 grammes, and sodium potassium tartrate 100 grammes, in a litre of water.

The mixture is shaken and filtered, and the filter washed with water until free from alkali, and thrown into 500 c.c. of water acidified with 5 c.c. of sulphuric acid. After the liquid has been well shaken for several minutes in contact with the air, decinormal permanganate solution is added drop by drop until a permanent pink tint is obtained.

If n c.c. be used in the titration, the amount of uric acid in a litre of the urine can be calculated by the formula,

$$\frac{n \times 0{\cdot}00745 \times 1000 \times 110}{82 \times 1000} = n \text{ decigrammes};$$

or, in other words, the number of c.c. used gives directly the decigrammes of uric acid.

The relation between decinormal permanganate and uric acid (1 c.c. = 0·00745 gramme) was obtained experimentally with a specimen of that acid purified by means of sulphuric acid. C. A. M.

Note on Kjeldahl's Method of Determining Nitrogen. Maquenne and Roux. (*Bull. Soc. Chim.*, 1899, xxi., 312-314.)—Referring to the precipitation of mercury by means of sodium sulphide, the authors point out that there are two main

objections to this course. Firstly, volatile sulphur compounds are formed, which distil with the ammonia, and interfere with the sharpness of the subsequent titration, especially when turmeric is used as indicator; and, secondly, the mercuric sulphide formed is not completely insoluble in alkaline sulphides, and there is nothing to prevent the formation of compounds of ammonia and mercury, which are not readily decomposed by alkalies, with the result that the yield of ammonia may be too low, as is shown by the figures in the subjoined table.

These drawbacks are obviated by precipitating the mercury from the acid solution by means of sodium hypophosphite. About 1 gramme of this salt is introduced into the acid solution while still warm, the whole heated to 60° to 70° C., then cooled, sodium hydroxide added, and the ammonia distilled in the usual manner.

The comparative results obtained by this modification, by the ordinary method, and by the soda-lime method were:

Material.	Kjeldahl's Method.		Soda-lime Method.
	Precipitation with Hypophosphite.	Precipitation with Sulphide.	
Cotton-seed cake	4·45	4·39	4·48
Colza cake	6·84	6·70	6·87
Wheat flour	1·86	1·89	1·91
Bean flour	5·24; 5·25	—	5·29
Powdered horn	14·31; 14·28	14·12; 14·11	14·30
Dried blood	7·73; 7·78	7·69; 7·79	7·78

C. A. M.

INORGANIC ANALYSIS.

The Colorimetric Estimation of Nickel. M. Lucas. (*Bull. Soc. Chim.*, 1899, xxi., 432, 433.)—The red colour which salts of nickel give with potassium or ammonium tri-thiocarbonate is proportional to the amount of nickel, and can be used for the colorimetrical estimation of that metal.

Ammonium tri-thiocarbonate is prepared by digesting freshly-prepared ammonium sulphide at a moderate heat for twenty-four hours with one-twentieth part of its weight of carbon bisulphide.

Potassium tri-thiocarbonate may be obtained by saturating one-half of a 5 per cent. solution of potassium hydroxide with hydrogen sulphide, adding the other half, digesting the whole at a moderate heat with a twenty-fifth of its volume of carbon bisulphide, and separating the dark-reddish liquid from the unaltered carbon bisulphide.

The darker-coloured of the two reagents is diluted with water until of the same colour as the other. Both are kept in well-stoppered bottles.

In order to obtain uniform and durable colorations with nickel, it is necessary to add a large excess of the reagents. But since, as a rule, the quantity of nickel to be estimated is less than 2 milligrammes in 100 c.c., the colour of the reagents themselves does not introduce a serious error. The colour produced by 10 c.c. of one of these in 100 c.c. corresponds to not more than one-tenth of a milligramme of the

metal, and, by using typical colour standards, the drawback becomes one of diminution of sensibility.

Cobalt salts give a brown coloration under the same conditions, so that it is necessary to separate any cobalt present before determining the nickel. Ammonium tri-thiocarbonate gives a much more pronounced colour with cobalt than does potassium tri-thiocarbonate—a property which may be used as a test for the presence of that metal.

Copper, too, gives a colour almost as pronounced as that of nickel. When present, it may be determined colorimetrically by means of potassium ferrocyanide and the amount deducted from the combined nickel and cobalt as estimated with tri-thiocarbonate, but it is preferable to remove it previously.

In analysing a steel containing nickel, 0·5 gramme of the sample is dissolved in *aqua regia*, and two successive precipitations made with ammonium hydroxide and ammonium chloride. The filtrate is diluted to 500 c.c., and three portions of 50 c.c. each taken. To the first is added 10 c.c. of the solution of ammonium tri-thiocarbonate, and to the second the same volume of the solution of potassium tri-thiocarbonate. If the coloration is a darker brown in the first than in the second, the presence of cobalt with the nickel is indicated, and a separation is made by one of the usual methods.

If not, the first of the test-tubes is compared with a standard colour-scale consisting of tubes containing the same volume of liquid and approximately the same proportion of ammonium salts, with gradually increasing quantities of nickel. These must be prepared with boiled water, and kept free from contact with the air. The tri-thiocarbonate is only added to them after the liquid has been diluted to the required volume.

The third portion of the ammoniacal filtrate is used for a corroborative determination.

Finally, another portion is tested with potassium ferrocyanide for copper, after evaporation of the ammonia. C. A. M.

Separation of Nickel and Zinc. E. Döhler. (*Chem. Zeit.*, 1899, xxiii., 399.)—The acid solution of the two metals, containing about 0·05 gramme of zinc, is evaporated nearly to dryness, diluted with water, neutralized with ammonia, and mixed with 0·2 gramme of sodium formate and 5 c.c. of formic acid. The liquid is raised to 60° C., and treated with a current of sulphuretted hydrogen for twenty minutes. The zinc sulphide is collected on a double paper, washed with sulphuretted hydrogen water, and either dissolved at once in hydrochloric acid, or dried, ignited in porcelain, and dissolved. The solution is evaporated till most of the acid is removed, diluted, freed from traces of iron, etc., with ammonia, and in the filtrate the zinc is titrated with sodium sulphide. For very exact work the zinc sulphide should be thrown down with sulphuretted hydrogen a second time, and estimated gravimetrically by ignition in a stream of hydrogen, as the volumetric process yields results slightly below the theoretical. Instead of the formic acid and formate, 1 gramme of sodium acetate and 40 c.c. of "acetic acid" may be employed, but the former method is preferable. F. H. L.

Estimation of Potash. E. W. Bell. (*Chem. News*, vol. lxxix., p. 135.)—To shorten the time required for a potash estimation, and to obtain a purer precipitate than by the ordinary method, the author recommends, in the case of *manures*, to well boil 5 to 10 grammes of the sample with about 150 c.c. of water, with or without a little hydrochloric acid; then render slightly alkaline with ammonia and add barium carbonate in large excess (about double the weight of the substance taken). After boiling for half an hour longer, the precipitate is filtered off, washed, and the filtrate and washings are made up to 500 c.c.

Fifty to 100 c.c. of the solution are evaporated to dryness with a small quantity of ammonium oxalate, gently ignited, treated with hot water, and filtered, the filtrate being evaporated with hydrochloric acid and platinum chloride and finished as usual.

In the case of *soils* (if the potash soluble in hydrochloric acid is required) the hydrochloric solution is rendered alkaline with ammonia, treated with barium carbonate, etc., as above, or the soil is moistened with strong sulphuric acid, gently ignited, and boiled with water, the barium carbonate precipitation and final treatment being as before, except that the ammonium oxalate and ignition are dispensed with.

For estimations in *vegetable substances*, these must be moistened with sulphuric acid, ignited, and treated in the same way as soils. C. S.

The Constitution of the Ammonium-Magnesium Phosphate of Analysis. F. A. Gooch and M. Austin. (*Zeit. für Anorgan. Chemie*, xx., 121)—The authors have carried out a series of experiments upon the precipitation of ammonium-magnesium phosphate under the various conditions that might occur in analysis. A few experiments were made to determine to what extent ammonium chloride might exert a solvent action upon the precipitate in presence of the precipitant. It was found that as little as 0·001 gramme of magnesium oxide, in the form of nitrate, in 500 c.c. of faintly ammoniacal water, could be detected by the opalescence produced on adding 1·75 gramme of microcosmic salt, even when 60 grammes of ammonium chloride were present. The authors consider that strongly ammoniacal fluids are unnecessary in the precipitation of ammonium-magnesium phosphate, and in nearly all the experiments mentioned the solutions and wash-water were made only faintly ammoniacal. In a series of experiments made by precipitating magnesium nitrate with considerable excess of microcosmic salt in the presence of varying amounts of ammonium chloride, the results showed, in all cases, errors of excess, the greatest occurring where the largest amounts of ammonium chloride had been used. When, however, the supernatant liquid was filtered from the precipitate by decantation, and the latter was redissolved in hydrochloric acid and reprecipitated with a faint excess of dilute ammonia, without any addition of ammonium chloride, the error disappeared altogether, and good results were obtained. If the precaution of redissolving be taken, the quantity of ammonium chloride originally present does not affect the final results, unless, indeed, the amount is so large that an appreciable quantity is left even after redissolving. The influence of free ammonia during the precipitation was also studied. The results indicate a tendency for free ammonia,

ammonium chloride, and excess of phosphoric acid to produce a salt containing a larger proportion of ammonia and a smaller proportion of magnesium than are contained in normal ammonium-magnesium phosphate. For the determination of phosphoric acid the authors recommend the observance of the following conditions: The phosphate solution to contain not more than 5 to 10 per cent. of ammonium chloride; the magnesia mixture to be only in slight excess; the ammonia, both for precipitation and washing, to be used sparingly; the precipitate to be redissolved and reprecipitated in cases where too much ammonium chloride, or double the theoretical quantity of magnesia mixture, has been used. H. H. B. S.

Determination of Sulphur in Iron Pyrites. O. N. Heidenreich. (*Zeit. für anorgan. Chemie*, xx., 233.)—When sulphuric acid is precipitated by barium chloride in the presence of a considerable quantity of iron, the barium sulphate is found to be contaminated with ferric sulphate (Jannasch and Richards, *Jour. pr. Chemie*, xxxix., 321-334). The author suggests that this drawback may be overcome by reducing the ferric salt by means of zinc before the addition of the barium chloride. This is only a preliminary note on the subject; but the author gives the results of three determinations made in this way with different quantities of the same sample of pyrites, which agree well, and he further mentions that the barium sulphate obtained in each case was almost white. H. H. B. S.

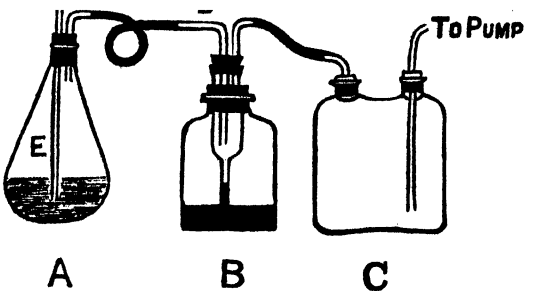
On the Influence of Hydrochloric Acid in Titrating with Sodium Thiosulphate, with Special Reference to the Determination of Selenious Acid. J. T. Norton. (*Zeit. für anorgan. Chemie*, xx., 221-229.)—It appears from the author's experiments that the influence of hydrochloric acid upon the thiosulphate depends primarily upon the quantity of thiosulphate present, and then upon the degree of dilution and the quantity of the hydrochloric acid. In titrating large quantities of thiosulphate with iodine in presence of hydrochloric acid, the temperature should be maintained at as nearly 0° C. as possible, and the titration should be carried out quickly. So long as the quantity of thiosulphate does not exceed 20 c.c. of a $\frac{N}{10}$ solution, the titration in cold solutions, varying in bulk from 100 to 500 c.c. at the commencement of the titration, proceeds pretty regularly, even when 10 c.c. of hydrochloric acid are present. When, however, the quantity of thiosulphate exceeds this limit, it is necessary to diminish the acid and to work with a solution having a bulk of 400 to 500 c.c.

In most cases in which this process is made use of the thiosulphate is run into the solution to be tested, and, since decomposition takes place at the moment when the thiosulphate meets the solution, hydrochloric acid ceases to have any influence. In Norris and Fay's method for the iodometric determination of selenious acid, however, an excess of thiosulphate is added simultaneously with hydrochloric acid, so that conditions prevail which render necessary the careful regulation of the quantity of acid and thiosulphate and the degree of dilution.

Norris and Fay's method is briefly as follows: A solution of selenious acid in ice-cold water is treated with an excess of a $\frac{N}{10}$ solution of thiosulphate in the

presence of hydrochloric acid, and the excess of thiosulphate is then titrated back with iodine.

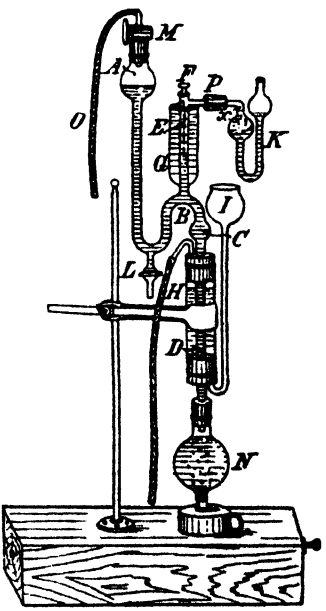
The author has made experiments to determine the exact conditions which it is necessary to observe in order to obtain accurate results by this method. The most important point appears to be the restriction of the excess of thiosulphate within narrow limits, which is not a difficult matter if the approximate percentage of selenious acid be known. The conditions should then be so arranged that never more than 20 c.c. of $\frac{N}{10}$ thiosulphate are used beyond the quantity required for the reduction of the selenious acid. If this be done, and the solution be diluted to 400 c.c., 10 c.c. of hydrochloric acid may be used without adversely affecting the results. If, however, the quantity of hydrochloric acid added be restricted to 5 c.c., which, in the author's opinion, is sufficient, the solution need not be diluted beyond 200 c.c. H. H. B. S.



A Study of the Relative Value of Lacmoid, Phenacetolin, and Erythrosine as Indicators in the Determination of the Hardness of Water by Hehner's Method. J. W. Ellms. (*Jour. Amer. Chem. Soc.*, xxi., 359-369.)—The principal conclusions arrived at are as follows: There is very little to choose between the three indicators, and with proper care and skill, and with a knowledge of the true end-point with lacmoid and phenacetolin, all may be said to be suitable for the purpose. Erythrosine, however, gives more uniform results and a larger percentage of the carbonates with low than with high amounts, whilst the reverse seems to be true of lacmoid and phenacetolin. If, therefore, uniformity of results within very narrow limits is desired, the preference should be given to erythrosine. Erythrosine may also be used with fairly turbid and coloured waters, and in this respect is preferable to either lacmoid or phenacetolin, which have a tendency to give too high results with such waters. H. H. B. S.

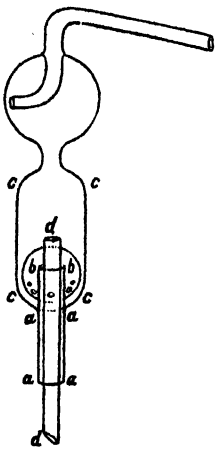
A Delicate Reaction of Hydrogen Peroxide. E. S. Barralet. (*Chem. News*, vol. lxxix., p. 136.)—The author proposes to utilize the colour change produced by the oxidizing action of hydrogen peroxide on ferrous ferrocyanide as a means of detecting the former when present in very minute quantities, 1 c.c. of a $\frac{1}{1\,85000}$ solution of hydrogen peroxide being sufficient to intensify the pale blue colour of ferrous ferrocyanide in 20 c.c. of the freshly-precipitated compound. The reagent should be freshly prepared for each test, or else be stored in a bottle under a layer of petroleum. C. S.

APPARATUS.



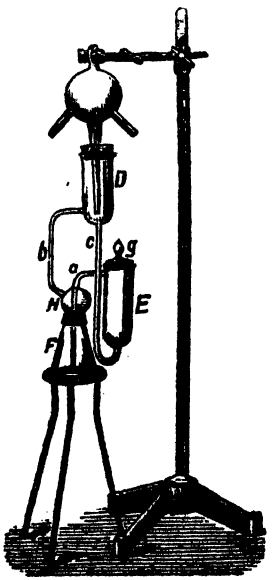
A Filter-Pump Accessory. H. Jervis. (*Chem. News*, vol. lxxix., p. 86.)—To prevent the reversal of current due to back pressure, the author recommends the arrangement shown in the drawing, in which C is the reservoir bottle, A the dissolving flask, and B the safety appliance. In this latter the drawn-out tube is held firmly in the neck of the bottle and dips just below the surface of the mercury. Owing to the narrowness of the tube, considerable pressure is required to lower the level of the mercury, and hence no air can pass; but should the water run back into

C, the compressed air forces the mercury below the bottom of the drawn-out tube, and escapes before the liquid in A is pushed beyond any given point in the vertical tube E. To render the degree of exhaustion constant, mercury is poured into B until it reaches nearly to the bottom of the larger tube D, the end of this tube becoming covered by the mercury as soon as the pump is started.



C. S.

Apparatus for Measuring the Gases dissolved in Water. F. C. G. Müller. (*Zeits. angew. Chem.*, 1899, 253.)—In the accompanying illustration this apparatus is drawn to a scale of 1 : 5. The flask *N* holds 100 c.c., and is completely filled with the sample, which has been made slightly alkaline. It is put in position, the stopcock *F* is withdrawn, and the whole pipette is charged with petroleum through *A* until the oil reaches the capillary *P*. *F* is then inserted and closed as against *K*, and the water is boiled for ten minutes to liberate the gases which collect in the graduated tube *E*, while the paraffin is driven back into *A*. The ebullition is conducted fast enough to fill *D* with steam, but not with sufficient rapidity to force the oil upwards out of *C*. The level of the petroleum is next adjusted by means of *L*, and the volume of gas read off, any bubbles in the burette being broken by sharply aspirating through *O*. *F* is then turned through 180°, and the oxygen is absorbed by forcing the gas into *K* several times, finally drawing it back into *E* to measure the residual nitrogen. Corrections for temperature, etc., are made by the help of a gas-volumeter. At the end of one test, by producing a partial vacuum in *A*, the oil can be kept from escaping while a fresh flask is put into position ; but it is advisable to wipe *E* out, which can be done through *F* after the petroleum has been drawn back into *A*. The apparatus is compact, and can be fitted into a portable case with a few spare flasks, so that with a second case holding standard alkali, phenolphthalein, a burette, and other apparatus for titrating the carbon dioxide, a complete analysis of the gaseous constituents of water can easily be carried out on the spot.



F. H. L.

Gas Washing Apparatus. O. Foerster. (*Chem. Zeit.*, 1899, xxiii., 196.)—This apparatus is specially designed for use during the estimation of nitrogen in

saltpetre by Kühn's process, its function being to return the condensible vapours to the flask in order to avoid the necessity for stopping the operation at intervals, lest the solution become too concentrated, and simultaneously to wash the permanent gases in the condensed liquid. The vapours leave the vessel through the annular space *a*, pass into the bulb *b*, and escape through the holes; the steam condenses in *c*, and gradually fills the lower part thereof until it reaches the level of *d*, when the surplus flows back regularly into the flask through the innermost tube. Thus, the vapours issuing from the various holes in *b* have to bubble through a column of the previously-condensed liquid. By bending the lower extremities of *a* and *d*, the former can be joined to the upper part of a hollow stopper which also carries a funnel and stopcock; the stopper itself fits the reaction flask, so that the whole arrangement may be used for charging as well as distilling off the contents of the vessel underneath. As a lubricant, a mixture of equal parts of ceresin and vaselin is recommended. F. H. L.

Apparatus for the Extraction of Liquids with Ether. F. Baum. (*Chem. Zeit.*, 1899, xxiii., 249.)—This apparatus has, *inter alia*, the advantage that it serves, without alteration or rearrangement of its parts, for the extraction of a solution by means of an immiscible liquid, and also for the distillation of the solvent from the extract. *H* is a hollow glass cap ground to fit on the outside of the neck of *F*. The vapours rise through *b*, condense in *D* and the condenser above, descend through *c*, pass through the material in *E*, and return viâ *a*. A small lateral hole is drilled in the stopper *g*, which can be placed in connection with a similar aperture in the side of *E*, thus bringing the interior to atmospheric pressure. The whole apparatus is slung from the condenser by the cork in *D*. *F* is also fitted with a plain glass cap, to be used during the weighing of the extract. *E* is filled almost up to the level of *a* with the aqueous liquid, and *F* is immersed in a water-bath; the holes in *gE* are in juxtaposition. When the operation is finished, the aqueous liquor is pipetted out of *E*; and as the ether continues to boil, it collects therein until *F* is practically free from solvent and merely requires to be dried. It is convenient to have several flasks like *F* all fitting the same stopper; if this be done, a second extraction can be started immediately. The new flask is placed in position, the fresh aqueous solution poured into *E* (which is, as just mentioned, full of recovered solvent); the ether is then displaced, runs into *F*, and the whole is ready once more. By the employment of a paper cone, etc., solids can be treated in *E* similarly. F. H. L.

ERRATUM.—Page 145, four lines from bottom, *for* "one-eighth of a gramme," *read* "0·8 gramme."

THE ANALYST.

AUGUST, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE COMPOSITION OF MILK AND MILK PRODUCTS.

By H. Droop Richmond.

(*Read at the Meeting, April* 12, 1899.)

Of the 36,399 samples analysed in the Aylesbury Dairy Company's laboratory during 1898, 29,707 were samples of milk; the average composition of 14,135 taken from the railway churns on arrival of the milk from the farms is given in Table I.; the composition of the morning and evening milk is given separately.

The mean composition does not differ appreciably from that found last year, the fat being slightly higher and the solids-not-fat slightly lower. As has been invariably noticed in former years, the solids-not-fat in July begin to fall, and attain a minimum in August. Usually a rapid rise in solids-not-fat takes place in September, but in 1898 the solids-not-fat remained low during this month, and did not rise till October. In the respect of low solids-not-fat, 1898 resembled 1893, and it may be remarked that both years were seasons of drought in the summer.

Fifty analyses have been made during the year, in which more figures have been determined than is usual in an ordinary milk analysis. They are tabulated below (Tables II., III., and IV.):

TABLE II.

TABLE IV.

Abnormal Milk.

Specific Gravity.	Total Solids.	Fat.	Sugar.	Proteids.	Ash.	Solids-not-Fat.
1·0318	11·75	3·20	4·77	3·11	0·67*	8·55
1·0285	12·03	4·04	3·65	3·54	0·80	7·99
1·0298	12·53	4·14	3·89	3·68	0·82	8·39
1·0288	12·56	4·39	3·82	3·55	0·80	8·17
1·0295	12·23	3·94	3·84	3·63	0·82	8·29
1·0282	12·90	4·81	3·70	3·59	0·80	8·09

The first sample in the table of abnormal milks was obtained from cows the supply from which was stopped because they were suffering from vaccinia. The last five were yielded by the same herd at different times; the quantity in this case was very small.

The following figures were found in the last five samples:

Insoluble Ash.	Soluble Ash.	Chlorine in Ash.
0·45	0·35	0·160
0·47	0·35	0·160
0·45	0·35	0·155
0·46	0·36	0·162
0·45	0·35	0·160

For comparison I have given below (*a*) a sample of milk yielded by the cows, which gave the five abnormal samples, to which 15 per cent. of water had been added, and (*b*) a sample of normal milk containing 10 per cent. added water:

	Specific Gravity.	Total Solids.	Fat.	Sugar.	Proteids.	Ash.	Solids-not-Fat.	Insoluble Ash.	Soluble Ash.	Chlorine in Ash.
(*a*)	1·0243	10·63	3·74	3·06	3·13	0·70	6·89	0·42	0·28	0·139
(*b*)	1·0280	11·24	3·45	4·02	3·09	0·68	7·79	0·44	0·24	0·094

The average composition of normal milk deduced from the above analyses is:

	Specific Gravity.	Total Solids.	Fat.	Sugar.	Proteids.	Ash.	Solids-not-Fat.
Morning	1·0325	12·32	3·44	4·71	3·43	0·74	8·88
Evening	1·0322	12·71	3·90	4·69	3·39	0·73	8·81

The average composition of the five abnormal samples very low in solids-not-fat is:

1·0290	12·45	4·26	3·78	3·60	0·81	8·19

It is seen that though the solids-not-fat are very low, the proteids and ash are above the average, and the whole of the deficiency falls on the milk sugar. Comparison with the watered milks shows that the rule for discriminating between abnormal and adulterated milks has held with these samples. I do not think that any analyst would be misled into reporting these abnormal samples as watered milks.

I would point out that the above analyses of normal milks confirm Vieth's ratio of sugar, proteids, and ash of 13 : 9 : 2 to a remarkable degree. The ratio found is 12·8 : 9·3 : 2, which is in excellent agreement.

It will be remembered that two years ago Storch published a research on a new proteid in milk, and concluded that each fat globule was surrounded by a "mucoid"

* These ashes are probably too low, as the muffle in which they were incinerated was accidentally allowed to get red hot for a few minutes.

envelope; according to him, for each part of fat in a globule there were 0·38 parts of mucoid envelope, which was composed of mucoid proteid, ash, and water, but which contained no milk sugar. I then pointed out that, were this the case, cream should contain a smaller amount of milk sugar per 100 of water than the original milk, and this difference should be slightly more accentuated when the cream and separated milk are employed. I have already published figures to show that there is no evidence of the milk sugar in cream being low, and the following figures further bear out this view:

	Cream.	Skim Milk.	
	Per Cent.	Per Cent.	Calculated for 6·77 Per Cent. Solids-not-Fat.
Total solids	36·06	9·41	
Fat	29·29	0·12	
Sugar	3·47	4·81	3·49
Proteids	2·76	3·70	2·69
Ash	0·54	0·78	0·59
Solids-not-fat	6·77	9·29	6·77

It is seen that the sugar in the cream is almost identical with the amount calculated to be present in 6·77 per cent. solids-not-fat from the skim milk, and the difference in the proteids is very small. Were Storch's hypothesis correct, the quantity of milk sugar would be $\frac{63{\cdot}96 - 29{\cdot}29 \times 0{\cdot}38}{63{\cdot}96} \times 3{\cdot}49$, or 2·90 per cent.

As the evidence on which Storch concludes that a membrane exists round each fat globule—the behaviour of milk with ether and the staining of a layer—is evidence only of a layer of some kind, and not of a membrane; as Béchamp has, under rather different conditions, obtained results on treating milk with ether which are diametrically opposite to those of Storch; and as the analysis of cream gives no evidence of any decrease in the milk sugar, or marked increase in the proportion of proteids with the thickness of the cream, I am unable to see that there is any justification for the view that each globule in milk is surrounded by a mucoid membrane; certainly the question is far from being settled by Storch's results.

The average composition of clotted cream fround during 1898 was:

	Maximum.	Minimum.	Average.
Total solids	73·03	63·87	68·84
Fat	66·98	55·12	61·97
Ash	0·84	0·46	0·56
Solids-not-fat	10·29	5·51	6·87

In the table below are given the maximum, minimum, and average figures for percentage of water and refractive index of fat in butters:

Table V.

Composition of Butters.

Description.	Percentage of Water.			Refractive Index at 35°.		
	Maximum.	Minimum.	Average.	Maximum.	Minimum.	Average.
English fresh	14·41	11·96	13·21	47·2°	44·9°	46·0°
English salt	14·29	12·27	13·22			
French fresh	18·72	13·13	15·48	46·1°	44·6°	45·4°
Danish salt	15·62	9·97	13·32	46·0°	45·1°	45·6°

A butter prepared in the Channel Islands had a refractive index at 35° C. of 43·6°, which is the lowest I have yet met with; its Reichert figure was 15·8 c.c.

It is well known that when milk is passed through a separator, a white or brownish deposit is thrown on the sides of the drum. This is often talked of as "dirt," "putrid slime," etc.; as a matter of fact, though it contains the dirt in the milk, "separator-slime" is a product derived from milk.

The following are three analyses of this product:

Percentage obtained.	Total Solids.	Fat.	Milk Solids Calculated.	Other Solids-not-Fat.	Ash.	P_2O_5.
0·029	29·2	1·3	7·2	17·5	3·2	1·28
0·031	27·5	4·1	7·4	13·7	2·3	0·94
0·036	26·4	3·9	7·5	12·8	2·2	0·91

If the milk be clean this substance is obtained white in colour, and probably consists largely of Storch's mucoid. The high amount of phosphoric acid in the ash suggests the presence of a compound rich in phosphorus such as this, and the quantity of phosphoric acid found agrees fairly well with the view that practically the whole of the other solids-not-fat are mucoid.

Discussion.

The President (Mr. Fisher) said that he had been struck with the author's remark about the deficiency in non-fatty solids which had prevailed towards the latter part of the previous year. From his own experience, he was inclined to think that some deficiency had continued through the winter, and had not even yet disappeared in districts where the food was rather poor, and where the cows had not been liberally treated during the winter months.

Mr. Richmond said that, on the other hand, the non-fatty solids in the milk which had come to his laboratory during the last month or two had been quite normal.

THE ESTIMATION OF ALCOHOL AND ETHER IN THE PRESENCE OF PETROLEUM ETHER.

By H. Droop Richmond.

(*Read at the Meeting, April* 12, 1899.)

Some time ago I found that mixtures of ether and petroleum ether containing some alcohol were accumulating in the laboratory, and I wished to know the proportions of each, with a view to seeing the best mode of treating them.

The following methods were found satisfactory for the analysis of such mixtures.

Estimation of Alcohol.—It was found that the decrease of volume observed on shaking the mixture with water saturated with ether did not represent the alcohol, as petroleum ether dissolves ether from etherized water, and the figure obtained was a resultant of the quantity of alcohol removed from the mixture, and the quantity of ether added to it. By shaking the ethereal layer a second time with water saturated with ether, the petroleum ether dissolves a quantity of ether from the etherized water equal to that dissolved on the first shaking. The difference in volume of the ethereal layer obtained by the first and second separations gives the volume of ether dissolved

by the petroleum ether from the etherized water, and on subtracting this from the volume obtained by the first separation, the decrease of volume due to the alcohol being dissolved can be calculated.

The following procedure was adopted: Shake 20 c.c. of the mixture with 25 c.c. of water saturated with ether; note the volume of the ethereal layer (call this A). Run off the aqueous layer from the ethereal layer, and shake the latter again with 25 c.c. of water saturated with ether; note the volume of the ethereal layer after the second separation (call this B). Then $2A - B$ will give the volume of ether and petroleum ether, and $(20 + B - 2A) \times 5$ the percentage of alcohol by volume in the original mixture.

Estimation of Petroleum Ether.—Prepare a mixture of 20 c.c. sulphuric acid (90 per cent. H_2SO_4) and 20 c.c. glacial acetic acid, and cool. Place 10 c.c. of the mixture to be examined (or of the ethereal layer left after the estimation of alcohol) in a burette, add the mixture of acetic and sulphuric acids little by little, keeping the burette corked, and shaking well between each addition; the mixture should be cooled. When all is added, shake vigorously, and allow to separate. The layer separating is petroleum ether.

The following examples will show the accuracy of the method, and many other estimations as satisfactory have been made.

	Experiment I.	Experiment II.
Composition: Alcohol	9·1 per cent.	19·7 per cent.
Ether	45·5 ,,	27·1 ,,
Petroleum ether ...	45·5 ,,	53·2 ,,
Volume A	18·9 c.c.	17·2 c.c.
,, B	19·65 c.c.	18·3 c.c.
Alcohol deduced therefrom	9·25 per cent.	19·5 per cent.
Petroleum ether	44·5 ,,	53·0 ,,
Ether (by difference)	46·25 ,,	27·5 ,,

Petroleum ether can be recovered from these mixtures by adding sulphuric acid little by little and shaking well, the flask in which the experiment is performed being kept cool; the layer of petroleum ether which separates only requires washing and re-distilling for use. The acid liquid may be used for regenerating ether if it is thought worth while.

THE INFLUENCE OF AMMONIUM SALTS ON THE PRECIPITATION OF NICKEL BY AMMONIA.

By Arthur Marshall.

(*Read at the Meeting, June* 7, 1899.)

When ammonia in not too great a quantity is added to an aqueous solution of nickel ammonium sulphate, after a time a light green flocculent precipitate forms. When I first observed this, I thought the precipitate must be due to iron or other impurity in the nickel salt. On examination, however, I found that the precipitate consisted of a nickel compound. As this behaviour was not in accordance with my preconceived

ideas, I carried out a series of experiments to investigate the causes which affect the precipitation of nickel by ammonia.

Fresenius, in his "Qualitative Analysis," makes the following remark: "Ammonia added in small quantity to solutions of protoxide of nickel produces in them a trifling greenish turbidity; upon further addition of the reagent this re-dissolves readily to a blue fluid containing a compound of protoxide of nickel and ammonia." If the ammonia and the solution of the nickel salt be mixed in the cold, and be not allowed to stand long, the behaviour is in accordance with Fresenius's statement. But if the liquid be boiled, a very voluminous precipitate may be obtained under certain circumstances, even in the presence of considerable quantities of ammonium salts. This precipitate differs from that formed in the cold, in that it cannot be entirely re-dissolved even by a very large excess of ammonia. A very faint turbidity remains; so slight, however, that it can only be detected with difficulty.

Other text-books on qualitative analysis contain statements less correct than that of Fresenius. Valentin, Thorpe, and Clowes all state that the precipitate formed on adding a small quantity of ammonia to nickel solution has the composition $Ni(OH)_2$. On this subject I have collected the following evidence:

André (*Comptes Rendus*, 1888, cvi., p. 907), using nickel chloride and an insufficient quantity of ammonia, found the precipitate to have the composition $NiCl_2$, $8NiO$, $13H_2O$.

Habermann (*Monatshefte für Chemie*, 1884, v., p. 441), using nickel sulphate and dilute ammonia and boiling, obtained a precipitate which on analysis proved to be $NiSO_4.6NiO.10H_2O$. Similarly from nickel nitrate he obtained a precipitate of the composition $Ni(NO_3)_2.7NiO.5H_2O$.

I myself carried out the following experiment: Two grammes of nickel ammonium sulphate, $NiSO_4.(NH_4)_2SO_4.6H_2O$, were dissolved in 220 c.c. of water. To this was added 20 c.c. of a solution containing 17 grammes of ammonia per litre. The ammonia added was about twice that calculated as being necessary to convert all the nickel into $Ni(OH)_2$. The liquid was boiled for a short time, and the light green precipitate was filtered off, washed, and dried to constant weight at 110° C. It weighed about 0·35 gramme. On analysis it proved to have the composition $NiSO_4.8NiO.16H_2O$.

	Calculated.	Found.
Ni	5·66	5·74
SO_4	9·20	9·21
8NiO	57·53	57·65
$16H_2O$	27·61	
	100·00	

Calculation shows that nearly 60 per cent. of the nickel was precipitated.

I have performed some hundreds of experiments to observe the conditions which affect the precipitation of nickel by ammonia. I give below a few of them to indicate the results which may be expected. Solutions were prepared of nickel salts, of ammonium salts, of acids, and of ammonia, all either of normal strength, or some multiple thereof. These were measured out into a flask in various proportions, and mixed or boiled together and the result noted. *E.g.*, 5 c.c. of $\frac{N}{1}$ nickel chloride

solution (containing 29·5 grammes Ni per litre) were mixed with 50 c.c. of 4N (four times normal) ammonia (68 grammes NH_3 per litre). The mixture was then boiled, no precipitate was produced; 20 c.c. of distilled water were then added, and the liquid was again boiled, still no precipitate formed. Another 10 c.c. of water were added, on boiling a slight precipitate was produced. Ten c.c. of 4N ammonium chloride solution were then added and the solution boiled, but the precipitate was but little affected. The addition of another 10 c.c. had also little effect.

Five c.c. of $\frac{N}{1}$ nickel chloride were boiled with 5 c.c. of 4N ammonium chloride, and 4N ammonia was added gradually, the liquid being raised to boiling after each addition. When 1·5 c.c. had been added the solution was distinctly turbid. When 3·5 c.c. had been added there was a considerable quantity of precipitate and the liquid began to turn blue. The quantity of precipitate then decreased with further additions of the ammonia, until, when 16 c.c. had been added, there was hardly any left. The addition of 40 c.c. of distilled water had no perceptible effect on the liquid, but when 100 c.c. had been added it became very cloudy. On again adding ammonia the cloudiness diminished, but when 35 c.c. in all had been added there was still some precipitate in suspension.

Five c.c. of $\frac{N}{1}$ nickel chloride were mixed with 10 c.c. of 4N ammonium chloride and 5 c.c. of 4N ammonia. The liquid was kept boiling and water was added gradually. When 110 c.c. had been introduced the liquid became cloudy. The last experiment was repeated, using 5 c.c. of ammonium chloride instead of 10 c.c. The liquid turned cloudy when 75 c.c. of water had been added.

Five c.c. of $\frac{N}{1}$ nickel sulphate were mixed with 40 c.c. $\frac{N}{1}$ hydrochloric acid and 20 c.c. of 4N ammonia, and water was added as before. When 150 c.c. had been added there was a slight precipitate. Many more experiments might be given showing the effects of slight variations of the various conditions.

I have examined the relative influence of the following acids and their ammonium salts on the precipitation: hydrochloric, sulphuric, nitric, acetic, oxalic, and tartaric acids. It makes no difference whether the acid and ammonia be added separately or the equivalent amount of a solution of the salt be used. Nitric acid has about the same effect as the equivalent quantity of hydrochloric acid. Sulphuric and acetic acid have a slightly greater tendency to keep the nickel in solution. Tartaric acid has a considerably greater effect, and if added in sufficient quantity entirely destroys the violet colour of the solution, changing it to a pale green. The colour may as a rule be re-produced by the addition of more ammonia. In the presence of oxalic acid ammonia in dilute solution produces a slight cloudiness in the cold. This re-dissolves on heating, but after a short time a gray granular precipitate forms.

I have also performed a few experiments on solutions of salts of other metals. The three remaining elements of Group III. B, viz., zinc, manganese, and cobalt, behave very similarly to nickel. Zinc is not precipitated quite so readily as nickel, but there is no great difference. Cobalt requires a larger proportion of ammonium salt to keep it in solution, when small quantities of ammonia are added. It is also more readily precipitated by the addition of water. Manganese oxidizes so readily in alkaline solution that it is difficult to obtain results of even approximate accuracy.

Calcium, barium, and strontium do not of course give any precipitate with

ammonia. Magnesium gives a precipitate, but an equivalent quantity of ammonium salt or acid entirely prevents precipitation, or will even redissolve a precipitate already formed. Apparently a double salt, such as $MgSO_4.(NH_4)_2SO_4$, is formed in solution, and this gives no precipitate with ammonia.

Conclusions.—Nickel and the other metals of Group III. B give precipitates with ammonia, unless there is present a very large excess either of ammonia or of an ammonium salt or of both. These precipitates probably in all cases consist of basic salts containing several molecules of the oxide of the metal combined with one molecule of the salt and several molecules of water.

Ammonium salts have more influence than equivalent quantities of free ammonia in keeping the nickel in solution. The precipitation takes place more readily and completely in dilute than in concentrated solutions. Precipitation may in many cases be brought about by simply diluting with water and boiling.

I cannot lay down any general rule whereby one may be certain not to get any precipitation of these metals under any circumstances, for the presence in solution of other substances such as iron or alkali salts makes them more liable to precipitate. It may, however, be stated that 12 equivalents of ammonium salt and 12 of free ammonia should be present for each equivalent of any metal of Group III. B. It is, however, advisable to have more than this amount present. The solutions should not be very dilute.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Areometric Determination of Fat in Milk. H. Timpe. (*Chem. Zeit.*, 1899, xxiii., 436, 455.)—On a previous occasion (*Chem. Zeit.*, 1894, xviii., 392) it was stated that this process was of wide application, but always gave results uniformly lower than those of the unmodified Soxhlet method, the difference being apparently proportional to the amount of fat at hand. To discover the reason for this peculiarity, the mechanism of the process has been carefully studied by noting the behaviour of filtered butter fat with the water and ether in the presence and also in the absence of the potassium hydroxide. From a large number of experiments on butters from different sources, it appears that a certain proportion of the material becomes saponified during the operation, and so does not pass into the ether. This proportion varies with the breed of the cows, with the amount and concentration of the alkali, and with the quantity of fat present; it is also dependent upon the temperature, wherefore the specified degree, 17·5° C., must not be departed from. The saponification represents no quantitative separation of the butter into its constituents; the olein is chiefly attacked, but the glycerides of solid fatty acids are also hydrolysed, and a repetition of the whole process produces further decomposition. For practical purposes it is necessary to accept some average value for this "saponification factor,"

and from four series of tests with Harz, Swiss, shop, and creamery butters, which gave 11·12, 9·89, 8·34, and 8·88 per cent. of saponified matter respectively, the author deduces a mean factor of 9·5 per cent.

It has been ascertained that no alteration of volume takes place when butter-fat is dissolved in ether, that the average specific gravity of the fat is 0·9520, and that the specific gravity of ether saturated with moisture, whether it be derived from pure water, or from dilute solutions of alkali metal hydroxides or carbonates, is constantly 0·7222 at 17·5° C. The usual figures given for the mutual solubility of ether and water do not prove quite correct, therefore special experiments have been made to determine the volumes produced by agitating known quantities of wet ether and water together. Collating the results, the formulæ for calculating the amount of fat in milk are somewhat modified from those given in 1894, and now become:

$$(1)\quad Z = A - 0{\cdot}075W.$$

$$(2)\quad F = 1{\cdot}4566Z\frac{S - 0{\cdot}7222}{(0{\cdot}9520 - S)\frac{vs}{100}},$$

where A is the weight of water-saturated ether taken, W the weight of water, Z the weight of aqueous ether left after agitation, S the specific gravity of the ethereal solution of fat, v the volume and s the specific gravity of the original milk, and F the weight of the fat it contains. The figures deduced from these formulæ for the quantity of fat in milk show a maximum difference of 0·04 per cent. from the Soxhlet process, and among themselves the several tests of one sample give a maximum difference of 0·035 per cent. The formulæ also exhibit the advantage that a small sample of milk can be analysed, since the volume of ether can be reduced at will. The method is equally available with milks containing more than 5·5 per cent. of fat. F. H. L.

Microscopy of Butter. A. Zega. (*Chem. Zeit.*, 1899, xxiii., 312.)—In order to obtain rapidly an idea as to the genuineness of a specimen of butter, and in the absence of a refractometer, the following process is suggested: The sample is melted and filtered into a test-tube, which is kept for two minutes in a boiling water-bath. By means of a hot pipette 1 c.c. is measured into a 50 c.c. stoppered tube containing 20 c.c. of a mixture of 6 parts of ether, 4 of alcohol, and 1 of glacial acetic acid. The whole is well shaken, and allowed to cool in water at 15° or 18° C. Pure butter remains clear, and only gives a slight deposit after standing one or one and a half hours. Margarine shows a deposit in one or two minutes, and in ten minutes yields a copious precipitate. Mixtures of butter with 10 per cent. of margarine begin to separate in about fifteen minutes. As soon as a few solid particles have fallen, they are withdrawn and examined under the microscope. Genuine butter appears in long, very narrow crystalline rods, often pointed at the ends, sometimes bent, and usually joined together centrally into more or less symmetrical open stars. Margarine crystals consist of bundles of minute needles packed closely together into circles, sheaves, or dumb-bell-like masses.

Similar experiments with lard and tallow are not so satisfactory. Pure lard crystallizes as broad rods with almost square ends, often cohering into stars and

brushes; tallow looks exactly like margarine; but when the two fats are present, the above process is not trustworthy. The best results are obtained by preparing the crystalline deposit as before, holding the tube for five minutes in water at 36° or 40° to effect partial re-solution, then permitting a second crystallization to take place at the ordinary laboratory temperature. Pure lard crystals thus appear as already described; 5 per cent. of tallow is shown by the presence of the sheaves or dumb-bells, while the lard plates are caused to look much smaller. F. H. L.

Detection of Caramel in Spirits and Vinegar. C. A. Crampton and F. D. Simons. (*Jour. Amer. Chem. Soc.*, xxi., 355-358.)—The authors make use of the well-known colour-absorbing power of Fuller's earth to distinguish between the natural colour which spirits acquire on storing in wood, and the artificial colour imparted by the addition of caramel. The earth appears to have a stronger affinity for the artificial than for the natural colouring matter. In the experiments cited, the difference in colour before and after treatment was determined by means of Lovibond's tintometer. Forty samples of spirits, which were known to be naturally coloured, furnished the following results:

	Per Cent. of Colour removed.
Maximum	25·0
Minimum	8·3
Average...	14·6

Whereas eighteen samples known to be artificially coloured gave the following figures:

	Per Cent. of Colour removed.
Maximum	54·1
Minimum	40·0
Average...	44·7

A sample of water-white spirits was coloured with caramel and treated with Fuller's earth, with the result that 70 per cent. of the colour was removed. It is necessary that the tests should always be carried out under precisely similar conditions and with the same earth, as the colour-absorbing power of different samples varies considerably. The test also appears to be applicable to vinegar.

H. H. B. S.

Presence of Barium Salts in Cayenne Pepper. H. Kaiser. (*Chem. Zeit.*, 1899, xxiii., 496.)—In the course of a discussion which has been proceeding lately in the *Chem. Zeit.*, as to whether an abnormal proportion of barium in a vegetable powder may be explained by the living plant having absorbed barium salts from the soil in which it was grown, the author remarks that this is impossible, inasmuch as barium in sufficient quantity is a vegetable poison. Cayenne occasionally contains the metal simply because, in order to give the substance a brilliant fiery colour, it is adulterated with a barium-ponceau lake; and the barium exists as sulphate or carbonate according to the composition of the base on which the colour is stained.

F. H. L.

The Assay of Belladonna Leaves and Some of its Preparations. F. X. Moerk. (*Amer. Journ. Pharm.*, 1899, lxxi., 105-120.)—After numerous experiments the author has found the following modification of Keller's process to effect a complete extraction of the alkaloids from a drug or preparation, although it is not a quick method.

The moisture is determined in 2 grammes of the powdered leaves at 100° C., without previous drying over lime or sulphuric acid.

To determine the extract 20 grammes of the powdered leaves are introduced into a small percolator (previously plugged with cotton wool) together with 50 c.c. of a mixture of 2 volumes of alcohol and 1 volume of water, and the mass stirred with an iron wire until the mixture is homogeneous. The sides of the percolator and the wire are then washed with 25 c.c. of the solvent and the whole allowed to stand for five or six hours. Percolation is then allowed to proceed until 75 c.c. have passed through, when the maceration is renewed for five or six hours. The alternate maceration and percolation are continued until 300 c.c. of the solvent have been used. By evaporating the percolated liquid in a weighed dish until the residue can no longer be stirred with a glass rod the yield of extract is obtained.

The extract thus obtained (or about 5 grammes of ordinary belladonna extract) is stirred with 10 c.c. of acidulated water (2 c.c. of U. S. P. sulphuric acid to 500 c.c. of water), the disintegrated mass transferred to a separating funnel, and the dish washed with small portions (2 c.c.) of acidulated water. The insoluble residue of chlorophyll, etc., is also washed in by means of three successive portions of 10 c.c. of a mixture of ether and chloroform (4 : 1 by weight). The dish is again washed out with the acidulated water until 25 c.c. in all of this has been used, the washings in each case being added to the liquid in the separator. Finally 20 c.c. more of the mixture of chloroform and ether are added, the whole shaken thoroughly, and after separation of the liquids the acid solution run off.

The shaking out is repeated with 15, 10, and 5 c.c. of the acidulated water, and the united acid solutions shaken in a separating funnel with 25 c.c. of a mixture of 2 parts of ether and 4 parts of chloroform by weight, and 8 c.c. of ammonium hydroxide (10 per cent.). The ether-chloroform layer is transferred to a smaller separating funnel and the extraction of the aqueous residue repeated with 15, 10, and 5 c.c. successively of the same solvent.

The author found that emulsification of the alkaloidal solution at this stage could readily be prevented by adding a fragment of stearic acid (15 to 20 milligrammes) little by little.

The ether-chloroform extract is filtered from the small separating funnel into a dry flask, and the solvent evaporated on the water bath until all odour of chloroform disappears. The residue is dissolved in 5 c.c. of ether, which is evaporated, and the residue again dissolved in 5 c.c. of ether, which is again evaporated. Finally, the residue is dissolved in 8 c.c. of neutral alcohol, 30 c.c. of water added, and the alkaloids titrated with standard hydrochloric acid, with hæmatoxylin solution as indicator.

The results obtained by this process with different commercial varieties of belladonna leaves were:

	Leaves.			Extract.
	Moisture Per Cent.	Extract Per Cent.	Alkaloids Per Cent.	Alkaloids Per Cent.
English, cultivated (Allen's)	8·40	*a.* 33·55 *b.* 32·55	*a.* 0·5996 *b.* 0·6054	*a.* 1·8510 *b.* 1·8280
German, cultivated ...	7·60	*a.* 36·55 *b.* 36·30	*a.* 0·5155 *b.* 0·5050	*a.* 1·5980 *b.* 1·5850
German, wild	6·80	*a.* 27·00 *b.* 27·45	*a.* 0·4997 *b.* 0·4997	*a.* 1·6998 *b.* 1·7133

The author points out that the yield of extract obtained from the leaves is from 20 to 24 per cent. higher than the yield usually published, and attributes this to the larger amount of solvent used in the extraction. C. A. M.

The Analysis of Commercial Veratrine. G. B. Frankforter and L. B. Pease. (*Amer. Journ. Pharm.*, 1899, lxxi., 130-133.)—The commercial products sold under the name of "veratrine" show a great variation, which is to be attributed partly to the difficulty with which the alkaloids, obtained from various species of *veratrum*, crystallize, and partly to the fact that several of these alkaloids have been known by the name of "veratrine."

Thus, Couerbe gave the name to the most important of the three substances which he isolated—an alkaloid with the formula $C_{34}H_{43}N_2O_6$. Merck assigned to veratrine the formula $C_{32}H_{52}N_2O_8$, and Wiegelin the formula $C_{52}H_{86}N_2O_5$. Wright and Luff (*Journ. Chem. Soc.*, xxxiii., 338) have isolated three bases, to one of which ($C_{37}H_{49}NO_9$) they assign the name of "veratrine," although the most abundant of the three is cevadine ($C_{32}H_{49}NO_9$). Hence three separate alkaloids have been known as "veratrine," any one of which might have been taken as official.

The authors have examined a number of specimens of commercial veratrine, and have found cevadine to be the predominating base in each case. In no instance was more than a trace of either of the other substances known as "veratrine" discovered.

The melting-points of the different samples examined varied slightly, although there was a comparative agreement in the general physical and chemical properties. On treating the drug with ether, the greater part dissolved, forming a colourless solution. The small quantity of insoluble matter was an amorphous powder, melting at 184° to 285° C. It did not fully answer the description of either of the other bases.

The following table gives the percentage of insoluble substance, and its melting-point in the case of the veratrine recently prepared by different manufacturers:

	Merck.	Tromsdorff.	Powers and Weightman.	Mahlenkrodt.
Insoluble substance, per cent. ...	0·86	3·89	3·6	3·26
Melting-point, ° C.	184°	285°	206°	231°

The soluble portion was identical with Wright's cevadine, as is seen by a comparison of the results of the analyses:

Calculated for $C_{32}H_{49}NO_9$.	Merck. No. 1.	Merck. No. 2.	Tromsdorff.	Powers and Weightmann.	Mahlenkrodt.
C = 64·96	64·6	64·5	64·72	64·74	64·82
H = 8·29	8·4	8·6	8·36	8·19	8·41
Melting-point	148° C.		147° C.	148° C.	148° C.

Two samples of the drug prepared some years ago were found to consist of a mixture of several substances, resembling the "veratria" prepared by Pelletier and Caventou in 1819 (*Ann. Chim. Phys.* (II.), xiv., 69). C. A. M.

TOXICOLOGICAL ANALYSIS.

Microscopic Identification of Blood. C. Strzyzowski. (*Oesterr. Chem. Zeit.*, 1899, ii., 334.)—A reagent, consisting of glacial acetic acid, mixed with 1·5 or 2 per cent. by volume of hydriodic acid, is prepared freshly each time it is wanted. The suspected sample is laid on a microscope slide, covered with a very small cover-glass, and a drop of the acid is applied to the edge in order that it may penetrate between the glasses. The liquid is boiled off over a minute spirit flame, and the residue is examined optically. From new or dried blood, the hæmatin crystals appear large and well formed in the shape of rhomboidal plates, with their characteristic coal-black colour. The process will detect 0·025 milligramme of fresh blood.

In those rare cases where the above acid mixture cannot be employed, a glycerin-sulphuric acid reagent may be substituted. This is prepared from 10 c.c. of glycerin and 2 or 3 drops of strong sulphuric acid. A cover-glass is moistened therewith, laid on the object as it rests on a slide, the liquid boiled for eight or twelve seconds, and examined with a power exceeding 400 diameters—preferably an immersion lens.

F. H. L.

The Detection and Estimation of Bromoform in Toxicological Work. A. Richaud. (*Journ. Pharm. Chim.*, 1899, ix., 232-236.)—The method commonly used for the detection of chloroform consists in decomposing it at a red heat into chlorine and hydrochloric acid, and collecting these in a solution of silver nitrate. In the case of bromoform, however, this method is unsatisfactory except as a qualitative test when large quantities are present. When the amount of bromoform does not exceed 50 centigrammes, the author finds that not more than 60 or 70 per cent. of the theoretical quantity can be recovered in the form of silver nitrate.

It is possible to completely remove bromoform from organic matter by means of a current of steam, the whole of it passing over with the first portions of the distillate, the total quantity of which need not exceed 75 to 100 c.c.

In order to estimate the bromoform thus recovered, the author has made experiments with various methods. Greshoff has described a process of estimating iodoform based on its decomposition with silver nitrate at a low temperature,

$$CHI_3 + 3AgNO_3 + H_2O = 3AgI + 3HNO_3 + CO,$$

but the author was unable to bring about a corresponding reaction with bromoform even by boiling the liquid under a reflux condenser.

By gently heating bromoform with alcoholic potassium hydroxide it is decomposed in accordance with the equation

$$CHBr_3 + 4KOH = 3KBr + KHCO_2 + 2H_2O.$$

The reaction is rapid, and when complete the alcohol is removed by evaporation, the residue neutralized with acetic acid, and the bromide determined volumetrically, or even gravimetrically if the solution be well cooled in order to prevent the reducing action of the formate. The author has obtained almost theoretical results by either method.

Like chloroform, bromoform is decomposed in the cold by an aqueous solution of potassium hydroxide, with the formation of potassium bromide, carbon monoxide, and water:

$$CHBr_3 + 3KOH = 3KBr + CO + 2H_2O.$$

The reaction takes place less readily with bromoform than with chloroform, but only a slight elevation of temperature is required to complete it in a relatively short time. The mixture of bromoform and aqueous potassium hydroxide is gently heated by means of a low spirit flame under a reflux condenser for about an hour and a half, and the resulting bromide determined in the usual manner. The author regards this as the most satisfactory method of estimation.

When bromoform is to be detected or estimated in substances which contain certain products of putrefaction or in fæcal matter, it is necessary to take into account the volatile substances which are simultaneously removed by the steam, and which reduce the silver nitrate added to precipitate the bromide. In such cases correct results may be obtained by evaporating the liquid containing the potassium bromide and impurities to dryness, and slightly igniting the residue before making the estimation. C. A. M.

ORGANIC ANALYSIS.

The Detection of Methyl Alcohol in Ethyl Alcohol. A. Trillat. (*Ann. de Chim. Anal.*, 1899, iv., 42-44.)—The author has simplified and rendered more sensitive the method described by him in a former paper (ANALYST, xxiv., 13). In the modified process a quantity of the alcohol to be tested, corresponding to 10 c.c. of absolute alcohol, is diluted to 150 c.c., and mixed with 70 c.c. of sulphuric acid (1 : 5) and 15 grammes of powdered potassium bichromate. After being shaken at intervals for twenty minutes the liquid is distilled, the first 25 c.c. being rejected, and the distillation continued until 100 c.c. have been collected.

Fifty c.c. of this distillate are mixed with 1 c.c. of rectified dimethyl-aniline, and transferred to a 75 c.c. flask, which is carefully closed with a ground-stopper and placed in a water-bath kept at 70° to 80° C. An occasional shake is given, and after three hours the condensation is complete.

The liquid is then rendered distinctly alkaline with sodium hydroxide, and the dimethyl-aniline distilled, the distillation being stopped when 25 c.c. have passed over.

The residue in the flask is acidified with acetic acid and shaken, and a few c.c. tested for methyl alcohol by adding 4 or 5 drops of water with lead dioxide in suspension (about 1 gramme in 100 c.c.) and boiling. If it be present a blue coloration

is formed during the oxidation, which may be compared with the colours yielded under the same conditions by standard typical solutions of methyl alcohol.

By this modification the author states that it is possible to detect as little as 0·2 per cent. of methyl alcohol in ethyl alcohol, whereas with the original method the limit of sensibility was about 1 per cent. By a preliminary fractionation of the liquid he has readily detected 1 part in 1,000.

The only precautions to be observed are to have the dimethyl-aniline quite pure, and to remove it completely from the liquid after the condensation.

C. A. M.

On the Detection of Methyl Alcohol in Commercial Spirits. A. Trillat. (*Journ. Pharm. Chim.*, 1899, ix., 372-375.)—As many of the spirits of commerce contain esters, colouring matters, and other substances which interfere with the application of the author's method of detecting methyl alcohol (see preceding abstract), it is necessary to treat the sample in the following manner before applying the test. Fifty c.c. of the liquid are mixed with 50 c.c. of water and 8 grammes of lime, and fractionally distilled with the aid of a Glinsky bulb-tube. The first 15 c.c. of the distillate are diluted to 150 c.c., mixed with 15 grammes of potassium bichromate and 70 c.c. of sulphuric acid (1 : 5) and left for an hour. The condensation with dimethyl-aniline and the oxidation are then carried out as described before.

In the case of absinthe, and, in general, of liqueurs which give a precipitate on dilution with water, 50 c.c. are mixed with an equal volume of water and 2 to 3 grammes of slaked lime, filtered through purified animal charcoal, and the colourless filtrate distilled.

The author has tested a large number of authentic samples of different kinds of spirit without finding any trace of methyl alcohol, but in several commercial samples, notably absinthe, kirsch, and rum, from 5 to 15 per cent. was present, which had evidently been fraudulently added.

Samples of Jamaica and Martinique rum and of cognac were compared with standard samples containing $\frac{1}{500}$ of methyl alcohol without giving any sign of the blue coloration. These results confirm those of P. Geerligs (*Bull. de l'Ass. des Chim. de Sucrerie*, 1898, No. 11).

On the other hand, certain genuine samples of brandy (*Marcs*) were found to contain about 0·25 per cent. of methyl alcohol, but as this was not an invariable constituent, the author suggests that its presence in these instances might have been due to defective distillation.

C. A. M.

A Simple Colour Reaction for Methyl Alcohol S. P. Mulliken and H. Scudder. (*Amer. Chem. Jour.*, 1899, xxi., 266.)—The test proposed depends upon the oxidation of methyl alcohol to formic aldehyde and the detection of the latter by its reaction with resorcinol and sulphuric acid. It is carried out as follows: A spiral copper wire is heated in the upper part of the flame of a Bunsen burner, and, while at a bright red heat, is plunged into 3 c.c. of the solution to be examined. If the solution be very dilute, this procedure must be repeated three or four times, and

in most cases it is desirable to repeat it at least once. Concentrated spirit should always be diluted before oxidation with the hot spiral. One drop of a 0·5 per cent. aqueous solution of resorcin is then added, and the mixture poured cautiously into a test-tube containing a few c.c. of concentrated sulphuric acid. Methyl alcohol is indicated by the production of a rose-red zone at the junction of the two liquids; but in and above this zone a scanty white or pinkish coagulum appears, which, on standing, increases in colour, and finally separates and rises in purplish-red flocks. The use of too large a quantity of resorcinol tends to destroy the purity of the rose colour, thus rendering the test less delicate. It is pointed out that the more common methyl esters and ethers are all slightly hydrolysed when dissolved in water, and consequently, as such solutions contain free methyl alcohol, they give this reaction.

The only other compounds which were found to give anything approaching to the reaction were the secondary and tertiary butyl alcohols, dimethyl-ethyl-carbinol, and formic acid. In the case of the secondary and tertiary alcohols, however, the pink zone is separated from the acid by a zone of lemon-yellow, and the red colouring matter does not separate in flakes. The coloration produced by formic acid is very faint; but to guard against mistakes arising from this cause, it is recommended that mixtures which react strongly acid should be neutralized with sodium carbonate before distillation. (*Cf.* ANALYST, xxii. 96.) H. H. B. S.

The Volumetric Estimation of Acetic Aldehyde. X. Rocques. (*Ann. de Chim. anal.*, 1899, iv., 13-17.)—The proposed method consists in treating the liquid containing the aldehyde with an excess of sulphurous acid or a bisulphite and titrating the reagent left uncombined by means of a standard solution of iodine.

For the process finally adopted as satisfactory the reagents required are: (1) A solution prepared by dissolving 12·6 grammes of dry sodium sulphite in 400 c.c. of water, adding 100 c.c. of sulphuric acid, and sufficient 96 per cent. alcohol to make a litre, and filtering from any crystals of sodium sulphate which may deposit. (2) A decinormal solution of iodine in potassium iodide. One c.c. of this corresponds to 0·0032 gramme of sulphurous acid and 0·0022 gramme of acetic aldehyde. The first solution is titrated with the second, and if the sulphite used was pure, 10 c.c. of the former should require 20 c.c. of the latter.

In the estimation of the aldehyde, 10 c.c. of the liquid under examination are placed in a long-necked flask with a mark at 100 c.c. Fifty c.c. of the sulphurous acid solution are added, the liquid made up to the mark with pure 50 per cent. alcohol, the whole well shaken, and the flask securely corked.

A blank determination is made at the same time by placing 50 c.c. of the sulphurous acid solution in a similar flask and diluting it with alcohol to 100 c.c.

The two flasks are immersed in a water-bath kept at 50° C. for four hours, after which their contents are cooled, 50 c.c. taken from each and titrated with the standard iodine solution, and the difference calculated into the corresponding quantity of acetic aldehyde.

If the liquid to be tested contain less than 1 per cent. of aldehyde, the reagents must be diluted. If the proportion of aldehyde be 0·5 per cent., the sulphurous acid

solution should be diluted with its own volume of 50 per cent. alcohol and $\frac{N}{10}$ iodine solution used; whilst with a percentage of 0·1 both solutions should be diluted to one-tenth their strength.

As sulphurous acid does not combine with paraldehyde the presence of that substance in the liquid does not affect the result, though obviously other aldehydes must not be present.

The following results are given to show the accuracy of the method:

Ethyl aldehyde in 10 c.c. of alcohol—

C. A. M.

The Halphen Reaction for Cotton-seed Oil. D. Holde and R. Pelgry. (*Chem. Rev. Fett. u. Harz. Ind.*, vol. vi., pp. 67, 68; 94, 95.)—The authors found that this reaction ceases to occur when the oil has been previously heated to 250° C. for a short time, and on the publication of Soltsien's results (*Zeits. öffentl. Chem.*, 1899, p. 106), according to which a temperature of 200° C. does not affect the susceptibility of the oil towards Halphen's reagent, they repeated their experiments at 210° and 250° C., with the result that the limit of sensitivity of the oil appears to lie between these temperatures. They point out that, although the probability is remote that heated cotton-seed oil would be used for adulterating edible oils, on account of its disagreeable flavour, this objection does not apply to oils for technical purposes.

C. S.

The Composition and Analysis of Acetone Oil. A. and P. Buisine. (*Journ. Pharm. Chim.*, 1899, ix., 375-377.)—The authors make use of the following method for the examination of acetone oil as manufactured from the washings of the *desuintage* of wool.

The density is determined with a hydrometer at 15° C. In the case of suint acetone oils it varies from 0·830 to 0·835.

For the determination of the solubility in water 10 c.c. of the oil are shaken for a few minutes in a stoppered graduated tube, with 40 c.c. of water, the tube allowed to stand, and the layer of acetone oil which separates read off. Suint acetone oil dissolves to the extent of from 77 to 82 per cent., the soluble portion being composed almost exclusively of primary ketones—dimethylketone and methylethylketone.

Its solubility in sodium bisulphite solution (30 Bé.) is determined by shaking 100 c.c. of the sample with 350 c.c. of the bisulphite solution at intervals during several hours, allowing the layers to separate, decanting the insoluble portion and measuring its volume. As the insoluble portion only amounts to from 6 to 9 per cent. it follows that suint acetone oil consists almost entirely of compounds of a ketonic nature, capable of combining with sodium bisulphite.

In the distillation of the oil the same quantity (250 c.c.) is always distilled under the same conditions and special note taken of the quantity distilling between 70° and

90° C. This fraction in suint acetone oil amounts to from 74 to 80 per cent., consisting for the most part of ethylmethylketone. The proportion of dimethylketone is very small, and never exceeds 5 per cent.

The results thus obtained with three samples of suint acetone oil of different origin were:

	I.		II.		III.	
Density at 15°	0·833		0·835		0·835	
	Per Cent.		Per Cent.		Per Cent.	
Portion insoluble in water	20		21·5		18

The heat of combustion determined in Mahler's bomb varied from 7,850 to 7,900 calories for 1 gramme of crude oil.

The authors state that they have found a great regularity in the nature of the products obtained in the manufacture as well as in the amount of the yield.

A sample of acetone oil was prepared from crude calcium acetate (pyrolignite), the yield being scarcely 5 per cent. of acetone. On analysis this crude product gave the following results:

Density at 15° C.	0·842	
	Per Cent.	
Portion insoluble in water	44	
Portion insoluble in sodium bisulphite	9	
Distillation from 60° to 70° C. ...	0	From 70° to 90°, 36 per cent.
70° to 76°	2	
76° to 80°	10	
80° to 85°	12

90° to 100°	28	
100° to 110°	10	
above 110°	26	
	100	

The pyroligneous acetone oils differ greatly in composition from the suint oils. They are much poorer in ketones, distilling below 90° C., especially ethylmethylketone, which is only present to about half the extent; but, on the other hand, they contain a far greater proportion of higher ketones, distilling above 100° C.

C. A. M.

Notes on Glycero-phosphoric Acid. J. Cavalier and Pouget. (*Bull. Soc. Chim.*, 1899, xxi., 364-366.)—Since Pelouze has shown that the glycero-phosphates of metals of the alkaline earths are less soluble in hot than in cold water, and are precipitated from a saturated solution on boiling, the authors have made experiments to determine the solubility of calcium glycero-phosphate in water at different temperatures. Their results show that 100 grammes of the solution contain the following quantities of anhydrous salt at the temperatures named:

C°.	Calcium Glycero-phosphate. Grammes.
16	7·9
36	4·4
51	2·3
77	1·3
86	1·25
100	1·15

The precipitate deposited on heating the solution is crystalline when it is formed slowly from a not too concentrated solution. It can be readily filtered and washed, and is completely soluble in water. The stability of the salt in solution resembles that of ethyl and methyl-phosphates. The authors prefer to purify calcium glycero-phosphate by precipitating it by heating its aqueous solution to 60° or 70° C. rather than by the addition of alcohol. They consider that little is gained by boiling the liquid.

Barium glycero-phosphate behaves differently, and its solutions are readily decomposed by heat, hence the method of purification by boiling the liquid is not suitable for the barium salt, and it is preferable to separate it by means of alcohol.

The method described by Cavalier (*Compt. Rend.*, cxxvii., 60) for the volumetric determination of esters of phosphoric acid in the presence of free phosphoric acid is also applicable to the determination of mixtures of glycero-phosphoric acid and free phosphoric acid. A solution of barium hydroxide is run into the cold solution until the colour of methyl-orange is changed. The liquid is then heated, and the titration completed with phenolphthalëin as indicator. The insoluble barium phosphate is filtered off, and the hot filtrate should be sufficiently dilute to retain the barium glycero-phosphate in solution. C. A. M.

The Composition and Reactions of Solanine. P. Cazeneuve and P. Breteau. (*Journ. Pharm. Chim.*, 1899, ix., 465-468.)—There is a considerable difference in the formulæ and melting-points assigned by different chemists to solanine. According to Zwenger and Kind it melts at 240° C., and has a composition corresponding with the formula $C_{43}H_{71}NO_6$. Kletzinsky gives the same melting-point, but the formula $C_{21}H_{35}NO_7$; Hilger states that it melts at 235° C., and has the formula $C_{42}H_{67}NO_{15}$; and according to Firbas its formula is $C_{52}H_{93}NO_{18}$, and its melting-point 244° C.

In the authors' opinion these differences are due to the methods of extraction adopted, which they consider are likely to bring about profound alterations in the solanine.

They recommend the following method of extracting the glucoside as the most suitable for obtaining it without alteration. The potatoes are allowed to germinate

protected from sunlight, and the shoots not exceeding 10 centimetres in length are intimately ground up with half their weight of slaked lime.

The mass is dried in the air at the ordinary temperature and extracted with cold 93 per cent. alcohol. The alcoholic extract, which has a slightly yellow colour, is evaporated *in vacuo* at 40° to 45° C. to the consistence of a syrup. On cooling this forms a crystalline mass, which is washed with petroleum spirit and ether, and crystallized three times from boiling 95 per cent. alcohol.

By this process the authors obtained a yield of about 0·5 gramme of solanine from a kilogramme of germs. It formed absolutely colourless needle-shaped crystals, which were insoluble in water and ether, soluble with difficulty in cold alcohol, but more easily soluble in boiling alcohol. It had a very bitter taste and a slightly alkaline reaction. It melted at 250° C., and had an elementary composition agreeing with the formula $C_{28}H_{47}NO_{10}.2H_2O$.

When hydrolysed by means of hydrochloric acid it yielded a crystalline product which dissolved in ether and melted at 190° C. (characteristics of solanidine), and a reducing sugar which furnished an osazone.

This solanine also differed from the products hitherto described in the nature of its colour reactions with nitric, hydrochloric, and sulphuric acids. With sulphuric acid (monohydrate) it was coloured but slightly yellow, the colour being chiefly at the edges and changing to faint rose and subsequently to violet. The solanines hitherto prepared give, on the contrary, pronounced colorations passing from orange to dark violet and brown. With nitric acid (specific gravity 1·5) the authors' solanine formed a colourless solution, which only became faint rose after a very long time, whereas in the case of other solanines the colourless solution rapidly assumes a purple coloration which soon disappears.

Hydrochloric acid (specific gravity 1·171) is usually stated to give a yellow colour with solanine, but the authors' glucoside remained absolutely colourless. On adding to their product drop by drop a mixture of sulphuric acid (6 parts) and absolute alcohol (9 parts) while still warm, the authors found that the crystals became bright green while the liquid surrounding them became a very faint rose colour. In the case of a solanine of German origin this reagent gave a blood-red coloration. C. A. M.

Determination of Unaltered Cellulose in Gun-cotton. G. Lunge and E. Weintraub. (*Zeits. angew. Chem.*, 1899, 473.)—The following process forms the concluding portion of a lengthy article upon the general characteristics of nitro-cellulose. It is based on the fact that an alcoholic solution of sodium ethylate decomposes the nitro-compounds, leaving the ordinary cotton intact. Two or 3 grammes of metallic sodium are dissolved in 100 c.c. of alcohol, the solution is filtered if necessary, and 100 c.c. of acetone are added; 150 c.c. of the reagent are mixed with 5 grammes of the cotton in a flask or basin at a temperature of 40° or 50° C., and stirred or shaken for twenty or thirty minutes. The mass is allowed to settle, the liquid poured off through a small filter, and the residue rinsed in alcohol; the precipitate is treated with water till the brown substance dissolves, the insoluble matter is brought on to the paper, and washed with hot water and very weak hydrochloric acid. If the

residual non-nitrated cellulose is large in amount, and if extreme accuracy is not required, this first product may be considered pure; for it will evolve no gas in the nitrometer, though giving a strong reaction with diphenylamine. To extract the last traces of nitro-cellulose, it should be treated again at the above temperature with 50 c.c. of the sodium ethylate and acetone reagent, and then filtered through a tared paper dried at 100° C. The product is almost colourless, but may be completely bleached with weak acid calcium hypochlorite. The process can be simplified by allowing the first action to take place in the cold for fifteen minutes to three or four hours according to the proportion of ordinary cotton expected, heating the second time as described.

The above scheme is applicable both to explosive cotton and to collodion cotton: substitution of the acetone by a mixture of ether and alcohol renders the analysis more troublesome and less accurate. A rough idea of the quantity of cellulose in explosive cotton may be obtained by merely dissolving it in acetone: more than 0·85 per cent. of unaltered cotton is indicated by insoluble fibres floating upon the top of the liquid. F. H. L.

Valuation of Indigo. W. Holdschmidt. (*Zeits. angew. Chem.*, 1899, 451, 475.)—The usual process for valuing indigo by heating it on the water-bath with strong sulphuric acid and then titrating the sulphonic acid with permanganate, presents two difficulties: (*a*) If the temperature rise too high, carbonaceous matter and sulphurous acid may be formed; and (*b*) the end point of the reaction is very troublesome to determine by simply watching the colour of the liquid, especially in such grades of indigo as contain much indigo red. These difficulties can be overcome by sulphonating in the cold with concentrated sulphuric acid mixed with 40 per cent. of phosphoric anhydride: 0·5 to 1 gramme of the finely powdered dry indigo is weighed into a tube, covered with 10 c.c. of the acid mixture, stirred at intervals with a glass rod, and kept in the desiccator for two hours or over-night. The mass is then poured through a funnel into a 500 or 1,000 c.c. flask filled one-third with water, the tube well rinsed out with cold water, the solution made up to the mark, and filtered quickly through a double paper. Twenty-five c.c. of the filtrate are next diluted with 100 or 125 c.c. of water, and titrated in a porcelain basin with centi-normal permanganate which has been standardized on oxalic acid of equivalent strength. The reagent is added at the rate of 120 or 130 drops per minute till the liquid is only faintly green, and the permanganate produces a dark cloud where it mingles with the indigo solution. Four more drops are run in with very gentle agitation of the liquid; the cloud is watched for, and when it completely disappears, the volume of permanganate is read off and 0·2 c.c. (corresponding to the 4 drops) deducted from the total. The amount of water, the speed of adding the reagent, and the illumination of the flask must be kept uniform in all tests. It is convenient to work by means of a powerful paraffin lamp.

The process employed by Donath and Strasser (*Zeits. angew. Chem.*, 1894, 47) for estimating indigotin after extracting indigo-gluten and indigo red by the aid of dilute hydrochloric acid and a mixture of ether and alcohol, gives very good results provided

the instructions are followed exactly. It is advisable, however, to wash the asbestos filter with water strongly acidified with sulphuric acid, to filter the diluted indigo solution through paper, and also as before to titrate by the "cloud" rather than by the colour of the liquid. The two methods then, with the exception of one abnormal specimen of "fine Bengal" indigo (which it appeared had been made by the patent "Coventry process"), gave concordant figures, lying well within the limits of error (0·6 per cent.) quoted by the previous authors.

Comparative dyeing experiments on wool showed that extracted indigo solutions produced pure uniform shades of blue, whereas the non-extracted solutions gave irregular and paler tints. The tests were but analogous to practical experience, for the depth of colour was not strictly proportional to the real amount of indigo present in the baths. In fact, only similar materials, *i.e.*, such as have been freed from red and gluten, or such as have not been so freed, can fairly be contrasted by dyeing methods; and only extracted indigos give trustworthy indications (within 2 per cent.) as to their actual content in indigo blue. Colorimetric trials were also carried out in Grosse's polarizing colorimeter, and emphasized the necessity for similarity between the samples. Two specimens of indigo, containing 64·9 and 62·7 per cent. of indigotin, used as standards as against two others containing by titration 45·43 and 58·3 per cent., made the latter to come out at 46·02 and 57·96 per cent.; but another pair, which volumetrically contained 46·38 and 47·4 per cent. by comparison with 48·9 and 59·1 per cent. standards, gave only 41·06 and 42·35 per cent. respectively, *i.e.*, 5 per cent. too little, presumably because the shades were divergent. (For full details respecting these dyeing and optical investigations and methods of manipulating the latter apparatus, the original communication must be consulted.)

An earlier process for estimating indigotin by a Kjeldahl nitrogen determination, after the glutinous matter, red, and brown, had been extracted with hot dilute hydrochloric acid, alcohol, and hot dilute potash, was outlined by Voeller (*Zeits. angew. Chem.*, 1891, 110). The idea is only feasible for high grade indigos, (1) because excessive handling with solvents may lead to the formation of isomeric bodies, (2) because lower quality samples contain other nitrogenous substances which are not capable of extraction. Nevertheless, as it has lately been shown that indigo red is a most important body, and serves to fix the blue on the fibre, it might be advantageous to submit the residue of the alcoholic (or ethereal) extract to a nitrogen estimation in order to determine approximately the proportion of red, for otherwise it is not easy to obtain this constituent in a form suited for weighing. The solutions of the gluten and the brown may be treated similarly, but the potassium or sodium hydroxide employed to dissolve the latter should not exceed 1 per cent. in strength. All these extractive matters may conveniently be calculated on the assumption that, like indigotin itself, they contain 10·687 per cent. of nitrogen.

It might be expected that, after all the isomeric bodies have been extracted, every indigo should give a practically identical result by sulphonation and titration with permanganate for the indigotin in it. This is not so, for further changes occur in the material during the treatment with alkali and the subsequent drying at 100° C. It follows, therefore, that when the nitrogenous non-indigo substances have been completely removed, the nitrogen content of the residue corresponds to the amount

of indigotin; but a titration of the extracted matters in no way represents the indigo blue in the original sample.

Copious tables recording the analysis of various indigos by the different processes mentioned above are appended. F. H. L.

Furcora Gigantea, a New Commercial Fibre. A. Herzog. (*Chem. Zeit.*, 1899, xxiii., 314.)—This new fibre is being introduced into the arts as a substitute for manilla, which it approaches closely in tensile strength. It is derived from a species of aloe, recently taken into cultivation in the neighbourhood of Shenstone, Natal.

FIG. 1.

FIG. 2.

The single fibres average 3 millimetres in length and 0·032 millimetres in diameter; the simple cells vary between 1·3 and 6 millimetres long by 0·021 and 0·042 millimetres wide. The general microscopic appearance of the substance is shown in the annexed drawings, Fig. 1 being a longitudinal section, Fig. 2 a transverse section; both are magnified 100 diameters.

Iodine and sulphuric acid colour the fibre yellow. Its methyl number is 9·29, corresponding to 17·56 per cent. of lignin in the dry material, a value which is practically identical with that found in the commoner *Aloe perfoliata* (17·22 per cent.). The ash of the fibre is poor in silica (3·78 per cent. of SiO_2) but very rich in lime. The average proportion of ash is 1·3 per cent. F. H. L.

INORGANIC ANALYSIS.

The Volumetric Determination of Bismuth. C. Reichard. (*Zeit. anal. Chem.*, 1899, xxxviii., 100, 101.)—A weighed quantity of the substance containing the bismuth compound is dissolved in acid, and an excess of alkali added to the solution. The bismuth is then oxidized by means of chlorine water, or, preferably, by passing a current of chlorine through the heated liquid. The precipitate is boiled until its colour changes from orange to dark red. The bismuthic acid is washed by decantation with water to remove the excess of alkali and chlorine, after which a sufficient quantity of a standard solution of arsenious acid in sodium hydroxide is added and the liquid boiled, until the red bismuthic acid is converted into the white hydroxide ($Bi_2(OH)_6$). When the reaction is complete the liquid is rendered strongly acid with sulphuric acid, filtered while hot from the precipitate, and the unoxidized arsenious acid in the filtrate determined by titration with permanganate.

It is advisable to use solutions containing only small quantities of bismuth in

order to shorten the time required for the reduction. A suitable strength mentioned for the arsenious acid solution is about 0·01 gramme of As_2O_3 in 1 c.c.

C. A. M.

Determination of Zinc in Ores containing Alumina. F. Jensch. (*Zeits. angew. Chem.*, 1899, 465.)—In the analysis of zinc ores it is often noticed that the precipitate produced by ammonia carries down with it notable quantities of zinc, and thus consists of a varying mixture of the oxides of iron, aluminium, zinc, and manganese. The author has investigated a number of different minerals to see whether it is the manganese or the alumina which causes this deposition, and he finds that the action is due chiefly to the latter. In most cases, however, a second, and in all cases a third, reprecipitation with ammonia suffices to obtain the whole of the zinc in the united filtrates.

F. H. L.

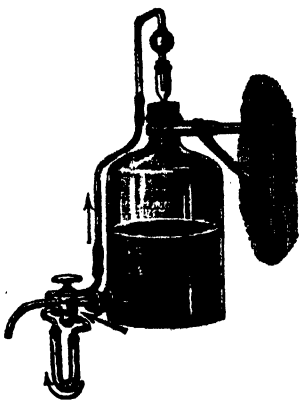
Determination of Ammonia, Nitrates, and Nitrites in Water. L. W. Winkler. (*Chem. Zeit.*, 1899, xxiii., 454.)—It is one of the inconveniences of the Nessler process for estimating ammonia in water that the tint produced by the sample under examination cannot be matched by running standard ammonium chloride solution into a mixture of ammonia-free water and the Nessler reagent. In the presence, however, of Rochelle salt this becomes possible, for instead of the usual turbidity a clear colour is formed, which lends itself properly to optical inspection. In two similar stoppered cylinders are placed 100 c.c. of the water to be analysed and 100 c.c. of ammonia-free water respectively; 2 or 3 c.c. of a cold-saturated solution of Rochelle salt are added to each, and then the same volume of Nessler's reagent. The cylinders are shaken, and standard ammonium chloride is dropped into the second from a small finely-graduated burette until the tints are identical. Turbid waters should be filtered, rejecting the first portions of the filtrate.

For the estimation of nitrates plus nitrites, two 50 c.c. flasks are taken and charged, one with 10 c.c. of the sample, the other with 10 c.c. of distilled water. To each are added 1 c.c. of a 2 per cent. solution of brucine sulphate and 20 c.c. of sulphuric acid. A solution containing 0·187 gramme of pure potassium nitrate per litre, of which each c.c. is equivalent to 0·1 milligramme of N_2O_5, is dropped into the standard flask till the yellow colours match. If the proportion of nitrates is very small, the quantities of water may be raised to 50 c.c., the other liquids being increased *pari passu*, and to insure great accuracy, the volumes in both flasks should be made identical before comparison. The organic matter in natural waters does not appear to affect the process, for when a bad spring water was boiled with acid permanganate (the excess being destroyed with oxalic acid) the results were the same. Ferrous salts must first be oxidized with permanganate. The brucine reaction indicates nitrites as well as nitrates; the former are determined as follows: 100 c.c. of water are filtered if necessary and freed from ferric iron (ferrous iron is of course immaterial) by treatment with sodium hydroxide, and brought into a 200 c.c. flask having a long narrow neck. Twenty c.c. of 10 per cent. hydrochloric acid and 2 or 3 c.c. of starch solution are added, and then 4 grammes of potassium bicarbonate are dropped in gramme by gramme in order to yield a current of carbon dioxide,

which serves to remove all oxygen from the water and from the flask. A small crystal of potassium iodide and 1 more gramme of the bicarbonate are introduced, and the free iodine is titrated with a solution of thiosulphate made by diluting 26·3 c.c. of he normal reagent to 1 litre (1 c.c. equals 0·1 milligramme of N_2O_3). The results of all three processes are satisfactory. F. H. L.

A Method for Facilitating the Colour Comparison in the Determination of Nitrates in Water by the Phenol-sulphonic Acid Method. F. X. Moerk. (*Amer. Journ. Pharm.*, 1899, lxxi., 157-161.)—The only drawback to this method is the difficulty sometimes experienced in matching the colour, owing to bye-colours being produced by other substances in the water. A correction can be made for these, however, by taking a duplicate portion of the sample of water and volatilizing the nitric acid by heating the residue on the water-bath with ordinary sulphuric acid. In the test proper with phenol-sulphonic acid the organic matter is acted upon as in the duplicate test, while the nitric acid forms a nitro-derivative. Two solutions are thus obtained, one representing only the colour derived from the organic matter, while the colour in the other is due to both organic matter and nitrates. These solutions are suitably diluted, and a sufficient quantity of the standard nitrate solution added to the duplicate to match the colour.

With reference to the determination of ammonia, the author states that the standard ammonium chloride solution gradually deteriorates, and should be re-standardized or replaced from time to time. C. A. M.

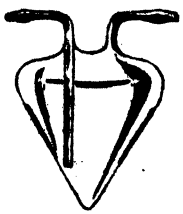


Atomic Weights for Industrial Purposes. H. Erdmann. (*Zeit. angew. Chem.*, 1899, 424.)—This article is essentially an attack on the Commission of the German Chemical Society for taking O = 16 as the unit in their new table of atomic weights (this vol., p. 83), and on W. Fresenius for recently retaining the units H = 1 and O = 16. There are various advantages derived from adopting H = 1 as the basis: all electro-chemical and weight-to-volume calculations are greatly simplified by reason of the fact that 1 litre of hydrogen at normal temperature and pressure weighs 0·0900 gramme; the atomic weights of silver and iodine become round numbers (107 and 126 respectively), and these are two of the substances most frequently determined. The employment of O = 16 destroys these conveniences, while this element is nearly always estimated by difference. The argument that the O = 16 system gives the approximate values C = 12 and N = 14 (instead of 11·9 and 13·9) is vitiated by the unwieldy number of hydrogen = 1·0075. Erdmann would like to see several years elapse with further accurate determination of the true atomic weights before any list claiming international adoption is finally drawn up. F. H. L.

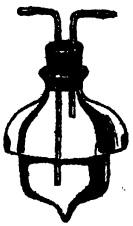
APPARATUS.

A Laboratory Ball-mill. H. Thiele. (*Zeits. angew. Chem.*, 1899, 597.)—The chief feature of this apparatus is in the device employed for rotating the mill. A horizontal, rectangular metal tray, fastened to the wall, contains two parallel lengths of gas-barrel covered with a wooden casing, which serve as supports and driving-gear

for the mill proper. One length runs in fixed bearings, and carries a pulley at the end, or is otherwise connected with the prime motor. The second revolves free, and can be dropped into slots at different distances from its neighbour, so as to accommodate mills of varying sizes. Stops are fixed at the ends of the tray in order to prevent the mill working its way over the ends of the rollers. Any convenient cylindrical vessel can be used as a mill, preferably one made of porcelain; while two or more of slightly different diameters can be revolved simultaneously. F. H. L.



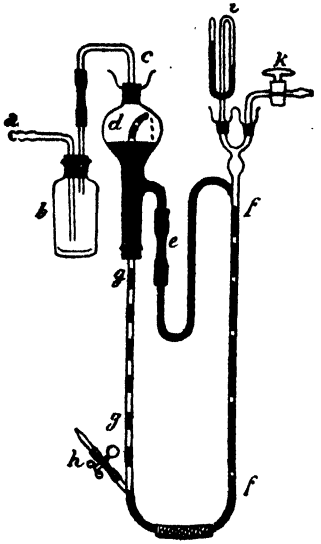
Storage Vessel for Delicate Volumetric Solutions. W. Steinfels. (Reprint from *Zeits. anal. Chem.*; through *Chem. Zeit. Rep.*, 1899, 146.)—The object of this apparatus is to prevent continual access of air and moisture to the protective material placed at the inlet of vessels containing unstable volumetric solutions, so that it may remain efficient for a greater length of time. The essential feature consists in a stopcock with three passages drilled in such positions that the liquid exit, the air entry, and the apertures of the guard tube are either all closed, or, after rotating it through 90°, are all simultaneously open. The sketch illustrates the general arrangement, and the arrows indicate the passage of air into the vessel. For alkaline liquids, the glass cock is replaced by three rubber tubes, controlled by a special "eccentric" clip, which acts in a similar manner. The bottle is slung by the neck, so that it can be shaken, and the bulb tube at the top serves to return any volatilized water.



F. H. L.

Some New Apparatus. H. Göckel. (*Zeits. angew. Chem.*, 1899, 494.)

Reflux Condenser for use with Beakers.—The object of this device is to enable an ordinary beaker to be employed for cohobating liquids, instead of the usual flask with vertical tubular condenser. The advantages are various: there is no cork or rubber to be attacked; the solid residue (after distillation) can be removed from the beaker with a spatula, and any volatilized solid matter can be scraped off the external surface of the condenser. As shown in the drawings, the apparatus is made in two forms; one fits a beaker of any size by virtue of its conical shape, the other rests on the top by means of its shoulder. Grooves are provided to permit entry and exit of air when lipless beakers are adopted.



Funnels for use with Filter-plates.—When filter-plates are employed with the pump in an ordinary funnel, they are very liable, especially if at all large in diameter, to slip out of position and so to dislodge the filter-paper. The new funnels accordingly are constructed with horizontal internal grooves against which the edges of the plate (or plates) have a bearing. Thus it is possible to put two or three plates of different sizes in one funnel, filtering the liquid two or three times in one operation.

Convenient media such as sand, glass-wool, etc., can also be packed between the plates when disposed in this fashion.

[All these articles are to be procured from Alt, Eberhardt, and Jäger, of Ilmenau.]

F. H. L.

An Automatic Mercury Pump. F. Friedrichs. (*Zeits. angew. Chem.*, 1899, 498.)—This apparatus has been designed to work with the minimum of mercury, and to be as simple and cheap as possible for ordinary laboratory work. The parts are connected with rubber tubes to make it easier to clean, and the rubber corks are provided with mercury seals. The flask *b* serves to catch any liquid that may flow back from the water-pump attached to *a*, and the manometer is intended as a check on the working of the apparatus rather than as a means of measuring the vacuum. Two clamps suffice to support it securely.

F. H. L.

REVIEW.

ANLEITUNG ZUR DARSTELLUNG CHEMISCHER PRÄPARATE. By Professor Dr. H. ERDMANN. Second edition. (Bechhold, Frankfurt.)

This is an excellent little book, giving explicit and at the same time concise directions for the preparation of typical inorganic substances, intended for the use of students. A good many books have appeared during the last few years dealing with organic preparations, while inorganic ones have been lamentably neglected. In the whole field of inorganic chemistry there is at the present time happily a revival of activity, and the same considerations which have led to the marvellous development of organic chemistry are now yielding copious results in inorganic chemistry.

The preparations chosen by Professor Erdmann cover a very wide field, and embrace preparations of compounds of thirty-five elements. It may safely be said that the student who has worked through this little work will have a wider and more useful knowledge of inorganic chemistry than he could possibly obtain by the usual course of "test-tubing."

Many of the preparations are chosen in view of their application to organic synthesis. Some of them are not hackneyed preparations, but are quite modern, the reduction even of manganese dioxide to fused metallic manganese by means of the Goldschmidt-Vautin reaction, which only dates back to 1898, being included.

O. H.

THE ANALYST.

SEPTEMBER, 1899.

OBITUARY NOTICES.

THE LATE SIR EDWARD FRANKLAND.

It is with deep regret that we have to record the death, full of years and honours, of one of the most eminent of our Honorary Members, Sir Edward Frankland, which took place on August 9, 1899. The deceased was born at Churchtown, near Lancaster, in 1825, and received his general education at the Lancaster Grammar School. He commenced his chemical career as a student under Hofmann at the Royal School of Mines, and afterwards studied in the laboratories of Giessen and Marburg under Liebig and Bunsen respectively. When quite a young man Dr. Frankland commenced that series of researches which was finally destined to yield such important results in the development of the theory of chemistry. These were at first of an analytical nature, and were aimed at the isolation and identification of the proximate radicles contained in certain organic bodies; afterwards problems of a synthetical nature were attacked; these consisted of the building up of organic bodies, and resulted in the discovery, in 1850, of the organo-metallic compounds of methyl and ethyl with zinc. The demonstration that such bodies could be produced was of the greatest theoretical value, since the study of their formation led to certain deductions being drawn having reference to the equivalence of the elements. These, which were communicated to the Royal Society in 1852, have had a vast influence on the course of chemical theory. In 1851 Dr. Frankland was appointed Professor of Chemistry at Owens College, Manchester, and it was there that his first work in relation to applied chemistry was carried out. It consisted in an investigation into the composition of the gases evolved by the various kinds of coal employed in the manufacture of illuminating gas. In 1865 he succeeded his former teacher, Hofmann, at the Royal School of Mines; and also undertook the continuance of the monthly analyses of the waters supplied to London, which had been commenced some months previously by Hofmann for the Registrar-General. Frankland, dissatisfied with the processes then in general use for this purpose, elaborated in conjunction with Armstrong the well-known process which bears their conjoint names. Dr. Frankland was appointed, in 1868, a member of the second Royal Commission on the Pollution of Rivers, which sat for six years, in the course of which a large amount of chemical work was performed that led to a more complete knowledge of the properties of the waters derived from the various water-bearing strata of this

country. In one of his experimental investigations he spent the night in company with Tyndall on the summit of Mont Blanc, determining the rate of combustion of stearin candles in order to discover if this was dependent on the density of the atmosphere. In conjunction with Fick and Wislicenus, Dr. Frankland made a series of determinations of the amount of nitrogen excreted by the human body during severe exercise; the interpretation of these demonstrated that all the force evolved could not be derived from the waste of muscular tissue alone, but must be obtained from the combustion of fatty and allied bodies. In addition to holding the official positions which have been already mentioned, Dr. Frankland was also Lecturer on Chemistry at St. Bartholomew's Hospital, Professor of Chemistry at the Royal Institution (where he succeeded Faraday), and at the Royal College of Science, from which he retired in 1885. He was elected a Fellow of the Royal Society in 1853, and was the recipient of a gold medal from that Society in 1857. The University of Oxford conferred upon him the degree of D.C.L. in 1873, and that of Edinburgh the degree of LL.D. in 1884. Dr. Frankland was President of the Chemical Society in 1871, and was also the first President, in 1877, of the Institute of Chemistry. His merits were fully recognised abroad, for he was either member or corresponding member of numerous foreign academies of science.

THE LATE PROFESSOR ROBERT WILHELM BUNSEN.

It is also with sincere regret that we announce the death, on August 18, 1899, at Heidelberg, of the world-renowned chemist Professor Bunsen, who had reached the mature age of eighty-eight years. Born at Göttingen, he studied science at the University of his native town, taking his degree of Ph.D. there in 1831, and afterwards continued his studies at Paris, Berlin, and Vienna. In 1836 he succeeded Wöhler as Professor of Chemistry at Cassel, and became Assistant Professor at the University of Marburg in 1838. In 1852, after a short interval at Breslau, Bunsen was appointed to the Chair of Experimental Chemistry at Heidelberg, and here, though he received a tempting invitation to Berlin, he spent the remainder of his active career, resigning his professorship in 1889.

Bunsen was an indefatigable investigator and a prolific inventor, several of his devices being of an eminently utilitarian nature. Amongst these may be mentioned the Bunsen battery and the Bunsen burner, the latter of which is now an almost universal household appliance. The truly marvellous discovery, in connection with Kirchhoff, of spectrum analysis, forming as it does a separate and distinct branch of chemical science, will most of all serve to keep his memory in remembrance. Amongst his numerous investigations were those on the explosive compounds of arsenic, an accident during which nearly cost him his life; those, in conjunction with the late Lord Playfair, into the chemistry of the gases evolved by blast furnaces; and those with Sir Henry Roscoe on actinometry and on the chemical action of light. As the result of a visit to Iceland in 1847, came the investigation into the geological conditions of that island and his theory of geysers. But that portion of his labours which appeals most directly to analytical chemists is the working out of his system

of gas analysis, which is so distinguished by the precision of its results that it may be said to have placed this branch of analysis on a firm and secure foundation. These are only a few of his many contributions to chemical and physical science, which are recorded in a numerous series of memoirs.

Pre-eminent as a teacher, and ardently devoted to his laboratory and students, Bunsen succeeded in forming at Heidelberg a school of chemistry rivalling that of Liebig at Giessen; whilst his kindly and genial nature endeared him not only to his numerous students, but also to all his colleagues.

Bunsen was the recipient of many orders and decorations, and also of many academical distinctions. Amongst these latter was his election to the fellowship of the Royal Society in 1858, the awarding to him of the Copley Medal of that Society in 1860, and also to himself and Kirchhoff of the Davy Medal in 1877.

In Bunsen we lose the last connecting link between the great German chemists of the past and those of the present time.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

ON SOME COMPARATIVE ANALYSES OF, AND DIGESTION EXPERIMENTS WITH, WHITE AND WHOLE-MEAL BREADS.

By Otto Rosenheim, Ph.D., and Philip Schidrowitz, Ph.D.

(*Read at the Meeting, June* 7, 1899.)

The distinct progress made in many branches of food technology, due to the substitution of methods based on scientific principles for empirical practices, does not apply to any extent to the large and important bread industry. There has been no lack of proposals in this direction, but owing partly to their impracticable nature, and partly to the conservatism of the industry concerned, they do not appear to have been adopted to any great extent.

One of the most inviting questions in this connection is the improvement of the nutritive value of bread by increasing its percentage of albuminous matter, which is very small as compared with the carbohydrates and other nitrogen-free substances. In this direction many attempts have been made to make use of the relatively large quantity of nitrogenous matter in the husks or outer parts of the cereals concerned, which at present is wasted in the manufacture of white bread, where only the finely-dressed flour obtained from the inner part of the grain is used.

Although whole-meal breads made from whole-grain flour show on analysis a higher percentage of albuminous matter and phosphates than bread made from white flour, digestion experiments* have shown that the nutritive value of these breads is not materially increased, and these results have found practical confirmation in the taste of the public, which has always evinced, and continues to evince, a decided predilection for ordinary white bread. The chief reason for this fact lies probably in

* *Cf.* Rübner, *Zeitschrift f. Biologie*, 19, and Meyer, *id.*, 1871.

the increased percentage of indigestible cellulose and the physical state of the same. It has been pointed out by different investigators (Lehmann,* Goodfellow,† Prausnitz‡) that the degree of fineness of these breads in general leaves much to be desired, and it is probably due to the mechanical irritation set up by the large flakes of indigestible cellulose in the intestinal tract that the peristaltic action is accelerated, thereby preventing the absorption of much matter which, under ordinary circumstances, would be completely assimilated. This increase of peristaltic activity may occasionally be desirable, but the effects aimed at in such cases are medicinal rather than alimentary.

We have recently had an opportunity of making some experiments with a whole-meal bread the chief advantage of which, according to the patentees, consists in the fact that the cellulose is very finely comminuted, the object of this being to avoid the undesirable results alluded to above. We have made a complete analysis of, and some digestion experiments with, this bread, and for purposes of comparison have similarly examined a white bread and a whole-meal bread of ordinary make under identical conditions, and venture to think the results may be of some interest to the members of the Society. The results of the purely analytical examination are set forth in

TABLE I.

Results of Chemical Analysis of Three Breads: I., Ordinary White Bread; II., Ordinary Whole-meal Bread; III., Patent Whole-meal Bread.

	Percentage Composition of					
	Breads as Examined.			Water-free Breads.		
	I.	II.	III.	I.	II.	III.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Water	39·10	40·18	48·83	—	—	—
Dry substance	60·90	59·82	51·17	100	100	100
Total ash	0·59	1·88	1·12	0·97	3·14	2·18
Phosphoric acid	0·16	0·51	0·43	0·26	0·85	0·84
Soluble matter	4·73	7·54	10·00	7·77	12·60	19·54
Total albumin	8·25	7·87	6·94	13·54	13·16	13·56
Pure albumin	7·34	7·86	5·52	12·05	13·15	10·78
Soluble nitrogenous matter	0·61	0·73	0·68	1·00	1·22	1·32
Starch	38·45	39·18	31·86	63·13	65·49	62·45
Sugar (maltose)	1·19	1·77	0·62	1·95	2·96	1·21
Dextrin	0·84	0·71	0·52	1·38	1·19	1·01
Cellulose	0·24	1·06	0·86	0·39	1·68	1·68
Fat	0·21	0·63	0·34	0·34	1·05	0·66
Acidity (lactic acid)	0·19	0·29	0·38	0·31	0·48	0·74
Loss of water in 15 days	9·23	—	7·60	—	—	—

It will be seen from the above table that as far as the two brown breads are concerned the analytical figures reveal no striking differences. The soluble matter is

* "Archiv. Hygien.," 19 vol., 73. † "The Dietetic Value of Bread," Macmillan, 1892.
‡ "Archiv. Hygien.," 17 vol., 626.

appreciably higher in III., and this bread has also a slight advantage in the total albumin and soluble nitrogen; on the other hand, the ordinary whole-meal (No. II.) contained appreciably more pure albumin (as determined by Stutzer's method) and fat. The quantity of cellulose was, curiously enough, identical, but the quality was very different. After removing starch, sugar, albumin, fat, etc., by the ordinary methods, the cellulose residue of II. was seen to consist of large, thick, non-transparent entire flakes of a brownish colour, whereas the patent bread cellulose was in the form of very thin, straw-coloured transparent flakes, mostly broken up into irregular shapes.

As far as the white bread is concerned, it will be seen that it contained appreciably less ash, phosphoric acid, and soluble matter than the whole-meal varieties, but its nitrogenous constituents (total, pure and soluble albumin) were, practically speaking, equal to those contained in the former.

The Digestion Experiments.—The digestion experiments were all carried out *in vitro*, and although it has often, and we think with justice, been urged that experiments conducted under these artificial conditions are no criterion for forming an opinion as to the actual processes and changes taking place in the body, yet we venture to think that, conducted on purely comparative lines and under absolutely equal conditions, they are likely to afford a valuable clue as to the relative merits of the different substances concerned, and are to a very great extent comparable *inter se*.

The plan of our experiments was to submit the breads to the action of the chief ferments to which they would be exposed during their passage through the body under conditions as similar as possible to those obtaining in natural digestion, and for this purpose we subjected them :—

(*a*) To the salivary digestive process ;

(*b*) To gastric, followed by the pancreatic, digestion ;

(*c*) To the pancreatic digestive process.

It was not thought necessary to make experiments with gastric digestion alone, inasmuch as bread is never digested by the gastric juice alone either in health or disease.

The digestion of bread, broadly speaking, consists, firstly, in the conversion of starch into sugar, and, secondly, in the transformation of insoluble nitrogenous matter into soluble albumoses and peptones. As a measure of the relative digestibility of the breads, we took on the one hand the quantity of starch converted into sugar, and on the other the percentage of soluble albuminoid formed from equal weights of bread in a given time, the results being calculated on the water-free substances. These figures are not strictly comparable *inter se*, owing to the different percentages of starch and nitrogenous matter in the various breads ; and to eliminate this source of error the results were also calculated on the original percentage of starch and nitrogenous matter.

(*a*) *Salivary Digestion.*—We were unable to find any record in literature of work on the action of the salivary ferments on bread, and this fact may perhaps lend some additional interest to the figures obtained. The measure of the digestibility of the breads when exposed to the influence of salivary digestion was the quantity of sugar formed (*a*) in five minutes, (*b*) after half an hour's exposure to the action of mixed saliva.

Method.—Saliva was collected from three observers, mixed, filtered, and then diluted to twice its volume with distilled water. To 2 grammes of each bread were added 30 c.c. distilled water and 30 c.c. of the mixed saliva, and the whole was then incubated at 35° to 40°. At the end of the proper period the mixtures were removed from the incubator, and further digestion was stopped by bringing them briskly to the boil. The sugar was then estimated in each case according to the usual gravimetric method. The results were as follows :

TABLE II.

Salivary Digestion. I., II., III. as in Table I.

	Breads as Examined.			Water-free Breads.		
	I.	II.	III.	I.	II.	III.
	Percent.	Percent.	Percent.	Percent.	Percent.	Percent.
Sugar formed by saliva :						
1. After 5 minutes' digestion ...	6·82	2·62	3·75	11·19	4·38	7·32
2. ,, 30 ,, ,, ...	13·18	5·98	6·94	21·64	9·99	13·56
Total sugar theoretically formable from starch				70·14	72·76	69·38
Percentage of sugar actually formed calculated to theoretical sugar :						
1. After 5 minutes' digestion ...				15·95	6·02	10·55
2. ,, 30 ,, ,, ...				30·85	13·73	19·54

On looking at the above table, it becomes apparent that, as far as salivary digestibility goes, the white bread was far superior to the others, and that the finely comminuted patent bread gave much better results than the ordinary coarse wholemeal bread.

B. Gastro-Pancreatic Digestion.—The measure of digestibility was the quantity of nitrogenous matter converted after ten hours' gastric, followed by six hours' pancreatic, digestion.

Method.—Two grammes of bread were mixed with 10 c.c. of a standard pepsin solution and 50 c.c. of water, incubated at 37° C. for ten hours, filtered, washed, and the residue then submitted to six hours' pancreatic digestion, as described under *C*. Results :

TABLE III.

Gastro-Pancreatic Digestion.

	Breads as Examined.			Water-free Breads.		
	I.	II.	III.	I.	II.	III.
	Percent.	Percent.	Percent.	Percent.	Percent.	Percent.
Nitrogenous matter digested after 10 hours' digestion with gastric juice, 16 hours' with pancreatic juice ...	6.18	4·28	4·80	10·14	7·99	9·38
Percentage of nitrogenous matter digested to total nitrogenous matter ...				74·89	60·71	69·71

Here also we see the decided superiority of the white bread over both the brown varieties, and of the patent bread over the ordinary whole-meal.

C. Pancreatic Digestion.—In this case the measures of digestibility were: (1) The quantity of sugar formed after (*a*) one hour, (*b*) seven hours, and (2) the quantity of nitrogenous matter digested after 11 hours.

(1) *Transformation of Starch.*—The pancreatic diastatic digestions were made upon the same plan as the salivary ones. A well-known standard solution of pancreatic juice was used. Each digestive mixture was made up as follows: Bread, 2 grammes; pancreas solution, 15 c.c.; distilled water, 45 c.c.; and a few drops of a saturated solution of sodium carbonate. These mixtures were left in the incubator at 37° for the necessary period, and further digestion was then stopped as before. While in the incubator the mixtures were from time to time stirred, and their reaction was seen to be alkaline; the sugar was estimated in each case as before. The results are shown in

TABLE IV.

Pancreatic Starch Digestion.

	Breads as Examined.			Water-free Breads.		
	I.	II.	III.	I.	II.	III.
	Percent.	Percent.	Percent.	Percent.	Percent.	Percent.
Sugar formed by pancreatic digestion:						
1. After 1 hour	21·32	8·52	11·55	35·00	14·24	22·57
2. After 7 hours	21·97	11·82	14·08	36·07	19·75	27·51
Percentage of sugar actually formed calculated to theoretical sugar:						
1. After 1 hour				49·90	19·57	32·53
2. After 7 hours				51·42	27·14	39·65

In this case also the white bread proved itself superior to the two others, not only relatively, but absolutely; and the patent bread gave better results than the coarse whole-meal bread. Another point worthy of notice is, that whereas the quantity of sugar formed in the case of the white bread does not materially increase after the first hour, the differences between the one and seven hour digestions as regards the other two breads is most marked. In the body, where the products of digestion are removed from the intestinal tract, it is most probable that the results would be still more favourable to white bread.

(2) *Pancreatic Transformation of Nitrogenous Matter.*—The measure of digestibility was the quantity of nitrogenous matter transformed after eleven hours' digestion.

Method.—Digestive mixtures made similarly to those used in the case of the pancreatic starch digestions were kept at 37° for eleven hours, and at the end of this period boiled, and then filtered through asbestos. After careful washing with distilled water, the nitrogen in the residue was estimated by the usual methods, and calculated to albumin by multiplication with the 6·25 factor; by deducting the figure thus obtained, together with the original soluble albumin from the total original insoluble albumin, the quantity of albumin actually digested was arrived at.

TABLE V.

Pancreatic Transformation of Nitrogenous Matter.

	Breads as Examined.			Water-free Breads.		
	I.	II.	III.	I.	II.	III.
	Percent.	Percent.	Percent.	Percent.	Percent	Percent.
Nitrogenous matter digested after 11 hours of pancreatic digestion... ...	6·55	5·48	5·56	10·75	9·16	10·86
Percentage of nitrogenous matter digested calculated on total nitrogenous matter				79·38	69·61	80·08

In this case it will be seen that the white bread and the patent bread were practically equal, but both considerably superior to the ordinary whole-meal.

Conclusions.—Although we do not desire to draw any sweeping conclusions from the above experiments, owing to their limited number and somewhat restricted character, we feel justified in saying that they tend to bear out the opinion now generally held in scientific circles as to the great superiority of white bread as far as digestibility pure and simple goes. It is usually believed that whole-meal bread contains considerably more nitrogen than the white article, but this was certainly not the case in the breads examined by us; and although they were selected with care, there is sufficient variation in ordinary flours to account for this apparent anomaly. The whole-meal breads certainly contained considerably more ash, phosphoric acid, and soluble matter. The results obtained with the patent brown bread, in which the grain and husk are very finely comminuted, supports the contention that the digestibility and wholesomeness of whole-meal bread can be greatly improved by careful and thorough grinding and disintegration of the cellulose.

DISCUSSION.

THE CHAIRMAN (Mr. Allen) inquired how much of the ash in these breads was due to salt; the ash in bread depended mainly on the quantity of salt employed. The question suggested itself whether one ought not to determine the quantity of starch rendered soluble rather than the quantity converted into sugar; but seeing that, at a specified temperature, the proportions of dextrin and sugar formed were constant, and that they varied with the temperature, the consideration was of secondary importance. It would, however, be interesting to know whether the sugar was calculated as dextrose or maltose. He thought it was quite clear that the duty done in the system by whole-meal bread, apart from its irritant powers, must be represented by the quantity of material actually digested; and although digestion experiments carried out in glass were necessarily of an empirical nature, it was only by proceeding tentatively in this direction that any true knowledge of the matter could be gained.

Dr. J. A. VOELCKER said that, regarding the matter rather from a cattle-feeding point of view, it seemed difficult to believe that the larger proportion of phosphoric acid shown in the whole-meal bread could be without value. In the case of the

patent bread, the question of its mode of preparation naturally arose. It was to be noted, however, that it contained considerably more water than either of the others. For the results of digestion experiments to be comparable, it was necessary that the different materials should be comparable as regards mechanical condition. The authors had attempted to insure this by reducing the whole-meal bread to the same condition of fineness as the others, but whether that was successful was certainly doubtful. He did not think it was possible by merely grinding one material to the same degree of fineness as another, to imitate the mechanical condition of the latter, when it had perhaps been quite differently treated *ab initio*. It seemed curious that so slight a difference as existed between the quantities of starch in No. 1 and No. 2 should be followed by so large a difference in sugar produced as was indicated by the salivary digestion experiment, and he thought it likely that, owing to their necessarily different mechanical composition, the two materials were in reality not being treated on exactly the same level. He agreed with the authors that the superiority of whole-meal bread had been exaggerated in some directions, but he was still open to be convinced that such constituents as the phosphoric acid and the soluble matters were without value, or that there was any reason for the less rapid production of sugar in the whole-meal bread other than that attaching to its different mechanical condition.

Mr. HEHNER said that many actual feeding-experiments were on record concerning the comparative digestibility of bread made of whole-meal and of white flour. 'A list of them was contained in the first volume of König, and they showed that while white bread was almost completely digested, both as regards nitrogenous matters and carbohydrates, brown or black breads gave far less favourable results. These physiological experiments were, therefore, in entire agreement with the artificial digestion experiments of the present authors.

Although the analyses showed that whole-meal flour was somewhat richer in nitrogen than white flour, this was a matter without real significance for the organism, as some of the nitrogen was unavailable to the digestive organs. It appeared to him that the cellulose envelope, which, of course, exercised a protective action over the cell-contents, did not explain the circumstance that the authors had found so low a proportion of starch to be converted into soluble products. It rather appeared as if the bran, with its high proportion of pentosans, exercised not only a protecting action, but also an inhibitive one, upon digestion. In the case of ruminant animals who had the power to digest cellulose and other carbohydrates, whole-meal would no doubt show more favourable results, but in the case of human beings, all evidence appeared to show the superiority of the carefully-prepared white over the whole-meal flour.

Analytical figures, taken by themselves, without either artificial or actual digestion experiments, could not show which of two or more vegetable substances would be the most useful to the organism.

Mr. ARTHUR MARSHALL inquired if the authors knew whether the flour used for the white bread was roller-milled or stone-milled. At least 90 per cent. of the white bread baked in this country was prepared from roller-milled flour, but a few of the best firms still employed stone-milled flour. The latter gives a loaf moister and of far

better flavour than the former. In roller-milled flours the germ of the wheat is entirely removed; consequently they contain a considerably smaller percentage of fats and albuminoids. In making whole-meal bread it is necessary to use a larger proportion both of salt and yeast. This would probably account for the greater percentage of ash and soluble matter shown in the analyses.

Mr. CHAPMAN said that the failure to separate the bran in whole-meal flour resulted in the presence of an active enzyme (cerealin), so that during panification, the conversion of starch into dextrin and sugar went on very rapidly. The bread consequently had a tendency to be soft and sodden, and the percentage of soluble matters in it increased. It was difficult, by the ordinary yeast process, to produce brown bread that did not contain an excessive proportion of water, and in making such bread it was customary to use, instead of yeast, hydrochloric acid and carbonate of soda. This fact might account for the high ash in the author's sample. The high proportion of soluble matter in the patent bread might have been due to the presence of this active enzyme, and to the starch having been in a condition particularly amenable to its action. Whole-meal bread was generally more acid than white bread, for its moist and clammy condition was very favourable to the progress of lactic fermentation.

THE CHAIRMAN (Mr. Allen) observed that for many years the percentage of ash in flour had been gradually decreasing, owing possibly to the increased employment of roller-milling processes. It used to be normally 0·72 per cent., but half this proportion was now very common.

Dr. SCHIDROWITZ said that the sugar in each case was stated in terms of glucose. It was not suggested that the comparatively high percentage of such constituents as phosphoric acid in brown bread was entirely without value, but he personally thought that, except under special circumstances, the question of digestibility was the most important one. He quite agreed that experiments on individuals were far preferable to artificial experiments, though even here the personal factor would have to be considered. He did not think that the excess of soluble matter in the patent bread was very extraordinary, seeing that the chief advantage of this bread was that the cellulose and other ingredients were very finely comminuted, and this fact also accounted for the relatively larger amount of starch converted. He did not actually know the terms of the patent under which it was manufactured, but believed that the whole grain was converted into flour in one operation.

OFFICIAL EXAMINATION OF WOOD-NAPHTHAS FOR METHYLATION PURPOSES.

(*Abridged from the "Pharmaceutical Journal," July* 15 *and August* 12, 1899.)

MAKERS of methylated spirits are, according to a notice just issued by the Commissioners of Inland Revenue, to be informed in future, as precisely as possible, what kind of wood naphtha will be accepted as suitable for methylating purposes, as well as the nature of the objections to any samples which may be rejected. All wood naphtha submitted for approval must consist entirely of substances derived

from the destructive distillation of wood. It must also be so impure as to make nine times its volume of spirit of wine sufficiently nauseous to be rendered incapable of being used as a beverage, or of being mixed with potable spirits of any kind without rendering them unfit for human consumption. Not more than 30 c.c. of the wood naphtha must be required to decolorize a solution containing 0·5 gramme of bromine; it must also be neutral or only slightly alkaline to litmus, and require at least 5 c.c. of decinormal acid to neutralize 25 c.c. of the spirit when methyl-orange is used as the indicator. No wood naphtha will be approved which contains (*a*) less than 72 per cent. by volume of methyl alcohol; (*b*) more than 12 grammes per 100 c.c. of acetone, aldehydes, and higher ketones, determined as "acetone" by the formation of iodoform according to Messinger's method; (*c*) more than 3 grammes per 100 c.c. of esters, determined as methyl acetate by hydrolysis.

We are enabled, through the courtesy of the officials at the Government Laboratory, to give the following details of the tests for wood naphtha:

Bromine Decolorization.

A standard bromine solution is made by dissolving 12·406 grammes of potassium bromide and 3·481 grammes of potassium bromate in a litre of recently boiled distilled water.

50 c.c. of this standard solution (= 0·5 gramme bromide) are placed in a flask of about 200 c.c. capacity, having a well-ground stopper. To this is added 10 c.c. of dilute sulphuric acid (1 in 4) and the whole shaken gently. After standing for a few minutes the wood naphtha is slowly run from a burette into the clear brown solution of bromine until the latter is completely decolorized. Not more than 30 c.c. of the wood naphtha should be required for this purpose.

Methyl-Orange Alkalinity Test.

The naphtha should be faintly acid to phenolphthalein; slightly alkaline or neutral, rarely acid, to litmus, and always alkaline to methyl-orange. 25 c.c. of the wood naphtha are placed in each of two beakers, and titrated with decinormal acid, using in the one case a few drops of litmus solution, and in the other of a solution of methyl-orange as indicator. With litmus usually 0·1 to 0·2 c.c. of decinormal acid is required to neutralize. With methyl-orange the total alkalinity should be greater —at least 5 or 6 c.c. of decinormal acid being required for neutralization.

The total alkalinity, less that given with litmus, is the "methyl-orange alkalinity," and, for the 25 c.c. of wood spirit, should not be less than is required to neutralize 5 c.c. of decinormal acid.

Estimation of Methyl Alcohol.

22 grammes of coarsely powdered iodine and 5 c.c. of distilled water are placed in a small flask and cooled by immersion in ice-cold water. Then 5 c.c. of the wood spirit (60·0 o.p.) are added, the flask corked, the contents gently shaken, and allowed to remain in the ice-cold bath for ten to fifteen minutes.

When well cooled 2 grammes of red phosphorus are added to the mixture of spirit and iodine in the flask, and the latter is immediately attached to a reflux condenser.

The reaction soon commences, and must be moderated by dipping the flask into a cold-water bath. (Spirit may be lost if the reaction is too violent.) After about fifteen to twenty minutes, when all action appears to have ceased, the water-bath under the flask is gradually heated to a temperature of about 75° C. (167° F.), and the flask, being occasionally shaken, is allowed to remain at this temperature for fifteen to twenty minutes. The source of heat is then removed and the apparatus left for an hour till it has cooled, when the condenser is reversed, and the methyl iodide slowly distilled off—first at a low temperature—the bath being allowed to boil towards the end of the operation only. The end of the condenser dips into water in a measuring tube, and the iodide is collected under water and measured at a temperature of 15·5° C. (60° F.).

The percentage (by volume) is found from the formula:

$$\frac{\text{C.c. methyl iodide found} \times 0{\cdot}647 \times 100}{\text{C.c. wood spirit taken.}} = \text{Percentage (by volume) of methyl alcohol.}$$

Or when 5 c.c. of spirit are taken:

$$\text{C.c. methyl iodide} \times 12{\cdot}94 = \text{percentage (by volume).}$$

Esters, acetals, etc., also yield methyl iodide by this process, and from the percentage of methyl alcohol calculated as above an amount equivalent to the percentage of these substances present must be deducted. Practically, however, methyl acetate is the only compound usually found in quantity sufficient to materially affect the result. The grammes of methyl acetate per 100 c.c. of spirit multiplied by 0·5405 give the equivalent of methyl alcohol to be deducted from the total percentage by volume calculated from the methyl iodide found.

The Acetone Reaction.

25 c.c. of normal soda are placed in a flask similar to those used in the bromine reaction. To this is added 0·5 c.c. of the naphtha. The mixture is well shaken, and allowed to stand five to ten minutes. Into it from a burette $\frac{N}{5}$ iodine solution is run slowly, drop by drop, vigorously shaking all the time till the upper portion of the solution, on standing a minute, becomes quite clear. A few c.c. more of $\frac{N}{5}$ iodine solution are added, as to get concordant results an excess of at least 25 per cent. of the iodine required must be added. After shaking, the mixture is allowed to stand for ten to fifteen minutes, and then 25 c.c. normal sulphuric are added. The excess of iodine is liberated, titrated with $\frac{N}{10}$ sodium thiosulphate solution and starch, and half the number of c.c. of thiosulphate solution used are deducted from the total number of c.c. of iodine solution used. The difference gives the amount of acetone by weight in the naphtha by the formula:

$$\text{C.c. } \tfrac{N}{5} \text{ iodine solution required} \times 0{\cdot}3876 = \text{grammes of acetone per 100 c.c. of wood naphtha.}$$

This includes as acetone any aldehydes, etc., capable of yielding iodoform by this reaction.

If the quantity of "acetone" is excessive, a less quantity of the spirit is taken, or 10 c.c. are diluted with 10 c.c. of methyl alcohol free from acetone, and 0·5 c.c. of the mixture is used.

Estimation of Esters.

5 c.c. of the wood naphtha are run into a silver pressure flask of about 150 c.c. capacity, together with 20 c.c. of recently-boiled distilled water. 10 c.c. of normal soda solution are added, the flask securely closed and digested for at least two hours in a water-bath at 100° C. (212° F.). The contents are then washed into a beaker, and titrated with normal acid and phenolphthalein. The difference between the number of c.c. of soda taken and of the acid required for neutralization may be calculated as methyl acetate (weight in volume) from the formula:

$$\frac{0{\cdot}074 \times \text{c.c. soda required} \times 100}{\text{C.c. naphtha taken.}} = \text{grammes per 100 c.c.}$$

Or if 5 c.c. of spirit are taken as above:

1·48 × c.c. soda required = grammes of methyl acetate per 100 c.c. of spirit.

FOODS AND DRUGS ANALYSIS.

A New Test for Cocaine. G. L. Schaefer. (*Amer. Journ. Pharm.*, 1899, lxxi., 222, 223.)—The tests commonly employed for the detection of other coca alkaloids in cocaine salts are the permanganate test for cinnamyl cocaine, and the ammonia (or McLagan's) test for alkaloids which resist the action of permanganate.

As various doubts have been expressed as to the value of the latter test, the author has devised a substitute for it, based on the fact that cocaine chromate is much more soluble in water, or water acidified with hydrochloric acid, than the chromates of the other alkaloids.

The following is recommended as a simple and satisfactory method of determining the purity of the salts of cocaine. In the case of the hydrochloride, for example, 0·05 gramme is dissolved in 20 c.c. of water, and to the solution are added 5 c.c. of a 3 per cent. solution of chromic acid and 5 c.c. of 10 per cent. hydrochloric acid, the temperature of the liquid being kept preferably at 15° C. With pure cocaine hydrochloride the solution will remain clear, but if more than traces of other coca alkaloids be present the liquid becomes cloudy, either immediately or after some time, according to the amount of impurity. C. A. M.

On the Relative Digestibility of certain Food Fats in the Human Alimentary Canal. (*Zeit. für Untersuch. der Nahr. und Genussmittel.*, ii., 484-506.)—This paper contains an account of experiments on digestibility which were made with three descriptions of margarine and a pure Holstein dairy butter. The procedure consisted in feeding a man of normal digestive powers with weighed amounts of the different fats, in addition to a mixed diet embracing beer, coffee, tea, sugar, bread,

lean beef and vegetables, and determining the undigested fat voided in the excreta. The amount of fat consumed per day varied between 112 and 148 grammes. The average results for periods of twenty-four hours were as follows:

Description.	Fat consumed: grammes.	Air-dried Excreta: grammes.	Dry Excreta: grammes.	Fat in Dry Excreta: per cent.	Total Fat: grammes.	Fat absorbed: per cent.
Margarine I.	138·35	47·57	43·08	12·16	4·62	96·68
,, II.	118·64	38·85	35·53	11·60	3·91	96·70
,, III.	112·89	35·01	32·19	10·78	3·46	96·93
Butter ...	111·79	46·29	42·33	11·88	4·82	95·69

In the following table, in which the total quantities for each period are given, regard is taken for the digestive fat consumed in the ordinary diet:

Periods.	Fat Consumed.			Fat Eliminated.					
	Total Fat.			Total Fat.			Undigested Fat.		Fat Absorbed: per cent.
	From Margarine or Butter: grammes.	From the Ordinary Diet: grammes.	Together: grammes.	From Margarine or Butter: grammes.	From the Ordinary Diet: grammes.	Together: grammes.	Of the Total Fat: per cent.	Of the Margarine or Butter: per cent.

H. H. B. S.

Hydrastine Periodide, and the Assay of Hydrastis Canadensis. **H. M. Gordin and A. B. Prescott.** (*Amer. Journ. Pharm.*, 1899, lxxi., 257-266.)—On adding a solution of iodine in potassium iodide to a solution of a salt of hydrastine a dense brown precipitate is obtained, which approaches a tri-iodide in composition, but appears to be a mixture of different periodides.

When, however, a weak alkaloidal solution is added to a large excess of iodine, a definite compound, hydrastine hydriodide pentiodide, is precipitated as an amorphous brown powder. This dissolves with difficulty in ether, benzene, or cold chloroform, but is more soluble in hot chloroform and alcohol, and dissolves readily in a mixture of alcohol and chloroform or alcohol and ether. When heated in water it fuses to a resinous mass.

The analysis of this periodide gave results corresponding with the formula $C_{21}H_{21}NO_6.HI.I_5$, from which its iodine factor was calculated to be 0·60403.

In the authors' iodometric estimation of hydrastine the details of the process resemble those of the general method described in a former communication (ANALYST, this vol., 74), and the only precaution to be observed is to insure the formation of the periodide by having the alkaloidal solution weak and the iodine in large excess.

In test experiments solutions were prepared containing 0·30 and 0·15 per cent. of hydrastine, and the amounts found by titration with iodine were 0·29 and 0·14 per cent. respectively.

The method worked out by the authors for the estimation of hydrastine and berberine in *Hydrastis Canadensis* is based on the following facts:

1. Hydrastine is soluble in absolute ether, berberine completely insoluble.

2. Berberine hydriodide is nearly insoluble, especially in the presence of a very large excess of potassium iodide.

3. Berberine is precipitated completely on adding to a very dilute solution 10 to 15 times its amount of acetone, and then rendering the liquid strongly alkaline with sodium hydroxide. This berberine acetone is readily decomposed by mineral acids, with the liberation of berberine.

In the assay, 10 grammes of the root are rubbed to a paste with a few c.c. of a mixture of 5 c.c. of ammonium hydroxide ("stronger ammonia"), 5 c.c. of alcohol, and 30 c.c. of ether.

Chloroform, which was used in the general method of extracting alkaloids (ANALYST, this vol., 8 and 74), cannot be employed here, since it combines with berberine, forming a compound not decomposable by acids.

The paste is left in a stoppered jar overnight, is then exposed to a current of air, and when all odour of ammonia has disappeared is kept *in vacuo* over sulphuric acid for five or six hours. The dry powder is introduced into a Soxhlet apparatus, the jar being rinsed out several times with powdered glass or barium nitrate, and is extracted with 40 to 50 c.c. of ether until a few drops of the extract give no reaction with Mayer's or Wagner's reagent.

The ethereal extract is poured into a flat evaporating dish, and the flask washed out several times with water containing about 2 per cent. of sulphuric acid. The washings are added to the main solution, and the dish exposed in a current of air at about 30° C. until the ether has evaporated.

The liquid is then transferred to a 100 c.c. flask and made up to the mark, giving a solution of hydrastine sulphate, of which each 10 c.c. represents 1 gramme of the root. Of this filtered solution 20 c.c. are run from a burette into a flask containing 20 to 30 c.c. of standard iodine solution (about 1 per cent.), and the amount of iodine consumed multiplied by 0·60403 gives the amount of hydrastine.

For a gravimetric estimation a second portion of 20 c.c. is shaken in a separating funnel with benzene and ammonium hydroxide. The colourless benzene layer, which contains the whole of the hydrastine, is transferred to another separating funnel, and shaken with water acidulated with sulphuric acid. Finally the hydrastine is extracted from this aqueous solution by means of ether and ammonium hydroxide, and the solution allowed to evaporate in a weighed beaker in a dark place, dried over sulphuric acid *in vacuo*, and weighed. The hydrastine is left in white crystals with a slight yellowish tint on the side of the beaker, which the authors attribute to the presence of traces of canadine.

In order to determine the berberine, the ether is removed from the Soxhlet extractor by means of a current of air, and the extraction continued with 40 to 50 c.c. of alcohol until the extract becomes colourless.

The alcoholic solution of berberine and extractive matters is transferred to an evaporating dish (the flask being washed with hot water containing a little acetic acid), and kept on the boiling water-bath, whilst water is added from time to time until the alcohol has been evaporated. A little more dilute acetic acid is now added, the dish covered, and the contents, when cold, filtered into an Erlenmeyer flask holding from 300 to 400 c.c.

From 6 to 8 c.c. of acetone are next introduced, followed by a 10 per cent. solution of sodium hydroxide, which is added drop by drop until the precipitate ceases to disappear on shaking, and the liquid becomes strongly alkaline. The flask is then closed, shaken in a circular direction for from ten to fifteen minutes, and allowed to stand in a cool place for three or four hours.

The supernatant liquid is poured on to a small filter, and the crystalline berberine acetone washed first by decantation and then on the filter until the washings are colourless. The filter is then pierced, and the precipitate returned to the flask, into which are also introduced 4 or 5 c.c. of 5 per cent. sulphuric acid, and sufficient water to make about 100 or 200 c.c. in all. When the flask is immersed in boiling water the precipitate is rapidly dissolved. The resulting solution is transferred to a long-necked flask, which is placed on a hot asbestos plate so that the liquid is kept gently boiling for an hour and a half or two hours, hot water being added from time to time if required.

After this the liquid is cooled, poured into a litre flask containing 100 c.c. of a $\frac{N}{20}$ solution of potassium iodide, made up to the mark, and allowed to stand overnight. The next day 500 c.c. of the liquid are filtered into another flask, and after the addition of 50 c.c. of $\frac{N}{20}$ silver nitrate and nitric acid, made up to a litre and filtered. Five hundred c.c. of this filtrate are titrated back with $\frac{N}{10}$ ammonium thiocyanate, ferric ammonium sulphate being used as indicator. Twice the number of c.c. of the thiocyanate solution used is equivalent to the number of c.c. consumed by the berberine, representing 10 grammes of the root. The amount of potassium iodide multiplied by the factor 0·167125 gives the percentage of anhydrous berberine in the root.

The results of the analysis of three samples of *Hydrastis Canadensis* by this method are shown below:

	Hydrastine.		Anhydrous Berberine.
	Iodometric.	Gravimetric.	
No. 1	2·29	2·29	2·52
No. 2	2·33	2·30	2·55
No. 3	2·35	2·28	2·47

With reference to the other *Hydrastis* alkaloid, canadine, the authors state that its proportion is too small to affect the results obtained in the determination of hydrastine or berberine. They consider it probable that the small traces present adhere to one or other of the other alkaloidal precipitates, for they have proved that no appreciable quantity of alkaloid remains in the root after the two extractions.

C. A. M.

Some Colour Reactions of Morphine and its Derivatives. R. Kobert. (*Apoth. Zeit.*, 1899, xiv., 259; through *Chem. Zeit. Rep.*, 1899, 158.)—With a mixture of 2 or 3 drops of formalin and 3 c.c. of strong sulphuric acid, morphine and its derivatives give the following visual and spectroscopic colour reactions. Morphine itself becomes purple-red, then violet, bluish-violet, and finally pure blue; in the spectroscope orange and yellow are suppressed. Dionine (ANALYST, 1899, xxiv., 128) turns dark blue, and in a narrow tube remains so for many hours; in the spectroscope it absorbs orange and yellow, but not so completely as morphine. Codeine or its phosphate, gives a reddish-violet changing to blue-violet; spectroscopically it also absorbs orange and yellow. Heroin (diacetyl ester of morphine), as base, behaves like codeine. Peronine (hydrochloride of benzylic ester of morphine) remains reddish-violet for several hours, and absorbs all light beyond and including yellow. Methyl-phenomorpholine, or its hydrochloride, becomes and remains intensely red; in the spectroscope it absorbs the yellow and green and part of the orange rays.

F. H. L.

Adulteration of Scammony with Galena and Starch. F. Baucher. (*Ann. de Chim. Anal.*, 1899, iv., 186, 187.)—A sample of scammony recently submitted to the author for analysis was regarded as suspicious from the presence of a number of small holes containing well-defined bluish-gray metallic crystals. On extracting the finely-powdered substance with ether, only 41·3 per cent. of resin was obtained, as against 75 to 80 per cent. yielded by commercial scammony of good quality.

The ash left on incineration amounted to 16·6 per cent., and had a reddish-orange colour, whereas the pure substance only yields from 3 to 8 per cent. of white or grayish ash.

The residue insoluble in ether contained the gray metallic crystals, which were identified as galena, and also a large amount of starch. C. A. M.

The Assay of Belladonna Leaves. F. X. Moerk. (*Amer. Journ. Pharm.*, 1899, lxxi., 320-326.)—Since the publication of his former paper (ANALYST, xxiv., 208) the author has made experiments with the object of improving the process therein described. He finds that the extraction of the leaves can be effected more rapidly and completely by means of a solvent consisting of 90 parts by weight of 95 per cent. alcohol with 10 parts of 10 per cent. ammonium hydroxide than by his former solvent.

The following method of working is now recommended: Twenty grammes of the powdered belladonna leaves are shaken at intervals, for from thirty minutes to an hour with 96·5 grammes of the solvent in a stoppered bottle, the liquid is then filtered into a dry flask, care being taken to avoid evaporation as far as possible. The flask and its contents are weighed, the solution transferred to an evaporating basin containing a small glass rod, and its weight found by weighing the empty flask.

The liquid is evaporated on the water-bath at 50° C., until the extract can no longer be stirred with the rod, and its weight now gives the amount of extract.

It is then washed into a separating funnel by means of successive small portions (1 to 2 c.c.) of a mixture of 0·5 c.c. of ammonium hydroxide and 10 c.c. of water,

and is extracted with a mixture of ether and chloroform. The remainder of the process is essentially the same as that described in the previous paper.

Some of the results thus obtained as compared with those given by the original method are shown in the following table:

	Modified Process.		Original Process.	
	Moisture. Per cent.	Alkaloid. Per cent.	Moisture. Per cent.	Alkaloid. Per cent.

C. A. M.

ORGANIC ANALYSIS.

The Valuation of Saccharin. E. E. Reid. (*Amer. Chem. Journ.*, 1899, xxi., 461-471.)—Remsen and Burton (*Amer. Chem. Journ.*, xi., 403) showed that benzoic sulphimide, when boiled with dilute acids, is converted first into *o*-sulphamine-benzoic acid, and then into the ammonium salt of *o*-sulphobenzoic acid, while *p*-sulphamine-benzoic acid is not affected. Hefelmann (*Ph. Cent.*, lxxxv., 107, and 1895, No. 16) has described a method of estimating benzoic sulphimide in which it is hydrolysed in this way by 71 per cent. sulphuric acid, and the ammonia produced liberated with alkali and distilled. The author has examined this method in comparison with the results obtained by hydrolysis with hydrochloric acid. As 1 c.c. of his standard acid was equivalent to 26 milligrammes of sulphimide, 26 × 25, or 650, milligrammes of the sample were taken for each analysis, so that the number of c.c. of acid neutralized by the ammonia multiplied by four gave directly the percentage of benzoic sulphimide.

In each case 0·650 gramme was mixed in a test-tube with 10 c.c. of 71 per cent. sulphuric acid, prepared by mixing 132 grammes of the pure concentrated acid with 37 c.c. of water. The test-tube was loosely closed by means of a cork, through which passed a glass rod, bent into a loop at the end, with which the mixture was frequently stirred during the heating. After being kept in the boiling water-bath for three hours, the contents of the tube were allowed to cool, diluted with water, distilled, after the addition of 15 grammes of sodium hydroxide, and the ammonia received in standard acid.

The following is a summary of the results in percentages of benzoic sulphimide thus obtained: Commercial saccharin, A, 54·8 to 55·8; commercial saccharin, B, 94·0 to 94·1; mixture of pure para-sulphamine-benzoic acid, and pure sulphimide (86·8 per cent.), C, 86·7 to 88·0; mixture containing 72·7 per cent. of benzoic sulphimide, D, 72·9 to 73·6; commercial saccharin, E, 98·5 to 99·1; commercial saccharin, F, 88·6 to 89·4; pure benzoic sulphimide from (? crystallised) acetone, G, 98·9 to 99·7; average, 99·2.

As most of the results with mixtures of benzoic sulphimide with the para-acid

gave results slightly too high, a number of determinations were made with a pure specimen of the latter, in which it was found that on the average 0·300 gramme yielded 0·51 milligramme of ammonia, equivalent to 5·9 milligrammes of para-sulphamine-benzoic acid. From this the author concluded that the para-acid was slightly hydrolysed by 71 per cent. sulphuric acid at 100° C. When the mixture was overheated, which happened on several occasions, through the water-bath becoming dry, the hydrolysis was considerable, and in one case amounted to 86 per cent. of the acid present.

For the hydrolysis with hydrochloric acid the following method was devised: 0·650 gramme of the saccharin is mixed in a 100 c.c. flask with 50 c.c. of dilute hydrochloric acid (120 c.c. of concentrated acid, diluted to a litre). The flask is closed with a cork, through which passes a glass tube 45 cm. long and 8 mm. wide, placed on a sand-bath, and its contents allowed to boil gently for two hours. The stopper is then removed, and the liquid evaporated to about 10 c.c., after which it is diluted, washed into the distilling flask, 20 c.c. of a solution containing 0·5 gramme of sodium hydroxide in 1 c.c. added, the ammonia distilled into standard acid, and the excess of the latter titrated back, with cochineal as indicator. Acid about $\frac{1}{4}$ N in strength is said to be the most convenient.

In the tabulated results obtained by this method the average with pure benzoic sulphimide was just 1 per cent. higher than that obtained with a similar sample in the sulphuric acid method, whilst the results of the analyses of test mixtures of sulphimide and para-sulphamine-benzoic acid were on the average 1 per cent. lower—a fact which the author attributes to the conversion of some of the latter by the sulphuric acid. In the analysis of samples of commercial saccharin the average results were 0·8 per cent. higher than those given by the same samples when hydrolysed with sulphuric acid.

Experiments made with pure para-sulphamine-benzoic acid showed that, under the conditions described above, it was not attacked by hydrochloric acid.

Benzoic sulphimide is readily converted into the sodium salt of *o*-sulphamine-benzoic acid by being boiled with sodium hydroxide solution, but is not broken down by the treatment. For instance, 650 milligrammes of saccharin E, when boiled with 75 to 100 c.c. of water, containing 10 grammes of sodium hydroxide, yielded only 0·05 milligramme of ammonia. On now adding an excess of hydrochloric acid to residue in the distilling flask, boiling the liquid for several hours, evaporating down, and then distilling with sodium hydroxide, an amount of ammonia corresponding to 98·5 per cent. of sulphimide was found.

From this it appears that benzoic sulphimide may be estimated in the presence of ammonium salts, or salts of other volatile bases; of benzamide, or amides of fatty acids; or, in fact, of any nitrogenous body which is readily broken down by boiling with a 10 to 15 per cent. solution of sodium hydroxide.

The following experiment is described to show the possibility of separating in this manner different classes of nitrogenous organic compounds. A mixture was made containing 0·1478 gramme of ammonium chloride, 0·5000 gramme of *p*-nitro-benzamide, 0·6500 gramme of benzoic sulphimide, and 0·3750 gramme of *p*-sulphamine-benzoic acid.

On distillation with 4 grammes of magnesium chloride and 0·5 gramme of sodium hydroxide, 47·9 milligrammes of ammonia were found, as against 47·1 milligrammes, the calculated amount in the ammonium chloride taken.

The residue in the distilling flask was mixed with 5 grammes of sodium hydroxide, and again distilled. The ammonia found amounted to 51·1 milligrammes, corresponding with 499 out of 500 milligrammes of *p*-nitrobenzamide.

The contents of the flask were then neutralized with hydrochloric acid, about 8 c.c. of the concentrated acid added, and the whole boiled for several hours and concentrated by evaporation. The ammonia obtained on distilling with sodium hydroxide corresponded to 99·1 per cent. of the saccharin present. An excess of sulphuric acid was added to the residue, and the mixture heated. On now distilling with sodium hydroxide, 36·2 milligrammes of ammonia were obtained, instead of the theoretical 33·7 milligrammes representing the *p*-sulphamine-benzoic acid. This high result was due to inadvertent overheating with the sulphuric acid, with the result that not only the para-acid had been broken down, but also some of the *p*-nitro-benzoic acid. Otherwise, it would finally have been possible to determine the nitrogen in the nitro-group by Kjeldahl's process.

In the analysis of pure para-sulphamine-benzoic acid heating with pure sulphuric acid alone at 230° to 260° C. is sufficient to produce complete hydrolysis. In the author's opinion, the decomposition can probably be effected at a lower temperature, and it is suggested that a means of determining *p*-sulphamine-benzoic acid in the presence of other nitrogenous bodies may be based on this property.

C. A. M.

The Occurrence of Estragol in the Essential Oil of Chervil. E. Charabot and L. Pillet. (*Bull. Soc. Chim.*, 1899, xxi., 368-370.)—Grimaux first discovered estragol, the isomer of anethol, in estragon oil (*Comptes Rendus*, cxvii., 1189), and it has since been found by different observers in various essential oils, including those of anise and basil.

The authors have obtained from 36 kilos of the fresh seeds of chervil (*Chærophyllium sativum*) 4·25 grammes of a clear yellow essential oil, with an odour recalling that of anise and estragon. On standing, a few crystals separated out, which were found to consist of a paraffin analogous to those found in a number of essential oils. The main constituent of the oil was estragol (paramethoxy-allyl-benzene), which was identified by converting it into anethol (paramethoxy-propenyl-benzene), and oxidizing the latter to anisic aldehyde. The authors point out that the result of their investigation adds another to the long list of essential oils containing phenols or phenol esters with side allyl chains [$R - CH_2 - CH = CH_2$].

These are of much more frequent occurrence in essential oils than are the isomeric compounds with side propenyl chains [$R - CH = CH - CH_3$] of which the only representatives known to occur naturally are anethol (iso-estragol), and probably asarone.

Among the allyl derivatives found in natural essences are: chavicol, estragol, eugenol, methyl-eugenol, ethyl-eugenol, betelphenol, safrol, and apiol. C. A. M.

The Volumetric Estimation of Aniline. M. François. (*Journ. Pharm. Chim.*, 1899, ix., 521-524.)—The following method is based on the action of bromine on aniline, as in the equation

$$C_6H_5NH_2 + 6Br = 3HBr + C_6H_2Br_3NH_2.$$

An aqueous solution of bromine is standardized, preferably with a solution of pure aniline hydrochloride prepared by crystallizing the salt two or three times and drying it over sulphuric acid. A solution of aniline hydrochloride containing 1·392 grammes per litre corresponds to one of 1 gramme of aniline in a litre.

In making an estimation, 10 c.c. of the solution of aniline hydrochloride are placed in a flask, and after the addition of two drops of a solution of indigo sulphate the solution of bromine is run in until the indigo is decolorized. The titration is then repeated with another 10 c.c., but this time the bromine-water is run in rapidly to within a few tenths of a c.c. of the first reading; the indigo sulphate is then added, and the titration completed.

An aliquot portion of the solution of aniline under examination, containing, according to a preliminary test, about 0·01 gramme, is titrated in precisely the same manner as in standardizing the bromine, and the percentage calculated.

The author has proved that the volume of the water in which the aniline is dissolved has no influence on the results, and has obtained the same figures with 0·01 gramme of aniline in 5 c.c. or 50 c.c.

When the aniline solution contains mineral compounds, a direct determination is not possible by this method. In such cases the aniline should be liberated by potassium hydroxide, distilled in a current of steam, and estimated in the distillate.

C. A. M.

A Colour Reaction distinguishing Metaphenylenediamine Hydrochloride from Paraphenylenediamine Hydrochloride. L. Cuniasse. (*Ann. de Chim. Anal.*, 1899, iv., 156, 157.)—The reagent consists of a 1 per cent. solution of acetaldehyde in 50 per cent. alcohol, with the addition of a few drops of acetic acid.

On adding to an aqueous solution of metaphenylenediamine hydrochloride several drops of this reagent, warming the mixture, and allowing it to cool, a brilliant yellow coloration with a marked green fluorescence is obtained.

Under the same conditions the hydrochloride of paraphenylenediamine gives a reddish-orange colour, without any trace of fluorescence. C. A. M.

Determination of the Iodine Value of Fatty Acids. A. Zega and R. Majstorovic. (*Chem. Zeit.*, 1899, xxiii., 597.)—The authors record some experiments in which they determined the iodine value of the fatty acids derived from (chiefly) maize-oil on samples of the acids that had been recovered several days previously. These gave figures 10 to 20 points below the normal, the deficiency rising with the time and temperature to which the acids had been exposed. It is highly important, therefore, that this estimation shall always be made under strictly uniform conditions [or immediately the acids are extracted ?]. F. H. L.

On the Baudouin Reaction. **W. Kerp.** (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 473-480.)—The work described in this paper was undertaken primarily with the object of assisting in the study of the question as to whether (as has been advanced on the strength of the Baudouin reaction), on feeding cows upon sesame, the active constituent of the oil passes into the milk. The author has studied the conditions under which furfural produces a red colour with hydrochloric acid, and the relation which this coloration bears to the sesame-oil reaction.

Commercial furfural is usually yellow or yellowish-brown, and requires to be twice distilled under reduced pressure in order to obtain a perfectly pure product. It is a very unstable body. On standing, it gradually acquires a yellow colour and an acid reaction, but the change can be retarded either by keeping the bottles in which it is stored as full as possible, or by the addition of a proportion of alcohol. Twenty per cent. solutions stored in full bottles in the dark keep exceedingly well. Solutions of 1 c.c. of furfural in 100 c.c. of alcohol remain almost completely unchanged, even when not kept exclusively in the dark. Furfural dissolves easily in strong hydrochloric acid. The solution, however, quickly acquires a violet colour, changing to red, and finally to black, with the separation of a black precipitate, and the same changes take place when hydrochloric acid is added to alcoholic solutions of furfural. The reaction depends upon various conditions, such as the absolute quantity and the degree of dilution of the furfural, and the quantity of hydrochloric acid used. It differs, however, from the sesame-oil reaction in the length of time which elapses before the coloration makes its appearance, the sesame-oil reaction being much quicker, and altogether more sensitive. Temperature has also considerable influence upon the course of the reaction. The experiments made in this direction show the necessity of carrying out the sesame-oil reaction at as near the ordinary temperature as possible. Experiments on the action of hydrochloric acid of different strengths on the same alcoholic furfural solution of 0·99 per cent. (volume) showed that acid of 1·127 sp. gr. produced no red-violet colour, even at increased temperature; only a blackish-gray colour developed after standing for eighteen hours, or on warming for half an hour. A comparison of the effects of different strengths of acid showed that while the Baudouin reaction would take place with acid of 1·127 sp. gr., it was less decided than when stronger acid was used, and quickly changed. In doubtful cases it is recommended to use acid of 1·16 sp. gr.

The smallest quantity of sesame oil which can be detected with certainty at the ordinary temperature lies between 0·005 and 0·0025 gramme, provided that the concentration of the sesame-oil mixture does not fall below 2·5 per cent. In proportion as the sesame-oil mixture is more dilute than this, the absolute quantity of the sesame oil must be increased, in order to obtain distinct coloration. In practice, 2 to 2½ grammes of sesame oil, corresponding with 20 to 25 grammes of margarine containing 10 per cent. of sesame oil, can be detected with certainty in 1 kilogramme of butter.

There seems to be no particular advantage in Sohn's proposal to use furfuramide in place of furfural. It is neither so easy to prepare in a pure state as furfural, nor does it keep better. H. H. B. S.

The Action of Silver Nitrate on the Fatty Acids of Cotton-seed Oil. E. Charabot and March. (*Bull. Soc. Chim.*, 1899, xxi., 552-554.)—In 1895 J. Dupont (*Bull. Soc. Chim.*, xiii., 696 and 775) discovered a volatile sulphur compound in cotton-seed oil, but did not determine its nature. The authors have therefore made experiments on the subject with a view of throwing light on the reaction which takes place in Milliau's modification of Becchi's test.

The fatty acids from 50 grammes of the oil were treated on the water-bath with a 30 per cent. solution of silver nitrate, and the resulting brown precipitate washed with hot water and alcohol, and extracted successively with petroleum spirit, benzene (free from thiophene) and ether. The residue was a homogeneous dark-brown substance, consisting principally of the silver salt of a fatty acid and of silver sulphide. This fatty acid melted at 52° C., and solidified at 52° C. It formed a white ammonium salt, which on treatment with silver nitrate gave a brown precipitate resembling the original brown residue.

As Dupont and Charabot have found in olive oil a volatile sulphur compound analogous to that of cotton-seed oil, the authors point out the necessity of caution in accepting the results of the silver nitrate test for the detection of cotton-seed oil in olive oil. C. A. M.

The Determination of the Molecular Weight of Soaps in Alcoholic Solution. F. Krafft. (*Berichte*, 1899, xxxii., 1584-1596.)—It is well known that aqueous solutions of soap undergo decomposition more readily than alcoholic solutions, and from a number of conclusions based on experiment the author has arrived at the theory that when a soap is dissolved in water it is dissociated into its separate components, the molecules of which revolve round each other in small enclosed paths forming part of a system.

This decomposition does not take place in alcoholic solution to any appreciable extent, and it is therefore possible to determine the molecular weight of soaps in such solution by the elevation of the boiling-point in the usual manner.

In a former communication (*Berichte*, xxix., 1328), a number of determinations were made by this method with sodium oleate dissolved in dilute alcohol, and the conclusion was arrived at that its molecular weight was double that calculated from the accepted formula. The author now finds that if absolutely anhydrous alcohol and dry soap be used the molecular weight is in close agreement with the calculated value, and that therefore molecular weights calculated from solutions which contain water have no real significance, since the soap is present in the solution in an incomplete colloidal condition.

The following results were obtained by the ebullioscopic method with potassium acetate (molecular weight, 98·18) dissolved in anhydrous absolute alcohol.

Alcohol. Grammes.	Potassium Acetate. Grammes.	Elevation of Boiling-point, °C.	Calculated Molecular Weight.
19·04	0·3586	0·232	93·3
19·04	0·7229	0·460	94·9
19·04	1·1755	0·734	96·7

The molecular weights found in this way with other pure soaps examined were: Potassium heptylate, $C_7H_{13}O_2Na$ (168·28), found 153·7 to 156·5; sodium laurate,

$C_{12}H_{23}O_2Na$ (222·3), found 237·2; sodium myristate, $C_{14}H_{27}O_2Na$ (250·3), found 253; sodium palmitate, $C_{16}H_{31}O_2Na$ (278·4), found 282·6; sodium oleate, $C_{18}H_{33}O_2Na$ (304·4), found 301·3 to 345·9; potassium oleate, $C_{18}H_{33}O_2K$ (320), found 347.

The author also shows in this paper that the salts of higher fatty acids do not raise the boiling-point of water when dissolved in it, and that the molecular weight of a crystalloid salt such as sodium chloride or bromide can be determined by the ebullioscopic method when dissolved in a not too concentrated soap solution. If, however, the soap be present in sufficient quantity to cause the solution to gelatinize or be salted out by the crystalloid salt added, the steam gives up so much heat to the membrane that the rise in temperature produced by the crystalloid is lost. This was found to be especially the case with potassium stearate, and it was necessary to use only moderately concentrated solutions of this in order to obtain the correct boiling-point on the addition of potassium bromide. C. A. M.

Estimation of Fat in Glue. W. Fahrion. (*Chem. Zeit.*, 1899, xxiii., 452.)—Ten grammes of the sample are broken up and stirred on the water-bath with 40 c.c. of 8 per cent. alcoholic soda till the alcohol has volatilized. If solution is not complete, more spirit is added and the evaporation repeated. The residue is taken up in hot water, and any insoluble matter which is inorganic in character is dissolved in hydrochloric acid. The whole is heated nearly to the boiling point for half an hour, rinsed into a separating funnel, and, when cold, extracted with ether and allowed to rest over-night. The two liquids are run off, the insoluble oxy-fatty-acids in the funnel dissolved in warm alcohol, mixed with the ethereal solution, evaporated, weighed, ignited, and weighed again. The acids, less the ash, give the fat in the glue; but two errors appear—the glycerin of the glycerides is not determined, and the oxy-fatty-acids are slightly soluble in acid. The deficiency, however, is very small, and the process gives higher results than that of Kissling. F. H. L.

Estimation of Indican. K. A. Wolowski. (*Wratsch*, 1899, xx., 482; through *Chem. Zeit. Rep.*, 1899, 170.)—Ninety c.c. of average urine, as passed throughout the twenty-four hours (diluted if dark in colour with 45 c.c. of water), are mixed with 10 c.c. of a 25 per cent. solution of lead acetate. The liquid is filtered, and divided in test-tubes into quantities of 5 c.c. each. To three tubes are added 0·05, 0·1, and 0·15 c.c. of a solution of potassium hypochlorite containing 1 per cent. of active chlorine, and the mixtures are allowed to rest for two or three minutes. Five c.c. of hydrochloric acid (specific gravity 1·19) are introduced and agitated with the samples; after four or five minutes 1 c.c. of chloroform is run in, and the tubes are inverted ten times, but not shaken. If the amount of indican is normal—6 or 7 milligrammes per twenty-four hours—the first tube exhibits a faint colour, the second a stronger one, and the third none at all. To obtain more accurate results, the chlorine reagent may be diluted to 0·1 per cent. in strength. For the calculation of the indican, only its proportion in reference to the solid matter in the urine is taken into account, the latter being deduced by Haisser's factor 2·33. Thus, if the specific

gravity of the urine is 1·018, it contains (18 × 2·33 =) 44 grammes per litre. In northern climates the mean amount of solid matter is 65 grammes and 0·0065 gramme of indican per litre, which corresponds with 0·76 gramme of chlorine. F. H. L.

The Stability of Oxalic Acid Solutions. W. P. Jorissen. (*Zeits. angew. Chem.*, 1899, 521.)—Although the literature of this subject is somewhat voluminous, the results appear inconclusive and contradictory, and the varying effects of light, moulds, and preservative agents upon standardized oxalic acid of different strengths have not been completely elucidated. For his own experiments, the author has prepared pure oxalic acid by re-crystallization, rejecting the first and last 10 per cent. of the product. The solutions were kept for fifty to one hundred days in bottles, which had been cleaned with boiling water in order to sterilize them and to dissolve superficial alkali, and they were finally titrated with permanganate or with standard soda. His investigations prove that normal oxalic acid is not permanent in light. In the dark, and in the absence of ferments, a solution remains unchanged even when only centinormal in strength. Fifty c.c. of sulphuric acid per litre is an effectual preservative in the dark against moulds and against decrease in strength. One gramme of boric acid is useless; 2 grammes only act efficiently in cold weather. A decinormal solution in 12·4 or 25 per cent. alcohol loses strength in thirty-six days even in the dark. In daylight, sulphuric acid and boric acid both increase the speed of oxidation; manganese sulphate acts similarly in darkness and in light.

F. H. L.

Estimation of Oxalic Acid in Urine. E. Salkowski. (*Centralbl. med. Wissensch.*, 1899, xxxvii., 257; through *Chem. Zeit. Rep.*, 1899, 189.)—Two hundred to two hundred and fifty c.c. of urine, or if the liquid is weak 500 c.c., are evaporated to one-third their bulk, mixed with 20 c.c. of hydrochloric acid (specific gravity 1·12), and extracted with 20 to 25 c.c. of ether saturated with alcohol, three such extractions being made, in order to separate the oxalic acid from the insoluble phosphoric acid. The united extracts are filtered through a dry paper and freed from solvent; the residue is diluted with water and evaporated to about 20 c.c., then filtered to remove resinous substances. The filtrate is made slightly alkaline with ammonia, treated with 1 or 2 c.c. of a 10 per cent. solution of calcium chloride, rendered acid with acetic acid and the calcium oxalate collected and weighed. F. H. L.

Detection and Estimation of Bile Pigments in Urine. A. Jolles. (*Zeits. physiol. Chem.*, 1899, xxvii., 83; through *Chem. Zeit. Rep.*, 1899, 148.)—For the detection of bile pigments, about 10 c.c. of urine are shaken with 1 c.c. of chloroform and 4 or 5 c.c. of 10 per cent. barium chloride solution. After standing a few minutes to settle, the liquid is pipetted off, and the residue agitated with 2 or 3 c.c. of Hübl's centinormal iodine solution and 1 c.c. of strong hydrochloric acid. In presence of bile pigments the precipitate, the chloroform solution, and the liquid floating on the latter are all coloured green or greenish-blue; traces of pigments cause the precipitate alone to be greenish.

For the quantitative estimation of bilirubin, 10 or 20 c.c. of urine are measured into a pear-shaped separating funnel with a very short tube at the base, mixed with 20 c.c. of chloroform, 10 c.c. of 10 per cent. barium chloride, and 50 c.c. of 1 : 5 hydrochloric acid. After agitation and separation 15 c.c. of the chloroform are run off into a graduated tube, and the few drops remaining in the stem of the funnel are returned by inverting the vessel and opening the stopcock; another 15 c.c. of chloroform are added, shaken up, and 12 c.c. drawn off; 10 c.c. of chloroform are then added, and 8 c.c. finally drawn off. The united extracts are washed with 30 c.c. of 1 : 1 hydrochloric acid to remove traces of urine mingled with the precipitate in the chloroform, and the solution is next brought into a stoppered flask by the aid of two rinsings with 25 c.c. of alcohol. 10 c.c. of centinormal Hübl solution are agitated with the liquid for five minutes, then 5 c.c. of 10 per cent. potassium iodide, 5 c.c. of fresh starch and 100 c.c. of water are added, and the whole is titrated with centinormal thiosulphate till the red-brown liquid above the chloroform is completely decolorized. Towards the end of the process this is best ascertained by allowing the solid matter to settle, withdrawing two samples of 2 or 3 c.c. of the clear liquid, dropping a little thiosulphate into one, and noting any further disappearance of colour. F. H. L.

[Thudichum has denied (*J. pr. Chem.*, 1896, [2], liii., 314) that bilirubin can be quantitatively oxidized to biliverdin by iodine in alcoholic solution (*cf. J. Chem. Soc. Abs.*, 1894, ii., 466, and 1896, i., 516).—ABS.]

Determination of Phenols in Urine. C. Neuberg. (*Zeits. physiol. Chem.*, 1899, xxvii., 123; through *Chem. Zeit. Rep.*, 1899, 189.)—The ordinary process of Kessler and Penny for the estimation of phenols in urine is incorrect when the liquid contains grape-sugar, so that the increased secretion of phenols which has been noted in cases of diabetes may be an analytical error. The following method avoids the defect. As in the Kessler and Penny process, the urine is freed from acetone, the phenols are liberated from their sulphonic acids, distilled off, and rectified over calcium carbonate to remove nitrous and formic acids. They are next brought into a 2-litre flask and mixed either with 3 grammes of air-dried lead hydroxide (freshly precipitated from the nitrate with baryta-water) and 5 c.c. of a strong solution of basic lead acetate, or with a solution of 1 gramme of sodium hydroxide and 6 grammes of lead acetate. The whole is heated on a boiling water-bath to yield lead phenolates and to volatilize aldehydes, the latter being completely removed by boiling for about five minutes over a naked flame until a few drops of the distillate no longer reduce ammoniacal silver solution. The contents of the flask are then rendered strongly acid with sulphuric acid, and the phenols are distilled over, repeating the operation twice again after water has been added to restore the original volume. This distillate is examined by the Kessler and Penny process; *i.e.*, it is made alkaline, warmed on the water-bath, treated with excess of decinormal iodine, cooled, and titrated with decinormal thiosulphate. Useful results can also be obtained without distillation by removing the lead sulphate, making the filtrate alkaline, and titrating as before; the titration cannot, however, be conducted in the presence of the sulphate. F. H. L.

INORGANIC ANALYSIS.

Detection and Estimation of Mercury Vapour in Air. Kunkel and Fessel. (*Verhandl. physik. med. Gessell. Würzburg*, 1899, xxxiii., 1; through *Chem. Zeit. Rep.*, 1899, 189.)—Fifty or a hundred litres of air dried over calcium chloride are led at a speed of eight or ten litres per minute through a dry tube 2 or 3 millimetres in diameter containing a few grains of iodine. Even 0·01 milligramme of mercury will be indicated by the formation of the red mercuric iodide; or, if the speed of passage be raised considerably and the quantity of iodine increased, by a partial production of the yellow iodide. To determine the proportion of mercury, the solid matter from the tube is taken up in a little potassium iodide solution, the undissolved iodine filtered off, the dissolved iodine combined with sodium hydroxide, the liquid treated with sulphuretted hydrogen, and the colour matched by means of a standard solution of mercuric chloride handled in a similar manner. One cubic metre of air will retain 6·7 to 14 milligrammes of mercury at temperatures of 16° to 23° C. when saturated therewith. Gold-leaf also removes mercury vapour completely.

F. H. L.

Estimation of Total Phosphoric Acid in Thomas Meal. C. Aschmann (*Chem. Zeit.*, 1899, xxiii., 435.)—To avoid the unpleasantness of working with strong hot acids, the following method of bringing Thomas meal into solution is advocated. A liquid containing 420 grammes of pure nitric acid (sp. gr. 1·2) and 50 grammes of concentrated sulphuric acid per 10 litres is prepared. Five grammes of the sample are agitated with 500 c.c. of the mixture for half an hour in Wagner's apparatus, at a speed of forty to forty-five revolutions per minute. The mass is filtered immediately, allowed to rest for twelve hours for the calcium sulphate to settle; then 50 c.c. are filtered off, treated with 10 c.c. of a solution of 500 grammes of citric acid in 1 litre of water, made just alkaline with ammonia (using a fragment of litmus-paper as indicator), and diluted with 50 c.c. of water. If the liquid remains perfectly clear for twenty minutes, the phosphoric acid is precipitated with Wagner's magnesia mixture, stirred for half an hour, and filtered after one or two hours' standing (longer is not harmful); but if silica falls during the twenty minutes, the nitro-sulphuric acid solution must first be precipitated with Wagner's molybdate. The said solution becomes cloudy after a time, owing to the deposition of free sulphur produced by the action of the nitric acid on the nascent sulphuretted hydrogen, but this is of no importance. Nitro-sulphuric acid dissolves some 90 per cent. of Thomas meal, the liquids filter easily, and the results agree well with the ordinary methods.

F. H. L.

Influence of Bacteria on the Decay of Cement. (1) **A. Stutzer and R. Hartleb.** (*Zeits. angew. Chem.*, 1899, 402); (2) **G. Barth.** (*loc. cit.*, p. 489.)—In 1896 Stutzer observed that the cement mortar which had been in use for eight or nine years as lining to a water-supply reservoir was converted into a brownish mud containing less lime and more iron oxide, etc., than the original cement. This disintegration he ascribed, and still believes to be primarily due, to the solvent action of the carbon dioxide in the water, which dissolved the lime of the cement in the form of bicar-

bonate. But on extracting further samples of the mud from the same reservoir lately with sterilized water, the present authors found that it was highly charged with nitrifying organisms; so much so, that when introduced into a 0·1 per cent. solution of ammonium sulphate, the ammonia reaction practically disappeared in fourteen days and nitrite reactions were given powerfully. A similar experiment with asparagine only gave a nitrite reaction after six weeks, but here it was necessary for ammonia first to be formed before nitrification could set in. A further test with a 0·1 per cent. solution of sodium nitrite showed that nitrates were formed but slowly. It would appear possible, therefore, in the case of waters containing any appreciable proportion of oxidizible nitrogenous matter, that this production of nitrous acid by the agency of micro-organisms may play some part in the destruction of cement. The parallel action that is noticed in sea-water, unless the cement is fortified by the addition of extra active silica, is due rather to the soluble sulphates than to carbon dioxide, which is not present in such large quantities as in fresh water; it has not been feasible to determine whether bacteria assist in this disintegration likewise.

With reference to this matter, Barth quotes another instance of cement decomposition occurring in three years where the water contained no unusual amount of carbon dioxide, and he seems to consider the previous explanation plausible. His figures for the original cement and for the soft brown mud are as follows:

	Cement.	Mud.
SiO_2	20·0%	33·21%
Al_2O_3	7·5%	21·84%
Fe_2O_3	3·5%	10·95%
CaO	63·0%	24·23%
MgO	2·0%	9·36%

F. H. L.

APPARATUS.

Bruhns' Improved Polarimeter. (*Zeits. angew. Chem.*, 1899, 694.)—In this apparatus the scale is engraved or etched on the long travelling quartz wedge itself, so that want of coincidence between the wedge and the scale is no longer possible. By this arrangement one single calibration of the scale suffices for the tabulation of its errors, and each time the apparatus is required for use it is only necessary to bring the zero-point on the short fixed wedge into unison with the zero-point of the travelling scale. In front of the polarimeter a disc moving on a pin eccentric to the axis of vision carries the telescope and a magnifier, either of which can be brought into the central position by turning a handle. The magnifier is focussed on the scale, while the telescope, being focussed on the far nicol, renders the scale temporarily invisible, and prevents it being in the way during adjustment. But as in half-shadow apparatus the scale is masked in the final position, the aforesaid moving disc is connected through its spindle with another quartz plate, which is brought into the field between the analyser and the wedge simultaneously with the magnifier, thus lighting the scale again without affecting its readings. The whole of the optical part of the apparatus is protected by a padded case to prevent changes of temperature and the frame of the wedge also carries a thermometer. F. H. L.

THE ANALYST.

OCTOBER, 1899.

THE ANALYSIS OF GOLDEN SYRUP.

By R. Bodmer, Norman Leonard, and H. M. Smith.

As the analysis of "golden syrup" has recently called for considerable attention on the part of public analysts, we venture to think that an account of the methods employed and the results obtained in the laboratory of Dr. Thomas Stevenson and in that of one of us (R. B.) may be of service to other members of the Society.

It would seem from the convictions which have been obtained under the Sale of Food and Drugs Act that "golden syrup" is required to be the product of the partial hydrolysis of cane-sugar (sucrose), and should therefore consist only of cane- and invert-sugar, besides water, mineral matter, and small quantities of organic impurities. A large proportion of the syrups now sold are, however, either mixtures of cane-sugar syrup with "glucose syrup" or else consist merely of "glucose syrup" sweetened by the addition of cane-sugar. These products are characterised by the presence of dextrin, maltose, and excess of dextrose. Since these last-named compounds are dextro-rotatory, dextrin being so to a very high degree, a determination of the rotatory power of the sample will at once afford a clue to its nature. Assuming genuine golden syrup to have a specific rotation $[\alpha]_D = +16°$ and glucose syrup $[\alpha]_D = +110°$, the percentage of glucose syrup present will be:

$$\frac{100([\alpha]_D - 16)}{110 - 16}.$$

A more extended examination is, however, usually desirable, and the following method of analysis has been found to be convenient.

Water.—A 10 per cent. solution of the syrup is made, and from the specific gravity (water = 1000) of this solution the solid matter, and hence the water, in the original syrup is calculated by using the well-known factor 3·86.

Rotatory Power.—The 10 per cent. solution is clarified, if necessary, by means of a little animal charcoal, placed in the tube of the polarimeter, and the angle of

rotation (a) observed. The specific rotation of the syrup is then calculated by the well-known formula,

$$[a]_D = \frac{100a}{lc},$$

where l is the length of the observation tube in decimetres and c is the concentration (grammes per 100 c.c.). Using a 2 decimetre tube and a 10 per cent. solution, the observed angle has simply to be multiplied by 5.

Reducing Power.—This is determined (a) in the original solution after suitable dilution, (b) after inversion of the cane-sugar, (c) after inversion of the cane-sugar, dextrin, and maltose.

(a) Ten c.c. of the 10 per cent. solution are diluted to 100 c.c., and the reducing power determined by means of Fehling's solution. We prefer the gravimetric process, using 20 c.c. of Fehling's solution for 10 c.c. of the diluted sugar solution.

(b) Ten c.c. of the 10 per cent. solution are diluted to 50 c.c. with water containing 5 c.c. of concentrated hydrochloric acid, heated for ten minutes at a temperature not exceeding 68°, cooled, rendered alkaline, and made up to 100 c.c. Ten c.c. of this solution may be treated with 25 c.c. of Fehling's solution.

(c) Ten c.c. of the 10 per cent. solution are diluted to 50 c.c. with water containing 1½ c.c. of concentrated sulphuric acid, heated on the water-bath for two to three hours, cooled, rendered alkaline, and diluted to 100 c.c. Thirty c.c. of Fehling's solution should be used for 10 c.c. of this liquid.

The reducing powers thus determined are expressed as percentages of glucose in the original syrup, and denoted by the symbols K_1, K_2, and K_3 respectively.

Ash.—Ten c.c. or 20 c.c. of the solution of the syrup are evaporated on the water-bath with a drop or two of concentrated sulphuric acid, and the residue ignited and weighed. The usual deduction of one-tenth is to be made from this "sulphated" ash.

Dextrin.—In the presence of dextrin, a turbidity is produced on adding alcohol to the solution of the syrup, but no great importance is to be attached to this test, since a similar turbidity has been noticed in the case of syrups made from coarse sugar, where there was no other evidence of the presence of dextrin. The quantitative estimation of dextrin by precipitation with alcohol was, as might be expected, found unreliable. The fermentation method is probably more accurate, but we have had no personal experience of this.

In the following table are given the results obtained by the application of the methods described to a number of samples received for analysis under the Sale of Food and Drugs Act. All were sold as "golden syrup" with the exception of No. 2, which was labelled as "amber syrup."

No.	Water.	Ash.	Specific Rotation. $[\alpha]_D$.	Reducing Power. Original. K_1.	After Inversion of Cane-sugar. K_2.	After Prolonged Hydrolysis. K_3.

26 ...	16·0	3·5	+75°	32·9	48·8	75·1

Of these samples, Nos. 1, 12, 13, 14, 16, 21 and 22 are, in all probability, unadulterated syrups prepared from more or less refined sucrose. Assuming the original reducing power to be due to invert-sugar and the increase in the reducing power on inversion to be due to cane-sugar, the composition of the genuine syrups may be expressed as in the following table:

	1.	12.	13.	14.	16.	21.	22.
Water	16·0	13·8	16·2	16·3	20·1	16·5	16·9
Ash	2·0	8·2	4·1	2·1	7·9	2·0	1·8
Cane-sugar	33·3	32·4	25·8	34·1	40·8	28·4	34·9
Invert-sugar	45·7	32·5	45·6	45·3	22·0	44·0	40·8
Organic matter other than sugar (by difference)	3·0	3·1	8·3	2·2	9·2	9·1	5·6
	100·0	100·0	100·0	100·0	100·0	100·0	100·0
Specific rotation, calculated ...	11·6°	14°	6·6	12·2°	22·1°	8·7°	13·8°
,, ,, observed ...	15°	17·5°	11·5	13°	25°	12·5°	16°

It will be noted that the specific rotation calculated on the above assumption is always lower than that actually observed, the difference being probably caused by substances included under the head of "organic matter." No. 13 was shown to be a beet-sugar product by the development of a slight fishy odour in the solution on keeping, by the high ash, and by the very small amount of phosphoric acid present (0·009 per cent. P_2O_5).

All the remaining samples are, to a greater or less extent, adulterated with glucose syrup, as is shown by the high rotatory power and the increase in reducing power after prolonged hydrolysis. The original reducing power (K_1) is here due, not only to invert-sugar, but also to dextrose (from starch) and maltose, whilst the increase in reducing power on prolonged heating with acid is caused by the inversion of dextrin and maltose. It should be theoretically possible to calculate the amounts of all these substances from the values obtained for the reducing power and the specific rotation of the mixture before and after the two inversions described above, but up to the present we have found that the errors of experiment and the disturbing influence of impurities are too great to allow of the necessary number of equations being obtained with sufficient accuracy for the desired purpose. Failing this, however, a convenient expression of the composition of the sample may be arrived at by treating anhydrous commercial "glucose" as an individual substance having a cupric reducing power of 53 and a specific rotation +134° for sodium light. (See L. K. Boseley, ANALYST, 1898, p. 125.)

If s is the percentage of cane-sugar (K = O, $[\alpha]_D = +66{\cdot}5°$), i that of invert-sugar (K = 100, $[\alpha]_D = -23{\cdot}1°$), x the commercial glucose, then the following relations hold:

$$K_1 = i + 0{\cdot}53x.$$

$$K_2 = i + 0{\cdot}53x + \frac{100s}{95}.$$

$$[\alpha]_D = \frac{66{\cdot}5s + 134x - 23{\cdot}1i}{100}.$$

Whence:

$$s = \frac{95(K_2 - K_1)}{100}.$$

$$x = 0{\cdot}685[\alpha]_D + 0{\cdot}16K_1 - 0{\cdot}455s.$$

$$i = K_1 - 0{\cdot}53x.$$

The following table shows the results obtained by the application of these formulæ to a few typical samples:

	5.	3.	2.	15.	24.	4.
Water	20·6	16·9	20·5	19·7	19·6	17·9
Ash	0·5	1·4	1·2	1·8	1·4	0·5
Cane-sugar	21·4	12·8	9·2	7·0	4·8	5·0
Invert-sugar	17·3	14·4	7·2			
"Glucose"	39·4	47·1	61·0	67·9	71·8	75·0
Organic matter (by difference)	0·8	7·4	0·9	3·6	2·4	1·6
	100·0	100·0	100·0	100·0	100·0	100·0

Since cane-sugar syrup contains from one-third to one-half its weight of cane-sugar, and glucose syrup contains an average of 82 per cent. of solid matter, these samples may be represented as containing approximately :

	5.	3.	2.	15.	24.	4.
Cane-sugar syrup ...	55	40	25	20	15	10
Glucose syrup	45	60	75	80	85	90

ON THE DETERMINATION OF THE IODINE VALUE.

By J. Lewkowitsch.

(*Read at the Meeting, June* 7, 1899.)

It is not my intention to add a new modification to those that have been published since the appearance of Hübl's classical paper on the determination of the iodine values of fats and oils; but as the theory of Hübl's process has at last reached a satisfactory solution, chiefly through the papers published by Wijs, I thought it might be useful to summarize the present position of this question.

The papers of Wijs have been fully abstracted in this journal, and I need therefore only refer to them (Analyst, 1898, xxiii., 238, 240). They corroborate Ephraim's experiments (Analyst, 1895, xx., 176) that ICl is added on to the unsaturated carbon atoms. It is true that Wijs assumes that the active agent in the Hübl solution is IOH; yet, as this leads to a somewhat artificial explanation of the chemistry of the process, inasmuch as some postulates demanded thereby are not borne out by experiment, it will be sufficient for practical purposes, as leading to the same analytical result, to adopt the explanation that ICl is absorbed by each pair of doubly-linked carbon atoms. Wijs proposed at first to use a solution of ICl in 95 per cent. acetic acid, but he has more recently replaced this by a solution of ICl in glacial acetic acid, as he must have found, like myself, that the former solution does not possess the stability he claimed for it. This is proved by the following figures, obtained in my laboratory by Dr. Peck :

Effect of Time on Wijs' Iodine Solution.

Time.	Solution of $I_2 + Cl_2$ in 95 per cent. Acetic Acid.	Solution of $I_2 + Cl_2$ in 99 per cent. Acetic Acid.	Solution of $ICl_3 + I_2$ in 99 per cent. Acetic Acid.
	Grammes of I, 1 c.c. of the solution is equal to :		
Original value ..	0·02682	0·02550	0·0259
After 16 hours ...	0·02642	—	—
After 40 hours ...	0·02625	—	—
After 64 hours ...	0·02581	—	—
After 2 months ...	—	0·02554	0·0258
After 3 months ...	0·01997	—	—
After 5 months ..	0·01911	—	—

The solution of ICl in glacial acetic acid is infinitely superior to the original Hübl solution as regards stability; furthermore, as it can be prepared rapidly, and as the time in testing is very much shortened, the process must be considered a very valuable one, all the more so as Wijs' maintains that his iodine values are probably the most nearly correct. As I have been using the Hübl solution for a number of years, and have determined the iodine constants for a great number of fats and oils by means of this method, it seemed to me necessary to ascertain whether all these iodine numbers could still be regarded as correct, especially so as Wijs had shown in one of his publications (ANALYST, 1898, xxiii., 241) that the iodine numbers obtained by his method for ten different oils were invariably higher by several units than those recorded by Hübl's process. Special stress has been laid on the fact that Wijs obtained for a sample of allyl alcohol the iodine value of 436·8 after ten minutes, whereas the Hübl solution gave him 425 after twenty hours' standing, whilst I had published a few years ago the iodine values of 349 to 376.* Since I calculated from some experiments given in Wijs' first paper the iodine value of 392, and, furthermore, since determinations made with different samples of allyl alcohol have no decisive value, I considered it necessary to examine, conjointly with Wijs, one and the same sample, although it is easy to see that allyl alcohol is not a specially suitable substance to decide the questions at issue.

Wijs was good enough to send me a sample of allyl alcohol which gave him by his method the iodine number 429. The experiments carried out in my laboratory by Dr. Peck gave the following results:

IODINE VALUES OF ALLYL ALCOHOL.

WIJS' METHOD.		HÜBL METHOD.
Solution $ICl_3 + I_2$.	Solution $I_2 + Cl_2$.	Solution two to three days' old.
419·09 419·09	420·09	421·27 421·27 421·87 422·17

I add some experiments also made by Dr. Peck on pure elaïdic acid, M.P., 44·5° C.:

IODINE VALUE OF ELAÏDIC ACID.

WIJS' METHOD.		HÜBL METHOD.
Solution $ICl_3 + I_2$.	Solution $I_2 + Cl_2$.	Solution two to three days' old.
88·66	88·96	88·24
88·93	88·89	—
—	89·98†	89·01†
—	89·98†	89·01†

These experiments, as also a further number of determinations made with cotton-seed stearin, prove conclusively that iodine determinations made with Hübl solution lead to correct results, provided that the Hübl method is applied in a proper

* This sample cannot have been pure, it must have contained some moisture.

† In these experiments the substance was made up to a known volume in the solvent, and aliquot parts of this were used in the test.

manner. This method has been described fully by me elsewhere, and I need not therefore refer to it here at any length. My conclusion that both methods yield practically identical results has since been fully corroborated by Wijs himself, who has shown the reason why different results were obtained by different observers when working with Hübl solution, although individual observers working under exactly the same conditions obtained identical results. He has also proved experimentally that the time during which the Hübl solution is allowed to act must not be chosen arbitrarily, and that it makes a considerable difference whether the blank test is done at the commencement or at the finish of the actual test; and he has further shown that the Hübl solution must have been allowed to stand one day before use, in order to attain a certain degree of stability, if I may so term it, and that this solution should not be allowed to act any longer than six or seven hours on the fat under examination. If these rules are adhered to, both solutions yield identical results.

In conclusion, I wish to tender my best thanks to Dr. E. L. Peck for his valuable assistance in the preparation of this paper.

DISCUSSION.

The CHAIRMAN (Mr. ALLEN) said that he had met with glacial acetic acid which contained a considerable proportion of sulphurous acid. It was purified almost entirely by partially freezing it, and allowing the unfrozen portion to drain off. Obviously the presence of such an impurity in the acetic acid would very greatly reduce the figure obtained in the original iodine titration.

Dr. LEWKOWITSCH said that, as has been done already by Wijs, great stress must be laid upon the importance of testing the glacial acetic acid, and ascertaining that it had no reducing effect upon permanganate.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Volumetric Estimation of Alcohols, especially of Fusel Oil in Brandy. F. Adam. (*Oesterr. Chem. Zeit.*, 1899, ii., 241.)—This process depends on the fact that acetyl chloride dissolved in chloroform reacts with alcohols, forming neutral esters (acetates); so that 1 molecule of the chloride mixed with 1 molecule of a monovalent alcohol liberates 1 molecule of hydrochloric acid (equivalent to 1 molecule of alkali), while 1 molecule of acetyl chloride mixed with 1 molecule of water yields 1 molecule of acetic acid and 1 molecule of hydrochloric acid (equivalent to 2 molecules of alkali). A 250 c.c. flask is joined by a well-fitting cork to a 100 c.c. separating-funnel, and both are thoroughly dried. The alcoholic liquid is placed in the flask, 25 c.c. of a 5 per cent. solution of acetyl chloride in chloroform are added, the funnel is put in position with its cock closed and half filled with water. After standing two hours, a set of Varrentrapp's bulbs charged with water (to retain any

escaping hydrochloric acid vapours) is connected with the top of the funnel, the stopcock is cautiously opened, and the water is allowed to descend into the flask. When the excess of chloride is decomposed, the mixture of chloroform and water with the water from the bulbs is titrated with normal alkali and phenolphthalein. In the meantime, the same volume of acetyl chloride solution (25 c.c.) is treated with 100 c.c. of water and titrated similarly, the difference between the two tests multiplied by the molecular weight of the alcohol giving the amount of the latter. Blank experiments on pure amylic alcohol show fairly satisfactory results.

To separate the fusel oil from the ethylic alcohol in brandy, the sample is diluted till its strength is about 20 per cent. by volume. It is shaken rapidly with exactly 25 c.c. of specially purified chloroform, the solvent run off, and a second 25 c.c. employed as before. The 50 c.c. of extract are agitated three times with 100 c.c. (each) of water, allowed to settle thoroughly, finally dried with anhydrous calcium sulphate, and filtered. Thirty-five c.c. of the chloroform are then examined as above. The chloroform should be purified by warming over acetyl chloride, followed by washing with alkaline water, and distillation over calcium chloride. An allowance of 0·3 c.c. of normal alkali must be made for the above quantities of brandy, etc., even in the absence of fusel oil, and this figure is to be deducted from the difference between the two titrations. The examples show a maximum error of 0·0072 gramme (mean 0·0031) in estimating from 0·03 to 0·3 gramme of amylic alcohol.

In an experiment in which 0·1992 gramme of amylic alcohol and 0·133 gramme of essential oil of caraway had been added to 200 c.c. of brandy, after distillation over potassium hydroxide, 0·198 of amylic alcohol was found. Evidently the addition of an essential oil of this class does not interfere with the determination, its phenol-like constituents and the acids combined therewith, are retained by the alkali. In the case of the esters of the higher alcohols of the fatty series, obviously the reverse would hold; but if the distillation over alkali were omitted, then these esters would exercise no disturbing action.

Experiments with absolute ethylic alcohol give errors ranging from −0·0086 to +0·0176 gramme in dealing with 0·228 to 0·346 gramme. Phenol cannot be determined in this manner; but other alcohols and mixtures thereof, or mixtures of alcohols with other bodies, should be amenable to the treatment, provided they are soluble in chloroform. In such cases the quantity of acetic acid neutralized may be expressed as a percentage of the alcohol or ethereal oil, and termed the "alcohol number."

The acetyl chloride solution should not be used till it has been kept one or two days, in order to give the water, alcohol, and hydrochloric acid opportunity to deposit or escape; after that it alters less in strength than might be imagined. F. H. L.

Detection of Liquorice in Wine. G. Morpurgo. (*Oesterr. Chem. Zeit.*, 1899, ii., 361.)—When a normal wine is treated with magnesia in the cold no ammonia is given off, but if the sample has been mixed with liquorice, at least in such proportion as will increase appreciably the amount of extract, ammonia is evolved distinctly. Two grammes of magnesium hydroxide and 25 c.c. of wine are placed in a 150-c.c. flask

closed with a cork, from which is suspended a moist strip of red litmus-paper. If the litmus remains unchanged for ten minutes liquorice is practically absent. Several samples of Malaga evolved ammonia, but these were of unknown origin; three specimens from a firm of good repute yielded none. Some samples of Turkish wine with a high content of extract also gave a blue coloration in half an hour; but all the other varieties of wine examined by the author liberated no ammonia, whereas the addition of 0·50 gramme of liquorice per litre determined a reaction in two minutes.

In doubtful cases, or where greater certainty is required, the glycyrrhizin must be tested for. 100 to 250 c.c. (according to the proportion of extractive matter) of the wine are mixed with powdered glass, evaporated, preferably on the water-bath, to a syrup, and strongly acidified with citric acid; the mass is rubbed down with alcohol, the solution filtered, and the residue extracted twice again. The filtrates are concentrated to a syrup and treated with 20 c.c. of alcohol and 50 c.c. of ether. After standing some time, the presence of liquorice is demonstrated by a brown deposit or skin which adheres strongly to the vessel. The liquid is poured off, the flask dried on the water-bath, and the mass dissolved in a little water. On adding ammonia it becomes greenish-brown, and after evaporation exhibits the characteristic taste and odour. A wine rich in extract and colouring matter may also leave a similar residue, but in this case it tastes harsh, and not sweet. If the aqueous solution is diluted with more water before introducing the ammonia, it becomes turbid if much liquorice is present; further dilution and gentle warming make the glycyrrhizin to cohere into a black resin-like mass, while the wine substances remain dissolved. To exclude the presence of dulcin or saccharin, the ethereal liquid poured away from the residue is evaporated, the solid matter is dissolved in water, mixed with a few drops of basic lead acetate, and evaporated again. When taken up in alcohol and the solution filtered, a colourless filtrate should result, evaporating without appreciable residue. If a residue be left, it should be examined for dulcin and saccharin according to the usual methods. F. H. L.

The Composition and Analysis of Chicory. J. Wolff. (*Ann. de Chim. Anal.*, 1899, iv., 157-162 and 187-193.)—Commercial chicory is the roasted product of the root of *Cichorium intybus*, which in the cultivated state the author found to weigh in the mean 325 grammes, whilst the root of wild-chicory from the outskirts of Paris weighed scarcely 30 grammes.

Starch does not appear to be present in chicory, but there is a considerable proportion of inulin $[6(C_6H_{10}O_5)+H_2O]$, the percentage being almost identical in the cultivated and wild products.

In the author's opinion it is probable that the small quantities of reducing sugar noted by other observers in chicory consist of lævulose derived from the inulin, and he considers it doubtful whether saccharose is a constituent.

According to Lescœur and Morelle, the specific rotatory power of inulin is $[\alpha]_D = -36·57°$.

It can be obtained from the root by extracting it with hot water containing a little calcium carbonate to prevent a partial conversion into lævulose, concentrating

the filtered liquid, and precipitating the inulin with alcohol. A small quantity of other substances is simultaneously extracted, including soluble proteids and a slight amount of synanthrose or lævulin, which has no action on polarized light, and which does not reduce Fehling's solution. On boiling with dilute acids synanthrose is converted into dextrose and lævulose.

In the analysis of green chicory 2·16 grammes of the freshly-pulped substance were mixed with 150 c.c. of water and a little calcium carbonate, and the liquid heated for two hours on the water-bath at 80° to 90° C., and finally brought to the boiling-point and left to cool.

After the addition of 10 c.c. of a concentrated solution of basic lead acetate and an excess of a concentrated solution of sodium sulphate, the volume of the liquid was made up to 200 c.c., and filtered. The reducing sugar was then determined by titration with Fehling's solution and by the polarimeter. By heating 50 c.c. of the solution with 5 c.c. of hydrochloric acid at 69° to 70° for twenty minutes, the inulin was completely converted into lævulose, which was determined polarimetrically and by titration with Fehling's solution. The difference between the reducing sugar found before and after inversion gave the lævulose corresponding to the inulin (180 of lævulose = 162 of inulin).

The method employed by the author to determine the effect of roasting on the chicory was similar to that described above, and is best shown by an example. Seven grammes of the finely-divided substance (18 per cent. of water) gave a solution containing 17·1 per cent. of reducing substances before decolorization and 10·9 after decolorization, the difference (6·2) being taken as caramels. The additional amount of reducing substances obtained after inversion corresponded to 7·2 per cent. of inulin.

When inulin is heated at gradually increasing temperatures, it produces lævo-rotatory products, which gradually give place to dextro-rotatory substances. When gently warmed it yields a small quantity of a gummy lævo-rotatory substance—pyrinulin. The effect of prolonged heating is to produce a very large proportion of pyrinulin and of dextrins (which do not reduce Fehling's solution) at the expense of the reducing substances.

In the subjoined table of the results of the analysis of different varieties of commercial chicory, the soluble matter was determined by extracting 2 grammes of the sample with a litre of boiling water, the extraction being repeated with more water until the extract was colourless. The residue was dried in the oven on a filter of known weight, and weighed, and from the result the soluble matter plus moisture was calculated.

The water was estimated by exposing a weighed quantity of the crushed substance in a vacuum over sulphuric acid for four or five days, and finally drying it at 100° to 110° for twelve hours.

The cellulose was determined directly on the substance by a method not mentioned.

For the estimation of the iron 10 grammes of the material were incinerated, the ash taken up with warm hydrochloric acid, and the solution diluted and filtered. A large excess of hydrochloric acid was added to the filtrate, and the iron titrated in the boiling liquid by means of a solution of stannous chloride standardized on copper.

C. A. M.

On the Active Principle of Cayenne Pepper. K. Micko. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 411.)—In a former paper (*Zeit. für Untersuch. der Nahr. und Genussmittel*, i., 818), the author published the results of an inquiry into the active principle of *Capsicum annuum*. He now shows that the same body—capsaicin ($C_{18}H_{28}NO_3$)—is also the active principle of *Capsicum fastigiatum*. The melting-point of capsaicin from *Capsicum annuum* was found to be 63·5° C., that from *Capsicum fastigiatum* 64° C. The reactions of the two bodies were identical; both gave the characteristic vanilla-like odour on dissolving in alcohol, decomposing with platinum chloride and evaporating, and both showed the same crystalline form, coefficients of solubility and chemical composition. H. H. B. S.

Determination of Digestible Nitrogenous Matter and Albuminoid Nitrogen in Foods and Feeding Stuffs. B. Sjollema. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 413-417.)—Stutzer's method for the determination of digestible albumin by the use of gastric juice has certain drawbacks. (1) The preparation of the fluid is unpleasant. (2) A fluid of sufficiently active properties cannot always be obtained, unless the stomachs of several pigs are used. (3) There is a difficulty in preparing fluid of uniform activity—a necessary requirement in making a long series of experiments. (4) Whenever a fresh fluid is prepared, it is necessary to determine the nitrogen contained therein, in order that the necessary correction may be made. These disadvantages may be overcome by substituting dry pepsin for Stutzer's fluid. The procedure recommended is as follows: Two grammes of the substance under examination are digested with 430 c.c. of water, 1 gramme of pepsin, and 16 c.c. of 10 per cent. hydrochloric acid, for forty-eight hours, at a temperature of 38° to 40° C., with frequent shaking. Three times during the digestion 11 c.c. of 10 per cent.

hydrochloric acid are added—viz., at the expiration of sixteen, twenty-four, and forty hours respectively from the commencement. The fluid is then made up to 500 c.c. The nitrogen is determined by Kjeldahl's method both in the insoluble residue as well as in the fluid. Comparative results by the two methods are given in the following table:

Description.	Nitrogenous Matter Dissolved on Digesting with		Difference.	Nitrogenous Matter left Undissolved on Digesting with		Difference.
	Gastric Fluid. Per cent.	Artificial Pepsin. Per cent.	Per cent.	Gastric Fluid. Per cent.	Artificial Pepsin. Per cent.	Per cent.

Dried potatoes	6·35	6·25	−0·10	0·85	1·10	+0·25

A modification of Stutzer's method for the determination of pure albumin is also proposed. In dealing with such substances as linseed cake, there is a difficulty in applying the copper method, owing to the slimy nature of the fluid obstructing the separation of the precipitate. The difficulty can be overcome by proceeding as follows: One gramme of substance is boiled with 50 c.c. of water, and, while boiling, 50 c.c. of 95 per cent. alcohol are gradually added. Fifty c.c. of cold water, 2 drops of a cold-saturated solution of alum, and the necessary quantity of copper solution are then added, after which the process is continued in the usual way. The filtration is carried out by means of a porcelain funnel, with the help of a filter-pump. In the examples given, the results agree well with those obtained by Stutzer's original method. H. H. B. S.

The Determination of Morphine in Opium. C. Montemartini and D. Trasciatti. (*Gazzetta Chim. Ital.*, 1899, xxix., 292-300.)—In a former communication (*Gazzetta Chim. Ital.*, xxvii., 302-335) the authors described a process of estimating morphine, which they termed the "sodium chloride method." In the present paper they reply to the criticisms of H. Thoms and of K. Dieterich (*Ber. d. deut. Pharm. Ges.*, viii., 124, 171), and point out that their directions were inaccurately translated into the German. A number of experiments are described to show that concordant results can readily be obtained, and finally the following outline of their process is given, including the modifications which their recent work has suggested.

Ten grammes of the finely-powdered opium are dried at 100° C., and macerated at intervals for an hour with 90 to 100 c.c. of a 20 per cent. solution of sodium

* Calculated upon the dry substance.

chloride. The supernatant liquid is filtered off, and the mass drained on the filter and again digested with about 60 c.c. of the same solution of sodium chloride. This digestion and filtration are repeated until the filtrate no longer gives any reaction with Fröhde's reagent.

The combined extracts are evaporated to dryness on the water-bath and the residue dried in the oven, finely pulverized, and extracted with boiling absolute alcohol until morphine is no longer removed. The alcohol is evaporated from this extract and the residue mixed with 15 c.c. of water rendered slightly alkaline with ammonium hydroxide, so that the odour of ammonia is still perceptible after the liquid has stood for twenty-four hours in an exposed place with occasional agitation.

The precipitate is collected on a weighed filter, washed, until the washings are colourless, with cold water previously saturated with morphine, dried at 100° C., and weighed. It is then transferred to a stoppered funnel and washed with successive portions of chloroform or benzene until, on evaporating a few drops of the filtrate and adding hydrochloric acid and then sodium hydroxide, no turbidity results. The filter is then again dried at 100° C. and weighed. C. A. M.

Estimation of Morphine in Opium. H. M. Gordin and A. B. Prescott. (*Arch. Pharm.*, 1899, ccxxxvii., 380; through *Chem. Zeit. Rep.*, 1899, 234.)—Three grammes of opium are rubbed down with a few c.c. of a mixture composed of 5 vols. of strong ammonia, 5 vols. of alcohol, 10 vols. of chloroform, and 20 vols. of ether. More of the liquid is then added till the opium is flooded, the vessel is covered up, and put on one side for five or six hours. 10 or 20 grammes of powdered sodium chloride are next stirred in, and the basin is placed in a current of air (stirring at intervals) till the solvents have evaporated. The residue is put in a desiccator overnight, the lumps are broken up, and the powder is brought into a percolator, rinsing out the vessel with common salt. The mass is then extracted very slowly with benzene so long as 10 drops of the liquid after evaporation and acidification yield a turbidity with 2 or 3 drops of Wagner's reagent. When all the opium bases excepting the morphine are thus shown to be dissolved, the solid matter is extracted with a mixture of 5 vols. of chloroform and 1 of alcohol until all the morphine is dissolved (using Wagner's test again). The solution is collected in a flat basin, the solvents are volatilised in a current of air, the residue is rubbed up with 50 c.c. of $\frac{N}{20}$ sulphuric acid, and brought into a graduated cylinder with the aid of water, where it is finally diluted to 90 c.c. 75 c.c. of this liquid (equal to 2·5 grammes of opium) are mixed with 35 c.c. of $\frac{N}{20}$ potassium hydroxide, and the excess of alkali is titrated with equivalent acid, using methyl orange paper as indicator. The volume of $\frac{N}{20}$ acid absorbed by the alkaloid is calculated into morphine by multiplying by

$$(0{\cdot}0142 \times \frac{100}{2{\cdot}5}) = 0{\cdot}568.$$

F. H. L.

Detection and Estimation of Ergot in Meal. F. Musset. (*Pharm. C. H.*, 1899, xl., 353; through *Chem. Zeit. Rep.*, 1899, 190.)—A mixture of chloroform and alcohol (about 10 : 1) is prepared having a specific gravity 1·435. Five grammes

of the sample are shaken with 60 c.c. of the liquid, and the whole is allowed to settle in a vertical tube; the meal sinks, the ergot and a few scales float. The floating particles and 2 or 3 c.c. of the solution are brought into another tube, mixed with the similar product from a second 5 grammes, and treated with alcohol till everything sinks. The liquid is poured away, the deposit placed on a microscope slide, and examined in xylene with a power of 800 diameters. The sclerotia appear as dark or almost black bodies; and when examined by reflected light they appear yellow with a tinge of green, thus being distinguishable from other opaque substances.

With the object of estimating the proportion of ergot, the author determines the cornutine, and calculates it according to the ratio 0·2 : 100. An amount of meal corresponding to 200 grammes of the dry material is spread out in a basin and placed for two hours under a bell jar, which also covers a small vessel containing ammonia. It is next shaken for an hour with 200 c.c. of ether, placed in a percolator, and treated with the same solvent till 450 c.c. have passed through. The ether is repeatedly extracted with 30 c.c. of 0·5 per cent. hydrochloric acid; the aqueous liquid is made alkaline with ammonia and extracted with ether, this treatment with ether being repeated several times. The final ethereal liquids are divided into two portions. The residue of one is moistened with 5 drops of strong sulphuric acid, and stirred with a rod moistened with ferric chloride, which gives a visible reaction with 0·1 milligramme of cornutine. The other half is extracted with hydrochloric acid; the ether dissolved by the liquid is evaporated, the aqueous solution diluted to 50 c.c., and mixed with 3 drops of potassium mercuric iodide. If only a faint turbidity is produced, the meal contains less than 0·1 per cent. of ergot. A strong turbidity is matched colorimetrically by tests with 50 c.c. of 0·5 per cent. hydrochloric acid and 3 drops of the double iodide containing from 0·3 to 0·5 milligramme of cornutine. F. H. L.

TOXICOLOGICAL ANALYSIS.

Notes on the Guaiacum Reaction for the Detection of Blood. E. Schaer. (*Amer. Journ. Pharm.*, 1899, lxxi., 361-370.)—From the author's experiments the following appears to be the most simple and reliable method of applying this test for the detection of blood in stains: The coloured spots are first moistened with acetic acid, and then extracted either with a 70 per cent. chloral hydrate solution, or directly with a 1 per cent. solution of guaiacum in chloral hydrate (70-75 per cent.). In the former case, which the author regards as preferable, an equal volume of the guaiacum chloral solution is added to the extract. This process has the advantage that if the stain happened to contain nitrites, the nitrous acid liberated by the acetic acid would give an immediate blue coloration with the guaiaconic acid of the guaiacum. Moreover, if the chloral hydrate extract contain only blood, the addition of the guaiacum solution to it will give a pale brown mixture, well adapted for obtaining a decisive zone reaction indicating the presence of hematin. This is tested for by pouring a layer of Hünefeld's turpentine solution, or of a solution of hydrogen peroxide, which has been proved to give no reaction with guaiacum, on the surface of the mixed liquid, when an intense blue will be formed at the junction of the liquids.

A suitable Hünefeld's solution may be prepared by mixing 15 c.c. of turpentine oil which has been exposed for some time to the light and air, and which does not change directly to blue in the guaiacum tincture, or 15 c.c. of a 3 to 5 per cent. solution of hydrogen peroxide, free from acids, with 25 c.c. of alcohol, 5 c.c. of chloroform, and 1·5 c.c. of glacial acetic acid.

In cases of very small stains, it is advisable to digest them in a flat porcelain dish with strong chloral hydrate solution, after first moistening them with acetic acid, and after thirty minutes' contact to pour on to the digested mass a correspondingly small quantity of the chloral hydrate solution of guaiacum, and when thoroughly mixed to add a few drops of the oxidizing reagent.

The author has found that very old blood-stains may be identified in this way, provided that a sensitive solution of the guaiacum prepared from quite fresh resin be used, and that the Hünefeld's solution, or solution of hydrogen peroxide, do not themselves give any coloration with guaiacum.

The zone coloration as thus obtained is much more stable than that obtained in the older methods, owing to the fact that its formation is progressive.

With regard to the possibility of confusing the blood reaction with the blue coloration given by the numerous compounds which directly colour the guaiacum resin, such as free halogens, permanganic acid, ferric and cupric salts, quinone, etc., the author remarks that in their presence the guaiacum tincture would *at once* become blue *before the addition* of Hünefeld's solution. In the case of other substances, however, such as white blood cells, and pus cells, and animal and vegetable enzymes, a false interpretation of the guaiacum blue reaction might be made. But the author has found that the "oxygen-transferring" power of the enzymes is destroyed or greatly weakened at 100° C., or by contact with dilute hydrocyanic acid. So that if the stain contained substances of the nature of enzymes instead of the constituents of blood, it will cease to give the guaiacum reaction after a short digestion on the hot-water bath, and a control experiment with hydrocyanic acid will give essentially negative results.

It is stated in conclusion that guaiaconic acid, as employed by Doebner (*Archiv. d. Pharm.*, 1897), gives a specially pure blue coloration when dissolved in 200 to 500 parts of chloral hydrate, and when the reaction is observed in a test-tube as a zone reaction. C. A. M.

ORGANIC ANALYSIS.

A Colour Reaction for Vinyl Alcohol. **E. Rimini.** (*Gazzetta Chim. Ital.*, 1899, xxix., 390-93.)—In the course of an examination of various methods of estimating fat in milk and cheese, the author obtained a violet coloration in Bondzynski's method, which is based on the Werner-Schmidt process (*cf.* Seyler, ANALYST, xx., 156).

This coloration was readily obtained by shaking a small quantity of cheese in a test-tube with hydrochloric acid (specific gravity 1·19) so as to dissolve the casein, adding a few drops of ether, again shaking and gently heating.

Having found that with pure ether recently distilled with lime no reaction was obtained, the author made a number of experiments with substances which might

possibly be present as impurities, such as methyl, ethyl, and amyl alcohols, aldehyde, furfural, formic, acetic, sulphurous, and ethyl sulphuric acids, and acetone, but in each case the results were negative.

Poleck and Thümmel have found that commercial ether invariably contains traces of hydrogen peroxide and of vinyl alcohol ($CH_2=CH.OH$), and the latter substance was found to be the cause of the reaction. It can be detected by adding mercury oxychloride to the ether, which gives a white precipitate of mercury vinyl oxychloride By distilling the ether over alkali this impurity is eliminated, and no coloration is given by the distillate in the Werner-Schmidt method.

Two theories are suggested to explain the formation of vinyl alcohol in ether. According to Schaer, it is due to the slow oxidation of the ether by the air, as in the equation

$$(CH_3 \cdot CH_2)_2 : O + O_3 = (CH_2 : CH \cdot OH)_2 + (OH)_2,$$

while, according to Richardson, the atmospheric oxygen, assisted by light, acts upon the moisture in the ether, forming hydrogen peroxide, and this in turn may oxidize the ether with the formation of vinyl alcohol.

The substance in the cheese taking part in the reaction was attributed to the casein or its decomposition products. Peptones were found to give a marked coloration, but if the decomposition of the proteid molecule had proceeded as far as the formation of amido-compounds or of phenols there was no reaction.

In the author's opinion these observations throw light upon Liebermann's reaction, according to which certain proteid bodies, when washed with alcohol and cold ether and heated with concentrated hydrochloric acid (1·19 specific gravity), give a violet coloration. As he obtained Liebermann's coloration when ordinary commercial ether was used, but not with purified ether, he considers that there can be no doubt that the reaction is due to the presence of traces of vinyl alcohol in the ether. C. A. M.

A Reaction for Ketones. Gillet and Hairs. (*Bull. de l'Ass. belge*, 1899, xiii., 170.)—On adding a large excess of Nessler's reagent to an aqueous solution of dimethylketone, a lemon-yellow crystalline precipitate is formed after a few moments. This reaction is also given by all the other ketones examined by the authors. It is extremely sensitive, detecting the presence of one drop of acetone in a litre of water, but in the presence of a large proportion of acetone the precipitate is not formed.

The compounds formed appear to be analogous to those obtained with Denigés' mercuric reagent (ANALYST, this vol., p. 93). C. A. M.

A Colour Reaction of the Benzoyl Compounds. G. Denigés. (*Bull. Soc. Pharm. Bordeaux*, March, 1899; through *Ann. de Chim. anal.*, 1899, iv., 199, 200.)—The reagent (1 c.c. of 30 per cent. formaldehyde in 50 c.c. of sulphuric acid) used by the author for the differentiation of different polyphenols (*Bull. Soc. Pharm. Bordeaux*, 1898, 241) can also be used for the detection of the benzoyl radicle (C_6H_5CO) in organic compounds. On warming a trace of the substance with 2 or 3 c.c. of this reagent in a tube containing a thermometer, a reddish-brown colour appears at about

120° C., and the liquid shows a large but not well-defined absorption-band in the green part of the spectrum.

This coloration is readily given by benzoyl chloride, benzoic acid, benzoyl acetic anhydride, benzamide, hippuric acid, and cocaine.

The same colour is produced by other compounds, but at temperatures other than 120° C. Thus, phenol, polyphenols and the opium alkaloids react in the cold, whilst salicylic compounds are coloured below 100° C.

The presence of the benzoyl group may be masked if the other groups of the compound give the reaction below 120° C., as is the case, for example, with benzaldehyde. C. A. M.

A New Method of Estimating Hydrazine. E. Rimini. (*Gazzetta Chim. Ital.*, 1899, xxix., 265-269.)—This is based on the reduction of iodic acid by the hydrazine and the titration of the unreduced acid with thiosulphate after elimination of the free iodine.

The reaction takes place in accordance with the equation

$$3N_2H_4 + 2HIO_3 = 3N + 6H_2O + 2HI.$$

The solution of the hydrazine salt is mixed with an excess of a solution of potassium iodate of known strength, and the liquid heated over a direct flame until the whole of the liberated iodine is expelled and the solution becomes colourless. It is then cooled, acidified with sulphuric acid, and titrated with decinormal thiosulphate.

It is stated that bromates are also reduced by hydrazine, but only on heating, while chlorates are not attacked.

The author has observed similar reactions in the case of hydroxylamine, phenylhydrazine, and semicarbazide, and is studying the applicability of his method to the determination of those compounds. C. A. M.

The Determination of the Dropping-point of Ceresin and Paraffin. Finkener. (*Mittheilungen aus. d. Königl. Techn. Versuchsanstalt*, 1899, vii., 100-103.)—On warming a mixture of chemically pure substances of different melting-points which have no chemical action upon one another except solvent action, the temperature remains almost constant about the melting-point of the lower melting constituent until this has ceased to dissolve the more solid constituent, and then rapidly rises.

As it is difficult in such cases to determine the exact melting-point, the author considers that the best method of determining the temperature at which the substance changes its state of aggregation is by taking its dropping-point under constant conditions.

He has therefore laid down the following conditions for the guidance of the Customs authorities in determining the dropping-point of ceresin and paraffin: The dropping-point is the temperature at which a drop of the substance under examination falls from the end of a glass rod 3 millimetres in diameter when slowly heated in a test-tube 250 millimetres long and 30 millimetres wide. The test-tube is immersed to four-fifths of its depth in water, the temperature of which is raised

about 1° C. per minute, and the thermometer is placed beside the rod in such a manner that its bulb is the same distance (about 30 millimetres) from the bottom of the tube.

In order to insure uniformity in the size of the drops, the substance is melted on the water-bath and the glass rod dipped into it to a depth of 10 millimetres, so that on solidification the adherent drop forms a hemisphere on the end of the rod.

In conclusion the author gives tables of the results of parallel determination of the dropping-point of a sample of ceresin, which tend to show that slight variations in the conditions, such as having the test-tube 26 millimetres wide instead of 30 millimetres, and having the thermometer in different positions in the tube, do not cause any considerable deviation.

A variation in the rate at which the temperature of the water is raised slightly lowers the dropping-point, as is shown in the following results :

Per Minute.	0·5° C.	1° C.	1·5° C.	2° C.
	75·1	75·0	74·6	74·1
	74·7	74·8	74·8	74·5
	75·0	75·1	74·8	74·3
	74·8	74·7	74·6	74·3
Mean ...	74·9	74·9	74·6	74·3

The author states that his results were confirmed with other samples of ceresin and paraffin. C. A. M.

On the New Method of Examining Ceresin used by the German Customs. **D. Holde.** (*Mittheilungen aus. d. Königl. Techn. Versuchsanstalt*, 1899, vii., 103-108.) —In order to distinguish ceresin from mixtures of ceresin and paraffin, the Custom House officials are directed to take the dropping-point of the sample in question (see preceding abstract). If this be 66° C., or higher, they may conclude that the substance is ceresin derived from ozokerite; whilst if it be lower than 66° C., the sample must be regarded as a mixture of ceresin and paraffin.

In criticising these directions the author points out that mistakes may readily be made by relying on the dropping-point as a conclusive test. Thus, mixtures of paraffin and ceresin can be prepared with dropping-points considerably higher than 66° C. Moreover, mixtures of pure ceresin and carnauba wax may "drop" far above that temperature, and the presence of paraffin in the mixture has but little influence in counteracting the effect of the carnauba wax. Then there are pure paraffins which melt above 66° C., as, for instance, some from Boghead coal, which in the author's experiments did not melt below 80° C., and others from Halle which had dropping-points of 65·7° C. and 66·4° C. Finally, it is possible to prepare from crude ozokerite of poor quality pure specimens of ceresin which themselves melt far below 66° C. These points are illustrated in a series of tabular results.

As regards the method of determining the dropping-point, the author remarks that a number of precautions are necessary if concordant results are to be obtained. Thus, if too much ceresin be attached to the end of the rod, the substance will drop too soon. On the other hand, if there be too little, the substance may be heated far

above its melting-point without falling. In order to avoid the necessity of making a large number of determinations, he recommends in preparing the drop, dipping the rod twice in the melted substance, and allowing the adhering material to cool to the temperature of the room before the second dipping.

It is further shown that the shape of the bulb of the thermometer and the distance of the mercury from the sides of the tube have more or less influence on the results, and it is therefore advisable to invariably use a thermometer with a cylindrical bulb about 5 millimetres in diameter, and to fix both the glass rod and the thermometer at a distance of about 10 millimetres from the sides of the tube by means of a cork support above them. C. A. M.

The Detection and Estimation of Traces of Iodine in Organic Substances. P. Bourcet. (*Bull. Soc. Chim.*, 1899, xxi., 554-556.)—The finely divided substance is fused with potassium hydroxide in a nickel basin. The fused mass is extracted with boiling water, and the solution thus obtained concentrated to half its volume. Dilute sulphuric acid (1 : 5) is then added to the cold liquid, care being taken to avoid heating. When neutral, the solution is again rendered alkaline with potassium hydroxide, and gradually mixed with half its volume of 95 per cent. alcohol.

The greater part of the potassium sulphate is precipitated, and is filtered off and washed with 30 per cent. alcohol. The filtrate is evaporated to a third of its original volume, and a fresh quantity of 90 per cent. alcohol added to it when cold. This precipitates a further amount of potassium sulphate, which is removed and washed as before. By repeating the concentration of the filtrates and precipitation with alcohol several times, the iodine is obtained in the alkaline liquids free from all potassium sulphate.

The filtrates are evaporated to dryness, and the residue slightly ignited, to destroy any residual organic matter. The residue is taken up in as small a quantity of hot water as possible, filtered, and a few c.c. tested for iodine by means of nitrous acid and carbon disulphide.

A table is given showing the amount of iodine per kilogramme determined by this method in various kinds of edible fish. The results vary from 0·2 milligramme in the fresh ray to 1·9 milligramme in the mussel and 2·0 milligrammes in the herring. C. A. M.

A. E. Shuttleworth's Method of determining Ash in Organic Substances B. Tollens. (*J. Landwirthsch.*, 1899, xlvii., 173; through *Chem. Zeit. Rep.*, 1899, 205.)—When vegetable or animal bodies are ignited, there is always a liability that the temperature may rise too high, and the ash sinter or fuse. In this case some of the silica may combine with the bases to form silicates insoluble in hydrochloric acid, so that when the ash is attacked with acid part may be left undissolved, and the percentage of "silica" appear higher than it should. To prevent this danger, Shuttleworth treats 5 or 6 grammes of the material to be incinerated with 20 c.c. of a 1 per cent. solution of calcium acetate and a sufficiency of water to moisten it thoroughly, then dries the mixture and ignites it. The calcium acetate not only

renders the mass more refractory, but also hastens the combustion. The reagent, which must obviously be pure, is best prepared from marble and hydrochloric acid, removing the iron, precipitating the calcium as oxalate, washing, igniting in a muffle, and dissolving the residue in dilute acetic acid to the above-mentioned strength.

Shuttleworth has also designed an apparatus for the ignition of organic matter in which loss of chlorides by volatilization is avoided, and which allows the ash of such substances as straw to be determined in less than four hours; but the furnace is not described in the German abstract. F. H. L.

The Determination of Sulphur in Russian Petroleum. G. Filiti. (*Bull. Soc. Chim.*, 1899, xxi., 338-341.)—The method here described is an application of that employed by Langbein for the estimation of sulphur in saccharin, and consists in oxidizing the substance in a calorimetric bomb in the presence of oxygen and a little water (ANALYST, xxi., 264).

The advantages claimed for this method over that of Carius are that it is possible to use a quantity 20 times as great for the estimation, and that the products of the combustion contain not more than traces of nitric acid, while the results are said to be exceedingly accurate.

The process also appears to be suitable for the estimation of phosphorus and halogens in volatile organic compounds. C. A. M.

The Determination of Total Sulphur in Coal. U. Antony and A. Lucchesi. (*Gazzetta Chim. Ital.*, 1899, xxix., 181-184.)—The following modification of Eschka's method (ANALYST, xiii., 17, 192) is recommended as giving accurate results in a much shorter time. One gramme of the finely-powdered coal is intimately mixed in a platinum crucible with an oxidizing mixture, consisting of manganese dioxide, 4 grammes; potassium permanganate, 1 gramme; and sodium carbonate, 2 grammes. A thin layer of the oxidizing mixture is placed on the top, and the crucible heated for thirty minutes, at first gently, and finally till its bottom is of a red heat.

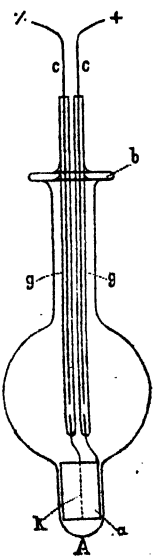
When cold the oxidized mass is transferred to a beaker containing 40 to 50 c.c. of water, the liquid boiled after the addition of nitric acid, filtered, and the sulphuric acid precipitated with barium chloride in the usual manner.

As manganese dioxide often contains sulphur, a blank determination with that to be used is advisable.

In the analyses of four samples of coal by this method, and by Eschka's, the results agreed closely.

Closely concordant results were also given by the two methods in the analysis of a sample of coal, to which had been added a considerable proportion of free sulphur, combined sulphur (pyrites), and organic sulphur (thiourea). C. A. M.

Reactions distinguishing between the Products of Peptic and Pancreatic Digestion. V. Harlay. (*Journ. Pharm. Chim.*, 1899, ix., 468-470.)—The juice of *Russula delica* contains a tyrosinase, which behaves differently with the products of



peptic and of pancreatic digestion. With the latter it gives a red coloration, which subsequently becomes black, while with the former it produces a red colour, which changes to green after some time. On treating this green liquid with a few drops of a solution of an alkali it is changed to bright red, the green colour being again restored on acidification. The final brownish-black colour given by pancreatic products does not change on the addition of an alkali.

Another distinguishing reaction is that given by bromine water. On adding to 5 c.c. of the solution containing the products of the pancreatic digestion of albumin or fibrin several drops of a saturated aqueous solution of bromine, there results a reddish-yellow precipitate, which dissolves on shaking, forming a reddish-coloured solution. This reaction is only obtained on adding the bromine little by little, and if too much be added a yellow precipitate is formed, which gradually changes to red and finally to dark violet. The presence of 1 per cent. of hydrochloric acid does not interfere with the reaction.

With the products of peptic digestion, the red coloration is not observed either in the acid solution or in the liquid neutralized with calcium carbonate. In the former case, bromine water does not give any yellow coloration unless it be added in excess, when a yellow precipitate is formed, which remains unaltered for a long time. Added to the neutralized solution, the reagent gives a slight turbidity, with a very faint violet coloration, whilst if it be added in excess, there is a yellow precipitate.

C. A. M.

An Electrolytic Method of Determining Nitrogen in Organic Substances. **C. C. Budde and C. V. Schou.** (*Zeit. anal. Chem.*, 1899, xxxviii., 344-48.)—The application of electrolysis to the estimation of nitrogen has been found by the authors to have considerable advantages over the usual methods of estimation. In their experiments they have made use of the apparatus shown in the accompanying figure. This consists of a round-bottomed flask, the bulb of which is made as small as possible, and, as a rule, contains not more than 50 c.c., although with substances which froth much it may be as large as 100 c.c. The neck of the flask is about 2 centimetres in diameter, and there is an extension in the bottom, A, holding about 10 c.c. The weighed substance is placed in this, and well mixed with 4 c.c. of fuming sulphuric acid and 8 c.c. of the ordinary concentrated acid, after which the electrodes are introduced.

The anode consists of a cylinder of platinum foil, *a* (about 0·1 millimetre thick, 50 millimetres wide, and 30 millimetres long), to the longest side of which is attached a platinum wire about 5 millimetres in length. The cathode, *k*, is a thick platinum wire about 18 millimetres long and 1 millimetre thick, which is fused on to a finer wire and then hammered out flat. Each of the thin platinum wires is fused into the end of one of the glass tubes, *g*, in which are inserted the copper wires, *c*, and the contact is completed by means of mercury.

The tubes are connected preferably by means of one of the glass attachments, *b*, fused on to each of them. When the electrodes are introduced these

attachments rest on the edge of the flask. On completing the circuit and connecting the copper wires with the poles of a battery of 8 volts, the strength of the current rises in a short time to 10 ampères, and the liquid becomes very hot. After about forty-five minutes the liquid is as a rule quite colourless, while in most cases about half the acid has been evaporated or decomposed.

When cool the liquid is distilled with alkali and the ammonia determined in the usual manner.

The following table gives the results of the determination of nitrogen in various classes of organic nitrogenous substances:

Substance.	Electrolytic Method. Nitrogen, per cent.	Theoretical. Nitrogen, per cent.
Strychnine	8·33	8·38
Morphine	4·70	4·62
Caffeine	28·72	28·86
Acetanilide	10·34	10·37
Diphenylamine ...	8·48	8·28
Asparagine	18·65	18·66
Quinolin tartrate ...	4·63	4·25
Egg albumin	12·55	—
Cocoa	3·33	—
Uric acid	32·78	33·33

It is essential to use a mixture of the fuming and ordinary acids, or the results will be too low, as is shown by a series of determinations. The apparatus here described can be obtained from Max Kaehler and Martini, Berlin. C. A. M.

INORGANIC ANALYSIS.

Estimation of Mercury in Urine by Amalgamation. Schumacher and W. L. Jung. (*Arch. experiment. Pathol.*, 1899, xlii., 138; through *Chem. Zeit. Rep.* 1899, 205.)—Jolles' process for estimating mercury in urine does not give exact results because the amalgamation is not quantitative, unless the gold is employed in a very fine state of subdivision. To bring it into this form, fibres of carefully-purified asbestos are well soaked in an almost neutral solution of gold chloride (prepared from the pure metal, and freed from excess of acids), and the salt is reduced by ignition in hydrogen. This gold-asbestos is used as a filter, and removes the whole of the mercury. Mercury precipitated by means of stannous chloride from urine which has been decomposed by treatment with hydrochloric acid and potassium chlorate still retains organic matter; therefore to obtain it in a form fit for amalgamation the whole process must be repeated a second time. F. H. L.

On the Determination of Potassium as Potassium Platinum Chloride. F. Bolm. (*Zeit. anal. Chem.*, 1899, xxxviii., 348-350.)—The following modification of a process used for a long time past in the laboratory of Fresenius is recommended by the author. The solution of platinum chloride used for the precipitation is diluted to such an extent that the precipitate is only formed on evaporating the liquid. The precipitate is collected on a filter previously treated with hot water and

alcohol, and is washed with 96 per cent. alcohol. After drying off the alcohol, the platinum salt is dissolved off the filter in hot water, evaporated in a glass basin on the water-bath, and dried to constant weight at 130° C.

After this the precipitate may be reduced to metallic platinum by Sonstadt's method, which consists in dissolving the residue in a little hot water and decomposing it with mercury on the water-bath until the supernatant liquid is clear. The weight of the platinum, multiplied by the factor 2·494, gives the amount of the original potassium platinum chloride.

The subjoined table gives the results of comparative determinations by these methods and by the more tedious one, in which the precipitate is weighed on the dried filter-paper :

Weighed on the Filter-paper, K_2PtCl_6 grammes.	Weighed in Glass Basin, K_2PtCl_6 grammes.	Weighed as Platinum, K_2PtCl_6 grammes.
0·0940	0·0936	0·0935
0·2851	0·2855	0·2861
0·1279	0·1276	0·1272

C. A. M.

Estimation of Calcium Carbonate in Soil. A. Stutzer and R. Hartleb. (*Zeits. angew. Chem.*, 1899, 448.)—This process has been designed to meet the requirements of agricultural laboratories, and to answer the question whether a particular soil would be improved by dressing with chalk or marl. The ordinary test of noting any effervescence on addition of acid is only trustworthy when sufficient chalk is present to leave no doubt on the point; and the regular methods of determining carbon dioxide by absorption are too tedious and costly for frequent employment. The process depends on the fact that calcium (or magnesium) carbonate is decomposed by boiling with a large excess (10 parts by weight) of an ammonium salt, evolving the quantitative proportion of ammonium carbonate which can be absorbed in standard acid. From 5 to 20 grammes of the sample are boiled with ammonium chloride and 200 c.c. of water for forty-five minutes in a flask of Jena glass, a blank experiment being made simultaneously in a flask of exactly the same material and with the same description of receiver. The examples quoted show a satisfactory agreement with the ordinary methods of analysis.

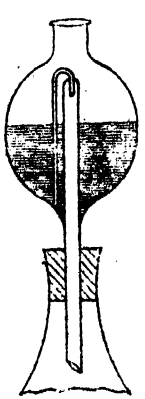
In the case of (tropical) soils containing much iron, some of which may exist as carbonate, the disturbing influence of this constituent may be eliminated by boiling the earth with water alone for half an hour so as to decompose the ferrous carbonate, then cooling, adding the ammonium chloride, and proceeding as before. Here the new process has an industrial advantage; for the absorption methods determine all the carbon dioxide, including that of the ferrous carbonate, whereas by volatilization as now described only the normal carbonates of calcium and magnesium are returned, which are precisely the substances of interest to the agriculturist. F. H. L.

Estimation of Carbonates in Soil. A. Mayer. (*Landw. Versuchsst.*, 1899, li., 341; through *Chem. Zeit. Rep.*, 1899, 205.)—The author states that a mixture of 1 part of "acetic acid" with 2 parts of water leaves ferrous carbonate practically unattacked; therefore the useful calcium carbonate, as distinguished from the useless

ferrous carbonate, may be estimated by treating the finely-powdered soil with such acid in Scheibler's apparatus, and calculating from the carbon dioxide evolved.

F. H. L.

The Analysis of Silicon. H. Borntträger. (*Zeit. anal. Chem.*, 1899, xxxviii., 350, 351.)—The following method was used by the author in the analysis of specimens of silicon prepared by the electrolytic process. Ten grammes of potassium hydroxide were dissolved in 100 c.c. of water in a silver basin, which was then gently heated on the water-bath while 0·5 gramme of the finely divided silicon was introduced little by little. After diluting with hot water, the liquid was filtered and the residue washed with hot water until the washings were no longer alkaline. It was then dissolved off the filter with hot hydrochloric acid, the solution evaporated to dryness, and the traces of silica separated in the usual manner. The small amounts of iron and aluminium were precipitated by ammonium hydroxide in the filtrate from the silica.



When these were present only in traces they were weighed together as oxides, and calculated into the metal by multiplying the result by 0·6. The difference between the impurities thus determined and 100 was taken as silicon.

In the following representative analysis the iron was determined by reduction with zinc and hydrochloric acid and titration with permanganate: Silicon, 98·53; iron, 1·04; and aluminium, 0·43 per cent.

APPARATUS.

Water-seal for Use when Boiling Liquids in a Reducing Atmosphere. H. Göckel. (*Zeits. angew. Chem.*, 1899, 620.)—This device is intended to be employed with flasks in which (for example) ferric iron solutions are being reduced by hydrogen. It preserves the liquid from contact with air; and, unlike the ordinary slit rubber valve, does not leave a high and dangerous vacuum within the vessel after its contents have been boiled and cooled. When inserted in the flask, the bulb is charged to just above the opening of the syphon tube with water or a solution of sodium bicarbonate; the main liquid can then be boiled briskly without driving the water out of the seal. When the flame is removed the bulb is filled up to the position shown in the diagram with a cold-saturated solution of sodium bicarbonate. As the pressure in the flask falls, liquid is sucked back through the syphon, which, on coming in contact with the acid, immediately liberates carbon dioxide, and soon restores and maintains the internal pressure equal with that of the atmosphere. In this manner, titration, etc., of the reduced solution can be safely postponed to a convenient opportunity.

F. H. L.

A Modification of the Sprengel Tube. A Minozzi. (*Gazzetta Chim. Ital.*, 1899, xxix., 406, 407.)—The tube shown in the accompanying figure was devised by the author as a convenient apparatus for determining the specific gravity of acids, while obviating all chance of losing any of the liquid by expansion on exposure to a higher temperature.

It holds about 50 c.c. from the mark on the capillary tube, *m*, to the extremity of the arm, *b*. In filling it the tubes *f* and *d* are fitted to *g* and *b* respectively, a mercury-pump being connected with *f*, while *d* is inserted through a cork pierced with two holes closing the bottle containing the acid.

The tube and the bottle of acid are both immersed in water at the required temperature, and when the liquid has been brought to the definite volume, the tube is closed by the stopper, *e*, and the cap, *c*. C. A. M.

MISCELLANEOUS.

WATER AND SEWAGE EXAMINATION RESULTS.

Report of the committee, consisting of Professor W. Ramsay (chairman), Dr. S. Rideal (secretary), Sir W. Crookes, Professor F. Clowes, Professor P. F. Frankland, and Professor R. Boyce, appointed to establish a Uniform System of recording the Results of the Chemical and Bacterial Examination of Water and Sewage.

The committee beg to report as follows: That it is desirable that results of analysis should be expressed in parts per 100,000, except in the case of dissolved gases, when these should be stated as cubic centimetres of gas at 0° C., and 760 millimetres in 1 litre of water. This method of recording results is in accordance with that suggested by the committee appointed in 1887 to confer with the committee of the American Association for the Advancement of Science, with a view to forming a uniform system of recording the results of water analysis.*

The committee suggest that in the case of all nitrogen compounds the results be expressed as parts of nitrogen over 100,000, including the ammonia expelled on boiling with alkaline permanganate, which should be termed albuminoid nitrogen. The nitrogen will therefore be returned as:

(1) Ammoniacal nitrogen from free and saline ammonia.

(2) Nitrous nitrogen from nitrites.

(3) Nitric nitrogen from nitrates.

(4) Organic nitrogen (either by Kjeldahl or by combustion, but the process used should be stated).

(5) Albuminoid nitrogen.

* British Association Report, 1889.

The total nitrogen of all kinds will be the sum of the first four determinations.

The committee are of opinion that the percentage of nitrogen oxidized—that is, the ratio of (2) and (3) to (1) and (4)—gives sometimes a useful measure of the stage of purification of a particular sample. The purification effected by a process will be measured by the amount of oxidized nitrogen as compared with the total amount of nitrogen existing in the crude sewage.

In raw sewage and in effluents containing suspended matter, it is also desirable to determine how much of the organic nitrogen is present in the suspended matter.

In sampling, the committee suggest that the bottles should be filled nearly completely with the liquid, only a small air-bubble being allowed to remain in the neck of the bottle. The time at which a sample is drawn, as well as the time at which its analysis is begun, should be noted. An effluent should be drawn to correspond as nearly as possible with the original sewage, and both it and the sewage should be taken in quantities proportional to the rate of flow when that varies (*e.g.*, in the emptying of a filter-bed).

In order to avoid the multiplication of analyses, the attendant at a sewage works (or any other person who draws the samples) might be provided with sets of twelve or twenty-four stoppered quarter-Winchester bottles, one of which should be filled every hour or every two hours, and on the label of each bottle the rate of flow at the time should be written. When the bottles reach the laboratory, quantities would be taken from each proportional to these rates of flow and mixed together, by which means a fair average sample for the twenty-four hours would be obtained.

The committee at present are unable to suggest a method of reporting bacterial results, including incubator tests, which is likely to be acceptable to all workers.

REVIEWS.

MILK, ITS NATURE AND COMPOSITION. By C. M. AIKMAN, M.A., D.Sc. London: A. and C. Black. Second edition, 1899, xxx., 180 pp.

The aim of this work is to give a short, popular statement of the more important facts of the chemistry and bacteriology of milk, and it is specially designed for students of agricultural science.

The work has been revised, but it is to be regretted that the revision has not been more thorough. On page 59 a correction has been made that the skin which forms on milk when heated consists chiefly of casein, and not, as is "erroneously supposed," of albumin; yet on page 171 the erroneous supposition is allowed to remain.

The manifest merits of the work—the able condensation into a small space of salient scientific facts, the lucidity and clearness of statement, and prominence of practical detail—are marred by faults and inaccuracies which a little more study and research and a little more care should have obviated. The most serious, from a practical point of view, is the statement that, working on a large scale, the separator yields about 93 per cent. of the fat in the cream; this means practically that separated

milk contains 0·25 per cent. of fat; if this quantity were found in a large dairy, it would mean either the dismissal of the man in charge as incompetent, or the replacement of the separator by one less faulty. Not more than 3 or 4 per cent. of the total fat should be found in the separated milk.

The analytical portion is very short, and working details are not given; the proportion of sulphuric acid used in the Leffmann-Beam method of fat estimation is given as double the proper amount.

Many of the faults are due to misuse of words; thus, "capronin" and "capronic acid" are used for "caproin" and "caproic acid," and "butin" (a word traceable to Heischmann) is given as a constituent of butter, but is found in no standard work on chemistry; "caseinogen" is used as synonymous with the "genuine" casein of Lehmann, and has not the significance assigned to it by Halliburton, who coined this name, and it is probably owing to the lax use of this word that the author appears to regard the product obtained by adding rennet to milk as identical, on page 29, with that produced by the action of acid, and as different on page 58.

We hardly expect in a work of this character to find the word "typhus" used to designate the disease known as "typhoid," or enteric fever. The late Ernest Hart certainly investigated no typhus epidemics, nor is it correct to speak of the Typhus bacillus. It is to be hoped that the word typhoid, to which the confusion is due, will soon cease to be an English word, and there will then be no chance of confusing enteric with typhus fever. H. D. R.

VICTOR VON RICHTER'S ORGANIC CHEMISTRY; OR, THE CHEMISTRY OF THE CARBON COMPOUNDS. Edited by Professor R. ANSCHÜTZ, University of Bonn. Authorized Translation by Professor EDGAR F. SMITH, University of Pennsylvania. Third American from the eighth German edition. Volume I.: Chemistry of the Aliphatic Series. Pp. 625. London: Kegan Paul, Trench, Trübner and Co., Ltd., 1899. Price 15s.

"Richter's Organic Chemistry" is certainly one of the standard works on the subject, and as such has had for many years a well-deserved and high reputation. It has passed through eight editions in German, and for English translations of the last three editions we are indebted to Professor E. F. Smith, of Pennsylvania. The latest edition is published in two volumes, edited by Professor R. Anschütz; the first of these deals with the aliphatic series, and the second (the English translation of which is not yet issued) with the aromatic series. From the first the work has been a comprehensive one, so much so, in fact, that the student acquainted with its contents might at least be said to have considerable acquaintance with the subject. It occupies an intermediate position between a text-book and a book of reference, yet the continual enlargement of successive editions must tend to bring it closer to works of the latter class. If, however, the lines on which it was originally drafted are to be preserved, the present enlargement of the text is fully justified by the important additions to our knowledge within recent years, and the advanced student will doubtless find it an invaluable *vade mecum*.

Apart, however, from the academical student, there are many professional chemists whose time does not allow them to follow closely all the latest researches

in specific branches of chemistry, but who nevertheless require to be posted up in the most recent facts and theories. To such, the present edition of "Richter's Organic Chemistry" will be of great service. It is quite unnecessary to plead the cause of organic chemistry, as it is self-obvious that something more than a mere superficial knowledge of that subject should be possessed by the modern analyst, who in his daily work is now called upon to separate and estimate various organic substances, and thanks to improved methods based on scientific principles, he is able to do this with an accuracy not inferior to that with which the constituents of a mineral may be estimated.

The subject-matter of the volume is well arranged, and the numerous paragraphs printed in smaller type will be found full of important supplementary information. Many references to original papers are given, and the editor seems to have exercised great skill in their selection. In the introductory portion, methods of elementary analysis and for the determination of molecular weights are described. The chemical constitution of carbon compounds is discussed, a particularly lucid exposition being given of the theory of molecular asymmetry, including the isomerism of optically active compounds and stereoisomerism, a branch of knowledge founded on the researches of Pasteur and developed by those of Van 't Hoff, Le Bel, von Baeyer, J. Wislicenius, and others. There are also remarks on the physical properties of carbon compounds and the action of heat, light and electricity on them. The general part calls for no additional remarks. The chemistry of the sugars, including the results of the remarkable researches of Emil Fischer, is dealt with in a plain and intelligible manner. Following a description of the simple sugars and their derivatives is a section headed "Carbohydrates," in which is to be noted the statement that these substances contain six, or a multiple of six, carbon atoms! But scant are the descriptions accorded to gums and other polysaccharides. The volume concludes with a few pages devoted to albuminous substances, etc. Under enzymes no mention is made of oxidizing enzymes, or of the enzyme of alcoholic fermentation, the latter phenomenon being attributed to an "organized ferment."

The whole work has doubtless profited by the fact that authorities in special fields of investigation have given the editor the benefit of their supervision of certain chapters. There appear to be no serious typographical errors, and considering the mass of detail brought together, this is certainly a circumstance which deserves commendation. Whilst, therefore, we are bound to admit that the translator has on the whole executed his task satisfactorily, there are certain paragraphs in which the diction is not the most elegant, and others where apparently too literal a rendering of the original text has been given. It is stated that "the presence of carbon in a substance is shown by its charring when ignited *away* from air." We read that "Michael offers the *thought*," etc. Carbocyclic compounds are referred to as "these ring-shaped bodies." What is doubtless in the original text expressed by the word "*Grenz-kohlenwasserstoffe*," is translated "limit hydrocarbons." There are also in one or two places cases of recapitulation, although as a rule this is avoided by cross-references. In conclusion, it may be worth mentioning that, although the volume bears the publishing date of the present year, the German edition appeared in 1898.

A. R. L.

THE ANALYST.

NOVEMBER, 1899.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

COFFEE EXTRACTS, THEIR COMPOSITION AND ANALYSIS.

By C. G. Moor and Martin Priest.

(*Read at the Meeting, June 7*, 1899.)

The various coffee extracts on the market show such remarkable variations in their composition that we thought it would be of interest to the members of this Society to record some figures recently obtained, and to invite discussion as to whether these articles ought to be dealt with under the Sale of Food and Drugs Act or not.

We give the figures obtained on 10 samples, 5 of which were sold as coffee extracts, 4 as coffee and chicory extracts, and 1 as coffee extract with sugar.

An exhaustive research on the composition of coffee extracts is to be found in the *Lancet* (special Analytical Sanitary Commission), July 7, 1894, in which figures are given on 14 samples of various kinds. In this paper it is stated that genuine coffee extracts contain about 0·5 per cent. of caffeine, and coffee and chicory extracts about 0·3 per cent.

Our figures are in fair agreement with these averages.

These very low caffeine figures are doubtless due to the unavoidable loss during manufacture, owing to the caffeine being precipitated as an insoluble tannate, which may sometimes be seen at the bottom of the bottle, and might (if a sample were divided into three parts) cause great variations in the composition of the three portions, unless great care is taken to thoroughly mix the contents. In some samples of coffee extract so much saccharine matter is added that the preparation is really a kind of treacle flavoured with coffee, and it is plain that Allen's comment (p. 553, Vol. III., part ii., "Commercial Organic Analysis") is correct, that "Coffee extracts are prepared with very limited success by subjecting roasted coffee to treatment with boiling water or steam, and adding the volatile products to the aqueous extract. The product is deficient in caffeine, and does not contain all the extractive matter of the coffee; nor when diluted with the appropriate amount of water is the colour the same as that of the freshly-prepared liquid."

The points which we suggest for discussion are these:

1. If sold as *coffee extract*, ought the article to contain a large amount of added saccharine matter unless its presence is declared?

2. As caffeine is probably the most valuable constituent of coffee, ought there not to be a minimum limit of caffeine for preparations of this class?

No.	Extract.	Ash.	N.	Caffeine.
1. Coffee extract	39·9	4·25	0·96	1·98
2. Coffee extract	27·9	0·95	0·15	0·47
3. Coffee extract and chicory ...	30·0	0·36	—	0·32
4. Coffee extract	34·8	1·28	0·23	0·54
5. Coffee extract	46·4	0·43	0·06	0·57
6. Coffee extract and chicory ...	37·6	0·36	—	0·02
7. Coffee extract	50·6	0·55	0·41	0·56
8. Coffee extract and chicory ...	48·6	1·87	0·37	0·26
9. Coffee extract and sugar ...	51·5	2·50	0·38	0·61
10. Coffee extract and chicory ...	48·5	1·14	0·30	0·28

Discussion.

The Chairman (Mr. Allen) said that the division of a sample of coffee extract into three parts would be rendered difficult by the fact that the caffeine and tannin separated out as a compound insoluble in cold water. Caffeine tannate, however, was easily soluble in hot water, as was well shown by an infusion of tea, which, on cooling down from a temperature at which it was perfectly limpid, became quite turbid, from the formation of a deposit of caffeine tannate. If, therefore, the task of division fell to the analyst, which in future it would not do, a fair sample could be obtained by simply warming up the extract before dividing it.

Mr. Hehner inquired whether the authors could explain the high percentage of caffeine in sample No. 1. It was about double that contained by coffee itself, and yet the total quantity of dry extract did not quite correspond with what would be expected if the sample were twice as concentrated as coffee.

Dr. Lewkowitsch said that caffeine was sometimes added in order to mask adulteration, as in the manufacture of artificial coffee-beans.

Mr. Cribb asked whether the authors had ascertained what the dry extract consisted of—whether, for instance, there was much caramel present.

Mr. Cassal said that to deal with coffee extract under the Sale of Food and Drugs Act as it at present stood would be a matter of very considerable difficulty. One of the first points would be to satisfy a bench as to the meaning of the term "extract." He would be glad to know in what way Mr. Moor would propose to arrive at a standard upon which a public analyst could work, and how he would propose to ascertain the degree of concentration of the extract, which he (Mr. Cassal) considered to be a necessary step before a certificate could be issued to the effect that a particular sample contained not less than so much treacle, or not more than so much coffee. Under existing conditions it would be very difficult to prove adulteration in the case of extracts. The points brought forward in the paper afforded additional evidence of the need of that Board of Reference, the establishment of which the Society had so strongly advocated.

Mr. Moor said that sample No. 1 had probably been enriched with caffeine, though this could not very well be ascertained. He had himself endeavoured to make coffee extract by boiling down *in vacuo*, but the caffeine separated out in such a way that it was impossible to prepare from the extract anything like a good imitation of coffee. The only one of these samples which at all resembled coffee was No. 1. He thought

(though from his own non-success in making an extract he could not be certain) that the caffeine present in this sample was in tolerably fair proportion to what would be obtained on boiling down an ordinary 10 per cent. infusion of coffee. This particular sample was not very highly coloured, but all the others no doubt contained a good deal of caramel. The excerpt quoted from Mr. Allen's book exactly represented the state of things at the present time. Coffee extract was a thing which ought not to be prepared at all. Its use was uneconomical, and in many cases it consisted of little else than treacle. If the division of samples was made by an inspector, it would be very unlikely that the proper proportion of caffeine would be contained in each third portion.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Question of the Retention of Phytosterin in the Animal System on Feeding with Cotton-seed Oil. C. Virchow. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, ii., 559-575.)—The author was induced to undertake the experiments described in this paper by the interest which has been lately shown in the question of the adulteration of lard with cotton-seed oil. The experiments were made upon dogs and pigs. These were first reduced to a very lean condition by depriving them of food, after which they were given cotton-seed oil in conjunction with other food, and were finally slaughtered as soon as they had recovered their condition. The fat was then examined. The results entirely confirm the observations of A. Bömer on cholesterin and phytosterin, and show that phytosterin is not retained in the animal fat. H. H. B. S.

On the Digestibility of "Palmin" in the Human Alimentary Canal. H. Lührig. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, ii., 622-632.)—"Palmin" is the trade name of a purified form of cocoanut-oil prepared by a secret process for use as an article of food. It is of a pure white colour, nearly free from water and acid, without granular structure, and of an agreeable nutty odour and taste. Cocoanut-oil being characterized by a relatively high saponification number, low iodine number, and high Reichert-Meissl number, it is easy to distinguish between a pure cocoanut-oil and a mixture of the butter with other fats. "Palmin" gave the following constants as the mean of several determinations:

	Melting Point.	Solidifying Point.	Iodine Number.	Saponification Number.	Reichert-Meissl Number.	Refraction at 40° C.
"Palmin"	25°	22·4	7·27	260·7	7·85	35·1
Insoluble Fatty Acids ...	25°-25·3°	22·8	6·90	271·1	—	18·1

A characteristic peculiarity of "palmin" is that it melts at 25° C., and then remains fluid below the melting-point until 19·8° C. is reached, when the thermometer rises rapidly, and remains between 22·3° and 22·4° C. until the fat has completely solidified again. The insoluble fatty acids of "palmin" also show the same peculiarity.

In two series of experiments, carried out upon the lines of the author's similar experiments with margarine and butter (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 484-506; ANALYST, 1899, xxiv., 237), it was found that from 95·5 to 97·3 of the fat was absorbed; hence the author concludes that the digestibility of "palmin" is not inferior to that of other foods. H. H. B. S.

Paraffin as an Adulterant of Oleomargarine. J. F. Geisler. (*Journ. Amer. Chem. Soc.*, vol. xxi. [7], pp. 605-608.)—The admixture of paraffin with oleomargarine appears to be on the increase of late, after a period of discontinuance subsequent to the revelations made in 1894, and the author has detected from 5 to 11·76 per cent. in samples recently examined. For its detection he recommends as a preliminary test a specific gravity determination; an abnormally low specific gravity of 0·9018 to 0·8907 at 100° F. (water at 100° F.), coupled with turbidity on saponification, are indications of the presence of paraffin. The solution will appear turbid if more than 2 to 3 per cent. of paraffin is present, and this can be collected for examination by careful alternate heating and cooling the solution. In one sample examined the fat—photomicrographs of which, showing irregular masses of paraffin, are given—did not melt clear below 106° F., congealing at 105° F., and yielding paraffin melting at 127°.

This adulteration is believed to be practised with the object of preventing the segregation of the solid and liquid fats in the mixture, and of imparting a texture resembling that of butter. C. S.

Studies on New Descriptions of Coffee. 1. Bourbon Coffee (Café Marron). T. F. Hanausek. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, ii., 545-550.)—This coffee has already been noticed by H. Trillich, who published a description and analysis (*Zeit. öffentl. Chemie.*, 1898, 542), and by A. Froehner ("Die Gattung Coffea und ihre Arten," Dissertation Rostock. Leipzig, 1898). It is the product of a wild coffee-tree, probably *Coffea bourbonica*. The beans are egg-shaped, and thinner and more slender than true coffee-beans, as well as somewhat different in size. Pearl-beans are often found, and for these Trillich's description "tear-shaped" is peculiarly appropriate. The ordinary beans are from 10·5 to 14 mm. long, 6 to 7 mm. broad, and 2 to 4 mm. thick. The pearl-shaped beans are from 10 to 12 mm. long, 4·5 to 5 mm. broad, and 4 to 4·5 mm. thick. The roasted beans measure from 12 to 15·5 mm. in length, 7 to 8 mm. in breadth, and 3 to 5 mm. in thickness, thus showing considerable increase in size over that of the raw beans. The weight of the roasted beans is, however, 33·7 per cent. less than that of the raw beans, 100 weighing in the raw state 15·28 grammes, and roasted 10·22 grammes. By its size and shape alone, therefore, this coffee can be readily distinguished from Arabian coffee. Most of the beans remain enveloped in their

husks, which give to them a dull, greyish, dusty appearance. The husks can, however, be completely removed by steeping in water. Cut sections of the dry beans show that the husk is threefold, as the author has shown to be the case in Arabian coffee (*Zeit. für Nahrungsm.—Untersuch., Hygiene und Waarenkunde*, 1893, 85 and 105). Trillich's statement that caffeine is not a constituent of this coffee is confirmed by the author. The paper is illustrated by diagrams, showing the botanical structure of the beans. H. H. B. S.

Detection of Fluorine in Wine. G. Paris. (*Chem. Zeit.*, 1899, xxiii., 685.)—The ash from 50 c.c. of wine is mixed with a little precipitated silica and 0·5 or 1 c.c. of strong sulphuric acid in a small platinum crucible. The lid, bearing a drop of water suspended from its convex surface, and with its concavity filled with cold water (for condensing purposes), is then put in position, and the whole is heated for five minutes over a very small flame. After cooling, the drop of water is transferred to a microscope slide previously coated with Canada balsam, and 2 or 3 crystals of pure sodium chloride are added quickly. In twenty or thirty minutes the slide is examined with the microscope, using a power not exceeding 100 diameters. Under ordinary light, if fluorine is present, the hexagonal crystals of sodium hydrogen silico-fluoride will be recognised; while, under polarized light with crossed nicols, darkness is produced when the axes of the prisms lie parallel to the principal section of one of the nicols. The test is extremely sharp, and will detect an addition of 0·01 gramme of dry ammonium fluoride to 50 c.c. of wine. Employment of calcium chloride before incineration is not necessary. F. H. L.

The Composition of Edible Locusts. P. Rœser. (*Journ. Pharm. Chim.*, 1899, x., 203-206.)—In the north of Africa locusts are prepared for food by removing their head, legs, and wings, steeping them in 50 per cent. brine, and drying them in the sun.

Three specimens thus prepared have been examined by the author. They weighed from 0·55 gramme to 0·695 gramme, and had the following composition: Water, 9·1 to 10·4; organic matter, 79·05 to 81·00; mineral matter, 9·9 to 10·6; nitrogen, 7·0 to 8·4; fat, 12·2 to 16·6; chitin (insoluble in acids and alkalies), 5·4 to 7·9; chlorides as sodium chloride, 3·83 to 4·18; phosphoric acid, 1·059 to 1·087; and silica and sand, 2·10 to 2·40 per cent., together with calcium, potassium, iron, and sulphuric acid.

The fat, which was almost completely saponifiable, melted at 24·5° C.

C. A. M.

The Characteristics of Croton Oil. W. Dulière. (*Ann. de Pharm. de Louvain*, 1899, 229 and 278; through *Journ. Pharm. Chim.*, 1899, x., 305, 306.)—According to the author, oils prepared by extraction with petroleum spirit or by cold expression closely resemble the officinal oil, but oils obtained by hot expression, or by extracting the non-decorticated seeds with ether, differ from it in colour, acidity,

and degree of solubility in absolute alcohol, although their chief chemical constants are practically identical.

In the following table of these constants, the acetyl value was determined by Lewkowitsch's method, which the author has found to yield very concordant results (*Journ. Soc. Chem. Ind.*, 1897, 507):

Specific gravity at 15° C.	0·9437
,, ,, at 100° C.	0·8874
Solubility in alcohol (92 per cent.)	1 in 63
Critical temperature of dissolution (Crismer)	54·8° C.
Refraction (Zeiss degrees)	+77·5 at 27° C.
,, ,, (Amagat and Jean degrees)	+35 at 22° C.
Acid value (Bürstyn)...	21·8
Saponification value	215·6
Solidification point of fatty acids	16·4° to 16·7° C.
Reichert-Meissl value	12·1
Iodine value, after two hours	100·37 to 101·91
,, ,, twelve hours	103·63 to 104·39
,, of fatty acids (two hours)	111·23 to 111·76
Acetyl value	38·64

The presence of castor oil may be detected by converting the ricinoleic acid into sebacic acid, but the reaction, although sensitive, is not quantitative. The author states, however, that the difference between the acetyl values of croton and castor oils enables one to estimate very closely the amount of the latter.

In order to detect hydrocarbons, which it is stated are frequently introduced into croton oil, the sample should be distilled in a current of steam. Their amount may be calculated from the saponification value. C. A. M.

Detection of Synthetical [Toluene] Benzoic Acid in the Resin Sublimed Product. P. N. Raikow. (*Oesterr. Chem. Zeit.*, 1899, ii., 121.)—The recognised test for toluene benzoic acid in the material nominally prepared from gum benzoin depends on the assumption that the former is always contaminated with chlorine combined in some form with the aromatic nucleus; and the official method of carrying it out consists in igniting the acid with calcium carbonate. The author finds that his phloroglucinol-vanillin reaction (ANALYST, 1898, xxiii., 99) is a far more delicate means of detecting the presence of chlorine, and, as regards the truth of the dictum that chlorine indicates synthetical benzoic acid, he has instituted certain experiments. Benzoic acid sublimed from the best Siam benzoin or from inferior specimens of the gum is free from chlorine, therefore the occurrence of a red colour with phloroglucinol-vanillin proves the addition of acid from the toluene. On the other hand, whilst the majority of benzyl preparations made ultimately from toluene contain chlorine, *e.g.*, benzoic anhydride, benzylic alcohol, benzoyl acetate, benzonitrile, benzamide, benzaldehyde, mandelic acid, and methylic benzoate; others are free from chlorine, *e.g.*, benzylphenylhydrazine, the nitro- and amido- benzoic acids, benzylidenacetone, and ethylic benzoate; and it has not been possible to ascertain definitely whether the absence of halogen is due to the further processes involved in the manufacture of the latter bodies, or whether the original benzoic acid itself was free from

chlorine. Benzoic acid containing chlorine cannot be freed from this impurity by sublimation, or by crystallization from hot water or alcohol, consequently the failure of the above or the official test does not seem necessarily to prove that the synthetical acid is absent. F. H. L.

Hydrogen Peroxide as a Test for Salicylic Acid. W. E. Ridenour. (*Amer. Journ. Pharm.*, 1899, lxxi., 414-416.)—On adding to a solution of sodium salicylate a small amount of an ammoniacal solution of ammonium carbonate, followed by hydrogen peroxide solution, a colour reaction is obtained which varies from light pink or peach to dark garnet, according to the amount of salicylic acid present.

In the author's test experiments the strength of the sodium salicylate solution used was 10 per cent., and the hydrogen peroxide solution contained 2·30 volumes of available oxygen. The presence of the ammonium carbonate solution was found to be essential to the reaction, and 5 c.c. of the U.S.P. solution were used in each case. The weakest solution of sodium salicylate which gave the reaction contained 1 part of salicylic acid in 2,083 parts of water. When stronger solutions of hydrogen peroxide than that mentioned above were employed, the colour was produced at first, but rapidly disappeared.

The author adds a table showing the influence of other chemical substances on the reaction, the colours given by 0·5 gramme of the compound with 1 c.c. of the salicylate solution being summarized in the following list: Ammonium oxalate, none; ammonium chloride, cherry; sodium benzoate, cherry; sodium benzoate, cherry; sodium and potassium tartrate, dark cherry; sodium phosphate, cherry; hydrogen ammonium fluoride, none; sodium borate, amber; sodium thiosulphate, light lemon; ammonium sulphate, cherry; gallic acid, lemon; sodium acetate, cherry; sodium sulphite, none; potassium citrate, none; potassium chlorate, cherry; sodium hypophosphite, cherry; lactic acid (75 per cent.), cherry; tannin, yellow; potassium iodide, amethyst; potassium bromide, cherry; alcohol (15 c.c.), cherry; glycerin (15 c.c.), deep peach; and phenol, cherry. In most cases where no colour was obtained a reaction was given by using more of the sodium salicylate solution, sodium sulphite, however, being an exception.

With the exception of gallic and tannic acids, none of these substances gave any colour reaction by themselves with hydrogen peroxide and ammonium carbonate.

C. A. M.

TOXICOLOGICAL ANALYSIS.

The Detection and Estimation of Free Phosphorus in Oils and Fats. E. Louïse. (*Comptes Rend.*, 1899, cxxix., 394, 395.)—The methods used for the detection and estimation of phosphorus in toxicological work are not available when only traces of phosphorus are present in a large amount of oil. For it cannot be volatilized in a short time with vapour, whilst if the current be continued too long some of the phosphorus will be oxidized and left behind. Other methods based on the oxidation of the phosphorus are, in the author's opinion, also inapplicable under these circumstances.

This difficulty may be obviated by diluting the oil with acetone and precipitating the phosphorus by means of a concentrated solution of silver nitrate.

Five grammes of the oil are made up to 100 c.c. with acetone and the liquid divided into 10 portions. To the first of these is added 1 drop of a 10 per cent. solution of silver nitrate, the liquid filtered, and the filtrate again tested with silver nitrate. If a coloration be obtained, the second tube is tested with 2 drops of the silver nitrate solution in the same way, and so on until the point is reached at which the precipitation is complete. Say, for example, that 2 drops have been found insufficient and 3 too many. Two drops of the 10 per cent. solution are then added to a fresh portion and the intermediate point determined by means of a 1 per cent. solution of silver nitrate. In this way traces of phosphorus in oil can readily be determined in terms of standard silver nitrate. C. A. M.

ORGANIC ANALYSIS.

Influence of Temperature on the Specific Rotation of Sucrose, and Method of correcting Readings of Compensating Polarimeters. H. W. Wiley. (*Journ. Amer. Chem. Soc.*, vol. xxi. [7], pp. 568-596.)—From the results furnished by a number of carefully-performed experiments on the alterations in the specific rotation of sucrose under the influence of temperature, and on the various factors affecting the same, all of which are given in detail, the author concludes that the mean variation for each degree C. is 0·00994, the specific rotatory power at 17·5° C. being 66·547, whilst at 4° and 40° (the limits of temperature investigated) the readings were 66·657 and 66·299 respectively; *i.e.*, the variation is in inverse ratio to the temperature. It appears, however, that the variations are not uniform, the rate of decrease being greater (nearly double), between 15° and 17·5°; 20°-25° and 30°-35° C. than elsewhere in the series. C. S.

The Estimation of Mannose in the Presence of Other Sugars. E. Bourquelot and H. Herissey. (*Journ. Pharm. Chim.*, 1899, x., 206-209.)—The authors have devised a method for the estimation of mannose, founded on the insolubility of its hydrazone in cold water, which in its general principles is the same as that worked out by Lintner and Kröber for the estimation of dextrose, lævulose, and saccharose (ANALYST, xx., 167).

They find that the results are accurate if the temperature be kept sufficiently low, and the solution contain from 3 to 5 per cent. of mannose. With weaker solutions the weight of the osazone is too low by about 0·04 to 0·05 gramme for each 100 c.c. of solution. The method is stated to be specially applicable to the determination of mannose in the products of the hydrolysis of vegetable substances where the mannose is frequently accompanied by galactose, arabinose, and compounds allied to dextrins.

The following examples may be quoted to show the authors' method of working, and the results obtained in test experiments:

A solution of crystalline mannose (0·8 gramme) and galactose (1·20 grammes), in

33·2 c.c. of water, was mixed with a solution containing phenylhydrazine (2·4 c.c.) and glacial acetic acid (2·4 c.c.) in 12 c.c. of water. The mixture was left for eight hours at a temperature of 10° C., and the precipitated osazone washed successively, on a double filter with the aid of a pump, with 10 c.c. of ice-water, 10 c.c. of alcohol, and 10 c.c. of ether, dried at 100° C. and weighed. The amount of osazone found was 1·195 grammes, as compared with the theoretical quantity, 1·20 grammes.

In like manner a mixture of 0·8 grammes of mannose and 1·20 grammes of arabinose yielded 1·195 grammes of osazone; and a mixture of mannose (1 gramme) and crude maltose containing dextrin (1 gramme), yielded 1·44 gramme, as against the theoretical amount, 1·50 gramme. C. A. M.

The Determination of Albuminous Substances in Urine. G. Denigés. (*Journ. Pharm. Chim.*, 1899, x., 97-102.)—The method described here is an application of the author's method of estimating casein in milk (ANALYST, xxii., 11, and xxiii., 38). Although the weight of proteid precipitated is not proportional to the mercury combining with it, it is possible to make a correct estimation, when the amount of albumin in the urine required for the analysis (150 c.c.) does not exceed 15 to 16 centigrammes.

Twenty c.c. of the mercuric reagent are mixed with 2 c.c. of glacial acetic acid, and after the addition of 150 c.c. of the urine, which must not contain more than 1·10 gramme of albumin per litre, the liquid is made up to 200 c.c. and filtered. Of this filtrate 125 c.c. are added to 25 c.c. of an ammoniacal solution of potassium cyanide equivalent to $\frac{N}{20}$ silver nitrate, the liquid filtered after two or three minutes, and 120 c.c. of this second filtrate titrated with decinormal silver nitrate solution until a faint but permanent turbidity results. The number of tenths of a c.c. (n) required, less the constant 48, gives directly the number of decigrammes of albumin in a litre of the urine.

In the case of there being impurities in the reagent, the constant required may not be exactly 48. This should be determined by mixing 10 c.c. of the mercuric reagent with 20 c.c. of the cyanide solution and 100 c.c. of water, and adding decinormal silver nitrate until there is a permanent turbidity, the number of tenths of a c.c. used giving the necessary constant.

If the urine contain more than 1·10 gramme of albumin per litre, it must be so diluted that not more than that proportion is present.

The author's mercuric reagent is prepared by dissolving 13·55 grammes of mercuric chloride and 36 grammes of potassium iodide in 100 c.c. of cold water, and diluting the solution to a litre.

This method is not applicable when the urine contains less than 20 centigrammes per litre, and the author therefore recommends the following process in such cases: An albuminous urine, the albumin in which has been previously determined gravimetrically, is distributed throughout a series of five tubes in such a manner that they contain albumin in the proportion of 1, 2, 4, 8 and 12 centigrammes per litre respectively. The liquid in each is diluted to 10 c.c., and 10 c.c. of the urine under examination is placed in a sixth tube. After the introduction of 2 c.c. of a 5 per cent.

solution of sodium metaphosphate, and 4 drops of sulphuric acid into each, the tubes are placed for five minutes in boiling water, and the opalescence in the sixth tube compared with that in the standard tubes.

This method gives good results with urine containing not more than 12 centigrammes of albumin per litre, but above that quantity the precipitate formed in the tubes on warming is of a flocculent character. Therefore, in the examination of urines containing between 12 and 20 centigrammes per litre there must be a suitable dilution.

When globulins are present in the urine, the total albuminous substances are estimated as described above, before and after saturation with magnesium sulphate, which removes the globulins. Two determinations are also necessary in the presence of alkaloids or peptones, viz., before and after the removal of coagulable albuminous substances by heat. C. A. M.

A Reaction for Benzidine and Tolidine. J. Wolff. (*Ann. de Chim. Anal.*, 1899, iv., 263-264.)—A small portion of the substance under examination is dissolved in 1 c.c. of cold glacial acetic acid, the test-tube filled to about three-quarters with water, and a few drops of water, with lead dioxide in suspension, introduced. A bright blue colour is immediately produced, which lasts for some time, but disappears on heating.

If to the solution of either of these bases in dilute acetic acid a few drops of bromine be added, there is a blue coloration, and on continuing the addition of bromine a blue precipitate is formed. The colouring matter thus obtained is stable at the ordinary temperature; it is insoluble in water and in alcohol. The colour disappears on adding ammonia, but reappears on again acidifying with acetic acid. In the presence of dilute mineral acids the oxidation of benzidine or tolidine does not give any blue coloration. The colour is obtained, though with less intensity, in the presence of dilute solutions of other organic acids such as citric, tartaric, and oxalic acids. C. A. M.

Determination by Combustion of Carbon and Hydrogen in Organic Substances containing Nitrogen. O. F. Tower. (*Journ. Amer. Chem. Soc.*, vol. xxi. [7], pp. 596-605.)—From the results obtained in the investigations described, it appears that, in the case of amido-compounds, there is no need to use a copper spiral in the combustion-tube, since no oxides of nitrogen absorbed by concentrated sulphuric acid or by soda-lime are formed, whilst of the nitro-substances (nitraniline, dinitrobenzene, and picric acid) examined, only the last-named gave off oxides—probably for the most part nitrogen peroxide—absorbed by the reagents. The formation of nitric oxide is not impossible, but as it is not absorbed unless further oxidized, it does not affect the accuracy of the determination of carbon and hydrogen. C. S.

Notes on Acetone Oil. **R. Duchemin.** (*Bull. Soc. Chim.*, 1899, xxi., 798-800.)—The author supplements the work of A. and P. Buisine (ANALYST, xxiv., 214), which dealt principally with suint oils, by analyses and remarks on the composition of pyrolignite oils. These are much less regular as regards the percentage of the various constituents. Thus, two samples contained about 23 per cent. of substances distilling below 90° C., and from 60 to 66 per cent. distilling between 90° and 110° C.; while two other samples of different origin contained only 30 to 35 per cent. of the former, and 27 to 35 per cent. of the latter constituents.

The following analyses are given to show the composition of three samples of acetone oil manufactured from gray acetate of lime, which the author found to contain only traces of propionates—a fact which accounts for the almost complete absence of methyl isopropyl-ketone and methyl propyl-ketone in the distillation products. The third sample was washed several times, as is customary in most French factories:

I. Distilling between ° C.	Per Cent.		II. Distilling between ° C.	Per Cent.		III. Distilling between ° C.	Per Cent.	
63– 70	20		18			70– 80	5	70° to 90°, 18 per cent.
70– 75	19	70° to 90° 51 per cent.	17	70° to 90°, 41 per cent.		80– 85	4	
75– 80	15		10			85– 90	9	
80– 85	12		10			90–110	2	
85– 90	5		4			Above 110	80	
90–110	2		2					
Above 110	27		39				100	
	100		100			Insoluble in water ...	70	
Insoluble in water	42					Insoluble in bisulphite ...	76	
Insoluble in bisulphite solution	35		48 33					

The variations in composition of commercial pyrolignite acetones are therefore to be attributed partly to difference in the composition of the calcium acetate and partly to the amount of washing which the acetone has received. According to the author, these oils can only contain traces of methyl propyl-ketone, but may contain up to 50 per cent. of their weight of products distilling below 90° C., and in particular of methyl ethyl-ketone. C. A. M.

On Hazel-nut Oil. **J. Hanus.** (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, ii., 617-622.)—This oil is contained in the hazel-nut (*Coryllus avellana L.*) to the extent of from 50 to 60 per cent. In the following table the constants found by the author are given side by side with those already published by other chemists, for comparison:

	Hanus.	Schädler.	Filsinger.	De Negri and Fabris.	Soltsien.	Schöttler.
I. Natural oil:						
Specific gravity at 15° C. ...	0·9169	0·9243	0·9146	0·917	0·9164	0·916
Saponification number ...	193·7	—	197·1	192·8	191·4	187·0
Iodine number	90·20	—	—	86·3-86·9	83·2	87·0
Hehner number	95·60	—	—	—	—	95·50
Reichert-Meissl number ...	0·99	—	—	—	—	0·99
Acetyl number	3·2	—	—	—	—	—
Glycerin per cent. ...	10·41	—	—	—	—	—
II. Insoluble fatty acids:						
Saponification number ...	200·6	--	—	—	—	—
Iodine number	90·60	—	—	—	—	—
Mean molecular weight ...	279·0	—	—	—	—	—
III. Unsaturated fatty acids:						
Saponification number ...	198·50	—	—	—	—	—
Iodine number	91·30	—	—	—	—	—
Mean molecular weight ...	282·0	—	—	—	—	—
Maumené number	36·2	—	—	—	—	—

The results of the analysis of the oil are as follows: Oleic acid 85 per cent., palmitic and stearic acids 10 per cent., glycerin (calculated from the saponification number) 10·41 per cent., and phytosterin 0·50 per cent. H. H. B. S.

The Examination of Wood-Tar Creosote. L. F. Kebler. (*Amer. Journ. Pharm.*, 1899, lxxi., 409-413.)—The composition of commercial creosote varies with the kind of wood employed for the distillation, and the methods employed for removing the creosote from the distillate. It consists of a mixture of phenoloid compounds, chiefly of several homologous series, and any of the following compounds may be met with: Phenol (boiling-point, 182° C.); paracresol (203° C.); xylol (220° C.); guaiacol (200° C.); cresol (219° C.); homocresol, or dimethyl-guaiacol (230° C.); and cœrulignol, or propyl-guaiacol (241° C.).

Wood-tar creosote was formerly regarded as consisting in the main of guaiacol and cresol, but at the present time the author states that it is difficult to purchase creosote containing more than 20 per cent. of guaiacol; and he regards the high percentage found by some chemists as being probably due to faulty methods of analysis.

The differentiation of different kinds of creosote is uncertain. Hirschsohn (*Pharm. Zeit. Russ.*, 1898, xxxv., 801) has described tests to distinguish beech-wood tar from the tars of birch, fir, and juniper; but, in the author's experience, the tests which will identify the unmixed products are uncertain in the case of mixtures.

Oak-wood creosote is much more caustic than beech-wood creosote, owing to the fact that the former contains a larger amount of monophenols and correspondingly less guaiacol than the latter. The proportion of cresol and its homologues is the same in both.

Pine-wood creosote (*Comptes Rend.*, cxix., 1276) distilling between 200° and 220° C., has been found to contain 40 per cent. of monophenols, 20·3 per cent. of guaiacol, and 37·5 per cent. of cresol and its homologues.

As regards the specific gravity of creosote, the United States Pharmacopœia fixes the lowest limit at 1·070, at 15° C.; while the British Pharmacopœia requires it to be not lower than 1·079, at 15° C. According to the author, the former limit can be readily met by a creosote which does not contain any guaiacol, and in his opinion the American standard should be raised.

The following analyses of six samples from different American makers are given to show that it is possible to judge as to the quality of a creosote by an analytical examination:

	Specific Gravity.	Boiling Point, ° C.	Per Cent. of Substance distilling between the following Temperatures. ° C. corrected.					
			1–200°.	200°–205°.	205°–210°.	210°–215°.	215°–220°.	220°–235°.
1	1·0748	195–224	5	34	26	23	6	3
2	1·0748	195–222	20	20	30	19	7	1
3	1·0650	210–238	0	0	0	30	25	40
4	1·0642	208–238	0	0	2	37	21	36
5	1·049	188–220	18	12	12	39	14	—
6	1·069	200–225	32	18	10	24	9	4

	Colour.	Reaction.	No. of c.c. of 7·5 per cent. NaOH required to dissolve 2 c.c. of Creosote.	Glycerin Water Test.	Twenty c.c. of Alcoholic KOH mixed with 1 c.c. of Creosote.	Guaiacol, Per Cent.	Potassium Guaiacol and Cresol, Per Cent.
1	Nearly colourless	Faintly acid	9	Normal	Crystals in 15 minutes; solid in 40 minutes	None	60
2	Nearly colourless	,,	8	,,	No crystals in 5 hours; solid in 18 hours	None	48
3	Amber	,,	9	Emulsion	Crystals in 4 minutes; solid in 15 minutes	8	60
4	Straw colour	Neutral	7	,,	Solid almost immediately	16	106
5	Nearly colourless	,,	8	,,	Solid on cooling	—	—
6	Nearly colourless	Faintly acid	8	Normal	Solid on cooling	—	—

The author points out that none of the samples complied with the requirements of the United States Pharmacopœia.

For the estimation of the guaiacol, the following process was used: 5 c.c. of the creosote are mixed with 50 c.c. of a 20 per cent. alcoholic solution of potassium hydroxide, and the resulting crystalline compounds of guaiacol and cresol, which deposit in from ten to thirty minutes, are pressed between filter-paper until dry. The mass is then mixed with 5 c.c. of 10 per cent. sulphuric acid, and the mixture heated for a moment until the guaiacol and cresol rise to the surface. Water is then added until the oily layer sinks to the bottom, the aqueous layer decanted off, and 4 c.c. of concentrated ammonium hydroxide added. The guaiacol immediately forms a hard crystalline compound, and after some time a semi-crystalline mass results from the combination of the cresol. On treating the mixed compounds with benzene (benzin), only the ammonium compound of guaiacol remains undissolved, and this can be

separated by decantation or filtration and washed. Finally, the residue is rendered acid with 10 per cent. sulphuric acid, and the guaiacol extracted with benzene, evaporated in a weighed basin, and weighed.

In order to differentiate creosote from coal-tar phenols, one volume of the sample is shaken with a mixture of glycerin and water (3 : 1), and left to separate. The diminution in the volume of creosote indicates approximately the amount of soluble impurities.

The barium hydroxide test for cœrulignol and other high-boiling constituents gave a negative result with each of the six samples.

In the author's opinion, the pharmacopœial requirements of creosote should be based on the following points: Physical appearance, reaction, solubility, specific gravity (not lower than 1·080, at 15° C.), boiling-point (200° to 220° C.), reaction with a 20 per cent. solution of potassium hydroxide in absolute alcohol, and a test for neutral oils. C. A. M.

The Characteristics of the Oil and Terpenes of Aralia Nudicaulis. W. C. Alpers. (*Amer. Journ. Pharm.*, 1899, lxxi., 370-378.)—The rhizomes used by the author contained from 40 to 60 per cent. of water, and after being dried at 100° C., yielded on the average 5·53 per cent. of ash, of which nearly a quarter consisted of chlorides and sulphates of sodium and potassium.

The volatile oil which was obtained from 50 kilos of the fresh roots by distillation with steam, and extraction of the essential oil from the distillate with chloroform, amounted to from 0·04 to 0·12 per cent.

It boiled at 260° to 270° C. under ordinary pressure, whilst the larger proportion of it distilled at 185° to 195° C. under a pressure of 88 mm.

It was found to consist principally of a sesquiterpene, $C_{15}H_{24}$, and an alcohol, $C_{15}H_{25}\cdot OH$(?), with a small quantity of a clear blue oil distilling at about 300° C., probably azulene $C_{16}H_{26}O$ (B.P. 302° C.).

The sesquiterpene had a specific gravity of 0·9086 at 20° C., boiled at 270° C., and had a specific rotation of $[\alpha]_D = -7$ to $-8°$. It formed oily addition-compounds with hydrochloric acid and bromine, and derivatives with nitrous acid.

When dissolved in three parts of glacial acetic acid, and mixed with an equal amount of glacial acetic acid previously saturated with dry hydrochloric acid, it gave a rose colour, which gradually became purple, and subsequently, in about ten minutes, sky-blue. The latter colour was permanent, and the liquid on distillation *in vacuo* yielded a blue liquid at about 140° C.

Other colour-reactions were obtained by dissolving it in chloroform and adding sulphuric acid, which produced a purple-red coloration, and by adding sulphuric acid to its solution in acetic acid which gave a light wine-red colour.

As these reactions and properties distinguish this sesquiterpene from isomeric compounds previously described, the author proposes for it the name *araliene*.

C. A. M.

The Composition of Colophony. R. Henriques. (*Chem. Rev. Fett. u. Harz. Ind.*, 1899, vi., 106-111.)—The work described in this paper was undertaken with the

object of determining whether the ester value of colophony was due to the presence of esters, and if not, what class of compounds were present.

Dark samples of colophony were used in the experiments, since these have a greater ester value than lighter specimens. Cold saponification was employed, as it was found that with hot saponification there was evidently a more deep-seated change.

The saponification value was determined by treating about 2 grammes of the substance with semi-normal alcoholic alkali, shaking for ten minutes until clear, and leaving the solution for about sixteen hours before titrating. Concordant results were obtained in this way, but the author considers that the results (about 3 units higher) obtained by leaving the liquid for forty hours, or by using normal alkali and leaving for 16 hours, may possibly be nearer the truth.

Dieterich concluded that there were no esters in colophony, since he was unable to isolate alcoholic bodies from the products of saponification, but the contrary is asserted by R. Schick (*Zeits. angew. Chem.*, 1899, 28) and others.

The author reasons that, if the ester value be due to the decomposition of esters, a new quantity of acids must result on saponification, so that if after complete saponification the resin acids be liberated, washed, and their acid value determined and calculated on the original amount of substance taken, this second acid value will be greater than the first, provided that there has been a decomposition of esters. Otherwise the two values will be identical or nearly so. In practical experiments they were found to agree within about a unit, and hence the author concluded that there could have been no decomposition of esters.

As considerably higher saponification values were obtained by using normal alkali and leaving the solution for forty hours, it was considered possible that the alkali acted on the acids, producing soluble acids of lower molecular weight. But since in one specimen the acid value was raised by saponification, but not raised in the case of another, the author regarded the question as open.

As it was possible that the constant ester value of colophony might be due to the presence of lactones, attempts were made to isolate such bodies, but they were not found at all, or at most in small amount (1 to 1·5 per cent.), the main constituents being resin acids and unsaponifiable matter (8 to 12 per cent.).

Finally, the conclusion was arrived at that part of the resin acids themselves were probably of a lactonic character, containing both carboxyl groups and anhydride groups, and forming, in addition to the alkali salts obtained by direct titration, higher basic salts on exposure to the action of alkali in excess.

In the author's opinion there is nothing to justify the view of Dieterich that the slow saponification of colophony is due to the presence of acids so weak that they can only combine with alkali gradually and after a long time. As opposed to this view, he points out that the whole of the colophony acids are soluble in a cold aqueous solution of sodium carbonate, and that if colophony be treated with a moderately concentrated cold solution of sodium hydroxide, ether extracts little but unsaponifiable matter from the liquid.

As there is a relationship between oxy-acids and lactone acids, and also a certain degree of proportion between the amount of the ester value and the insolubility of the

acids in petroleum spirit, the author has applied Fahrion's method of estimating oxy-acids to the separation of the lactone acids (ANALYST, xxiii., 275).

Fifty grammes of colophony (saponification value, 189·8; acid value, 158·7) were left overnight in contact with four or five times the volume of petroleum spirit. The supernatant liquid was decanted, and the residue boiled with four successive portions of petroleum spirit, dissolved in a hot solution of sodium hydroxide, cooled and filtered. The filtrate was acidified, and the resin acids filtered off, washed and dried. They were then pulverized, again boiled with petroleum spirit, dissolved in ether, the solution filtered, the solvent evaporated, and the acids dried at 100° C. In two determinations with the same sample of colophony they amounted to 36 and 37·2 per cent. respectively.

The resin acids soluble in petroleum spirit were of a light yellow colour, resembling that of the finer kinds of colophony. Their acid value was 164·4, and their ester value 4·0 to 4·8. By further treatment with petroleum spirit, this ester value was reduced still more.

The insoluble acids were much darker, and on treatment with alkali yielded an intense reddish-brown solution. Their saponification value was about 196, their acid value 151·3 to 151·7, and their second acid value 144·8 to 147·6. Under the influence of hot saponification these values were greatly increased and not concordant, saponification values of 274 and 324, and a second acid value of 317·8, being obtained.

A further proof of the greater decomposition effected by hot saponification was shown by the fact that the recovered acids were no longer completely insoluble in petroleum spirit, and, unlike those from the cold saponification, gave an intense yellow colour on treatment with that solvent.

As additional evidence that the constant ester value of the acids insoluble in petroleum spirit was due to the hydrolysis of the lactone groups, these acids were converted into calcium salts before and after saponification, and the amount of calcium in each determined. This was found to be 7·11 per cent. before and 9·30 per cent. after saponification.

The author has not yet determined the exact point at which this decomposition of the lactone groups is complete.

The well-known Storch's reaction with acetic anhydride and sulphuric acid was given by the insoluble acids as readily as by the soluble acids.

It was found that the light yellow varieties of colophony also contain traces of the lactone acids insoluble in petroleum spirit. In one experiment the author isolated 0·4 per cent. with the same characteristics as that obtained from the darker specimens.

From these experiments the following conclusions were finally arrived at:

1. Colophony does not contain esters.

2. Acid anhydrides are not present in any quantity, but in the main unsaponifiable matter and free resin acids.

3. These acids can be separated by means of petroleum spirit into normal soluble acids and insoluble acids having the character of lactone acids.

4. The soluble acids have only an acid value, whilst the insoluble acids have a high constant ester value in addition to their acid value. C. A. M.

Analysis of Indiarubber Articles. R. Henriques. (*Zeits. angew. Chem.*, 1899, 802.)—The author's processes, which were originally described in the *Chem. Zeit.*, 1892, xvi., 1595; 1893, xvii., 707; 1894, xviii., 411 and 905 (ANALYST, xviii. 13, 227; xix. 111; xxii. 134), have stood the test of time; but, having been altered in certain particulars, are worth recording anew.

(1) *Estimation of total Sulphur and Metals.*—A 6 cm. hemispherical porcelain basin holding 30 c.c. is charged with 10 c.c. of pure strong nitric acid, covered with a watch-glass, and placed on a warm water-bath. 1 gramme of the sample (rasped or cut up) is weighed off, and a fragment dropped into the acid; as soon as red vapours appear, the rest is cautiously added at such speed that the reaction is continuous without becoming stormy—it can be controlled by removing the basin from the water-bath, or by heating it more strongly. When everything is dissolved, the cover-glass is wiped with a few pieces of paper which are dropped into the liquid, the whole is evaporated to a syrup, 20 c.c. more nitric acid are introduced, and the evaporation is repeated till most of the free acid is driven off. The mass is then stirred up with a mixture of 5 parts of sodium carbonate and 3 parts of potassium nitrate, covered with a layer of the same (using about 5 grammes altogether), warming, if necessary, on the water-bath till all carbon dioxide is evolved. The basin is then covered with a similar vessel, concave side down, and heated with great care and very slowly over a minute flame, which is gradually urged till the mass becomes black. The temperature is next raised until the salts fuse, the upper basin being removed towards the end of the operation. If successful, the cover only contains brown products of distillation which are free from sulphur; but if spitting has occurred, some particles may adhere to the upper basin, and must be separately fused with the saline mixture. Finally, the melt is extracted with boiling water and filtered; the solution is acidified and silica and sulphuric acid determined; the insoluble matter is taken up with warm hydrochloric acid to separate silica from the metals, which are then severally estimated as usual. In the case of rubber goods containing cinnabar a separate portion is taken, which, after decomposition with nitric acid, must be treated with water, and in the filtrate the heavy metals must be thrown down with sulphuretted hydrogen.

(2) *Estimation of Rubber Substitutes in Vulcanised Products.*—This process, though tedious, has not been found capable of simplification; it remains as outlined in the *Chem. Zeit.*, 1892, 1625, and 1894, 411 (ANALYST, as cited above). A small improvement consists in removing the partially-dried caoutchouc mass from the filter, drying and weighing it separately, instead of employing a tared paper and weighing rubber and paper together.

(3) *Estimation of Unsaponifiable Oils in Vulcanised Products.*—Mineral oils, rosin oil, and paraffin are to be found in many varieties of rubber goods; especially such as have been worked up a second time. After the mass has been treated with alkali, dried and weighed, the product is rubbed out in a basin and extracted with ether as long as the solvent becomes coloured; the solution is simply poured off, the residue is dried again and weighed, the loss being unsaponifiable oils. Ash and combined sulphur are determined on the product freed from oil.

(4) *Estimation of Rubber Substitutes in Non-vulcanised Products.*—Although suited for the examination of non-vulcanised "patent" rubber plates, the regular process is not available for the treatment of sheets composed of soft rubber and substitutes; the difficulty, however, is only due to physical causes, and the following modification avoids it: 5 grammes of the sample are boiled under an inverted condenser with 25 c.c. of benzene for an hour, and allowed to rest over-night. 25 c.c. of normal alcoholic alkali are added, and the boiling is repeated for four hours. The solvents are removed on the water-bath, and the residue is rinsed into a large basin with hot water. It is extracted with boiling water several times, the alkaline liquor being simply poured away; the rubber that remains is kneaded and boiled till no longer alkaline, and it is finally dried to constant weight at 100° C.

(5) *Estimation of Unsaponifiable Oils in Non-vulcanised Products.*—The ether process described in (3) obviously cannot be employed in the present instance; hot acetone is used similarly. But as the residual rubber is not easily brought into a condition fit for weighing, the extracts are run into a flask and the acetone distilled off; the oils are taken up in ether, filtered into a tared beaker, and themselves dried and weighed.

(6) *Estimation of Carbon Dioxide.*—Chalk, magnesium carbonate, white-lead, and zinc carbonate are common loading materials; but as the respective oxides are sometimes employed in their stead, it is often necessary to determine the carbon dioxide. Vulcanised goods are finely rasped and treated in Geissler's apparatus, charging the reaction-flask with dilute copper sulphate solution in place of water, as sulphides are frequently present. From non-vulcanised goods, the rubber must be partly or wholly removed by boiling with nitrobenzene, and the residue powdered and examined as before.

Henriques remarks that he is unable to obtain uniform satisfactory results with Weber's solvent for indiarubber (nitrobenzene). Non-vulcanised materials, and such as are only lightly vulcanised and loaded, dissolve readily; but neither hard rubber goods, nor soft and heavily-loaded articles, can be completely separated therewith; the liquids yielded by the latter class of wares, moreover, are exceedingly difficult to filter. F. H. L.

INORGANIC ANALYSIS.

Modification of Pierce's Method for the Determination of Arsenic in Ores. J. F. Bennett, junr. (*Journ. Amer. Chem. Soc.*, vol. xxi. [5], pp. 431-435.)—The original method being rendered inaccurate by the solubility of silver arsenate in an excess of acid or alkali and in ammonium nitrate, by the extreme fineness of the precipitate and by the inadequacy of litmus as an indicator, the author proposes the following modification:

One-half gramme of the finely-powdered substance is fused with 3 to 5 grammes of sodium carbonate and potassium nitrate in equal parts, about one-third being used as a cover. On cooling, the mass is extracted with boiling water and filtered. The filtrate, which contains the arsenic as alkali arsenate, is strongly acidified with acetic

acid, then boiled to expel carbon dioxide, and, after cooling, treated with a few drops of alcoholic phenolphthalein and sufficient sodium hydroxide to give an alkaline reaction, the purple-red coloration produced by an excess of alkali being discharged by acetic acid. A slight excess of neutral silver nitrate is then well stirred in, and the whole left to settle, away from direct sunlight; the supernatant liquid is poured off through a filter, and the precipitate washed by decantation with cold water, thrown on the filter and washed thoroughly. The funnel being then filled with water and 20 c.c. of strong nitric acid, this liquid is run through the filter into the original beaker, the residue washed thoroughly with cold water, and the filtrate made up to about 100 c.c. and titrated with standard potassium thiocyanate (Volhard); or the silver is determined by scorifying the filter and precipitate, and cupelling, the first method being adopted when chlorides are present. C. S.

Valuation of Gold Samples. W. Witter. (*Chem. Zeit.*, 1899, xxiii., 522.)—A short time ago Bock stated that the ordinary process of gold cupellation was no longer delicate enough for modern requirements, and he propounded a new method of investigation based partly on electrolysis (*Chem. Zeit.*, 1897, xxi., 973; 1898, xxii., 358). The present article describes experiments carried out at the request of the Hamburg Mint to ascertain how great is the difference between the results of wet analysis and dry assay, whether assay is accurate enough to govern large financial transactions, whether Bock's process is better than cupellation, and whether it is always applicable. Starting with four carefully-analysed samples of gold—an unmelted electrolytic product, commercial electrolytic fine gold, washed gold as sent from Hong-Kong, and gold coinage (900°)—using always the same quality acids, lead, and cupels, and the London Mint system of treating the rolls (Rose, "Metallurgy of Gold," 1896, 445), the author found, as first enunciated by Rose, that the temperature of the muffle is a most important, though often overlooked, factor in obtaining correct figures by cupellation. Employing Heraeus's platinum-rhodium element with a Keiser and Schmidt galvanometer, he deduced the following as the proper working temperatures: Chemically pure gold, 960° C.; less fine gold, 950° to 960° C.; gold containing a very little platinum, 1000° to 1010° C.; 973° malleable gold containing silver and copper, 960° C.; coinage metal (900 parts Au, 100 parts Cu), not exceeding 920° or 930° C.; 720° gold with silver and copper, below 900° C. The detailed figures show also that when an approximately pure gold, such as an electrolytic product, comes to be assayed, the result of the test cannot be checked on absolutely pure metal; because (presumably) of the platinum in the former, which demands a higher temperature. Therefore the temperature of cupellation must be determined; and when a good pyrometer is not at hand, a series of alloys with melting-points rising by 20° or 25° between 850° and 1050° C., should be provided as guides. Analyses of the rolls obtained from the four varieties of metal mentioned above proved them to contain from 99·8576 to 99·8786 per cent. of gold, while the cupels retained 0·0370 to 0·0891 per cent.; the difference between the weights of the rolls and the true gold in them ranged between 0·1226 and 0·1424 per cent.; therefore the proportion of gold volatilised was between 0·0335 and

0·0890 per cent. These results fairly bear out Napier's statement that, according to the composition of the material, the difference between the amount of gold in the sample and in the roll (as determined by analysis) varies between 0·12 and 0·14 per cent. It is thus necessary to watch that the weight of foreign metals in the rolls shall equal the weight of gold volatilised; but that this is practically possible the author's experiments demonstrate. In short, if the temperature be kept at the proper point, the yield of the cupellation process will not differ from the theoretical by more than 0·2 part per 1000.

Now, especially with high-grade samples, a wet analysis cannot safely be conducted by determining directly the amount of gold; for, as Krüss's researches have shown (Liebig's *Annalen*, 1887, ccxxxviii., 67), precipitation of pure gold chloride may lead to errors ranging between −0·4 or −1·4 part to +0·3 part per 1000. Thus, the foreign metals must be estimated, a process which requires at least four weeks, and quantities of 50 or 100 grammes for its successful operation. Very low quality gold cannot be assayed, and analysis becomes necessary; but such specimens are rarely met with at the present time. Gold is usually sold in parcels of 5 to 25 kilos., each of which is tested; therefore the sum in dispute, assuming the two tests to differ by the maximum amount (0·4 part per 1000), is comparatively small; and owing to the greater rapidity of assay, the interest on this sum is less than when a wet analysis is insisted on. On the whole, if properly conducted, cupellation yields quite satisfactory results, and an analysis is seldom of practical value.

In Bock's process the sample of gold is melted with silver in a graphite crucible, the product rolled out, melted again, once more rolled, and then treated as usual with nitric acid of the specific gravities 1·2 and 1·3. The rolls are next electrolysed for ten minutes, washed, etc., and ignited. Bock omitted to specify the exact strength of the current; Witter finds as the maximum to avoid danger of disintegration, 1 ampère (ND_{100}) calculated on the cathode, using 1 part of 1·2 nitric acid and 5 parts of water as the electrolyte. It seems better, however, to allow the current to pass for twenty or thirty minutes at a density of less than 1 ampère (0·05 to 1·0) in order that all silver, and all other metals that are removable, shall be dissolved. Nevertheless, the whole of the silver and other metals cannot always be removed, and it is sometimes necessary to repeat the process; on the contrary, losses may occur in the crucible and by disintegration during boiling or during electrolysis. As the result of a large number of trials, Bock's method appears to give average errors of +0 to +0·2 part per 1000. Bock's process has the advantage of not needing so much previous experience to bring it to a successful issue, and of leaving cupellation available as a check; but it is not suited to all varieties of impure gold. Primarily intended for coinage metal, it can also be employed on any silver and copper alloys that are malleable; brittle alloys, by simple fusion with silver, still remain brittle, and so they cannot be beaten or rolled out ready for the electrolytic treatment. In laboratories where frequent analyses of a uniform malleable quality of gold have to be made, Bock's process is to be recommended; but in places where the samples vary widely, a preliminary dry assay is indispensable, and it depends entirely upon circumstances whether the electrolytic method is applicable to control the results. F. H. L.

Determination of Gold, and its Separation from Platinum and Iridium. L. Vanino and L. Seeman. (*Ber.*, 1899, xxxii., 1968.)—When a solution of gold chloride is mixed with hydrogen peroxide and sodium (or potassium) hydroxide, the metal is completely thrown down in the cold within the space of a few minutes; whereas precipitation with ferrous sulphate or oxalic acid requires several hours. So delicate is the reaction that it will detect 0·03 milligramme of gold in 10 c.c. of a liquid, the other tests beginning to fail between 0·09 and 0·06 milligramme per 10 c.c. A test with ferric chloride, hydrochloric acid, and a fragment of zinc, stated by its author to be capable of detecting 1 part of gold per 1,000,000 (*Pharm. C. H.*, xxvii., 321), is equally sensitive with the present one, giving a reddish coloration in fifteen minutes with 0·03 milligramme per 10 c.c., but failing with half that amount.

For quantitative purposes a dilute solution should be warmed after the metal has fallen, and after warming hydrochloric acid should be added to bring the precipitate into a state fit for easy filtration; the acid, however, must not be introduced before warming. Silver may be estimated similarly.

Platinum and iridium are not precipitated by alkaline hydrogen peroxide in the cold, so that they can be separated from gold by the above process; ruthenium is attacked, and is therefore not amenable to like treatment. F. H. L.

Separation of Iron and Aluminium by Volatilising the Ferric Chloride. F. A. Gooch and F. S. Havens. (*Zeits. anorg. Chem.*, 1899, xxi., 21.)—When ferric oxide is heated to 180° or 200° C. in a stream of dry hydrochloric acid gas, the bulk of the material (about 90 per cent.) is rapidly converted into chloride and volatilises; the residue is almost black, insoluble in water, slightly soluble in cold (aqueous) hydrochloric acid, but fairly soluble in the hot acid, yielding a solution of ferric chloride. This dark substance, presumably an oxychloride, is only attacked by gaseous hydrochloric acid at the above temperature quite slowly, producing finally a whitish residue composed essentially of ferrous chloride, which is scarcely capable of volatilisation at 500° C. This phenomenon of dissociation can be prevented, and complete volatilisation attained, either by first heating the oxide to 450° or 500° C., and then passing a rapid current of hydrochloric acid vapour, or by carrying out the process at 180° or 200° C. in an atmosphere of hydrochloric acid containing a little free chlorine—the latter method is distinctly to be preferred. Mixtures of ferric oxide with alumina (0·1 to 0·2 gramme of each) can thus, as the examples quoted show, be quantitatively separated at 200° by treatment with the two gases for from half-an-hour to one hour. F. H. L.

Volumetric Estimation of Nickel and Zinc in German Silver and Similar Copper Alloys. J. Jedlicka. (*Listy chemické*, 1899, xxiii., 25; through *Chem. Zeit. Rep.*, 1899, 256.)—One gramme of the finely-powdered alloy is dissolved in the minimum of nitric acid, and evaporated on the water-bath with a little sulphuric acid. The residue is diluted, neutralized, freed from iron with sodium succinate, the copper is reduced with sulphurous acid, thrown down with potassium thiocyanate, and the sulphurous acid driven off from the filtrate. The liquid, which

contains the nickel and zinc (it must not contain any ammonium salts), is heated to boiling in a large porcelain basin, mixed with sodium carbonate solution, and oxidized with sodium hypochlorite, keeping the whole faintly alkaline, so that the nickel may be completely thrown down as peroxide. In order to make the precipitate filter easily, only the smallest necessary quantities of the reagents are added; and to prevent it adhering to the vessel, the parts of the basin uncovered by the liquid are cooled with water before introducing the hypochlorite. The precipitate, consisting of nickel peroxide and basic tin carbonate, is boiled and washed by decantation three times, and filtered through asbestos. It and the asbestos are next rinsed into a beaker, and decomposed by stirring and warming to 40° or 50° C. with the needful volume of semi-normal oxalic acid, which is partly oxidized and partly combines with the nickel and zinc. When the last dark-coloured particles of nickel peroxide have disappeared, the carbon dioxide is driven off by boiling, and the solution is titrated with $\frac{N}{2}$ alkali; it is then diluted sufficiently, acidified with sulphuric acid, and titrated with permanganate containing 10 or 15 grammes of the potassium salt per litre. Small amounts of cobalt (0·3 to 0·5 per cent.) cause a trifling error, but the process only occupies two or three hours, and with care gives results within 0·1 or 0·2 per cent. of the truth. F. H. L.

The Volumetric Estimation of Sulphur in Iron by means of Arsenious Acid. J. Thill. (*Zeit. anal. Chem.*, 1899, xxxviii., 342-344.)—This method is based on the liberation of sulphuretted hydrogen and its subsequent absorption by decinormal arsenious acid solution, 1 c.c. of which is equivalent to 0·002556 gramme of hydrogen sulphide, or 0·0024045 gramme of sulphur.

In making an estimation of the sulphur in iron, steel, etc., the usual method of liberating the sulphur as hydrogen sulphide, and absorbing the gas by a reagent, is followed. Care must be taken, however, that the hydrochloric acid used to dissolve the metal is added as slowly as possible. After the requisite quantity of acid has been added, and the contents of the flask have begun to boil, the flame is so regulated that the boiling only just continues. In this way the distillation of too much hydrochloric acid is prevented.

For the absorption, the author prefers the apparatus devised by E. Franke, but states that the well-known apparatus of Weigert and von Reis can also be used, though with the latter it is advisable to place an additional condensation bulb between the generating and absorption flasks. The latter is charged with 25 c.c. of a decinormal solution of arsenious acid and 50 c.c. of a cold-saturated solution of sodium bicarbonate.

When the iron is completely dissolved the current of carbon dioxide is passed through the apparatus until the whole of the sulphur has been precipitated as arsenious sulphide, which takes place in about ten minutes. The liquid is then rendered acid by means of a few c.c. of hydrochloric acid, made up to 500 c.c., shaken and filtered. The residual arsenious acid is titrated in an aliquot part of the filtrate in the usual manner.

The following are some of the results obtained by this method and by the hydrogen peroxide method:

	Hydrogen Peroxide Method. Sulphur, per cent.		Arsenious Acid Method. Sulphur, per cent.

C. A. M.

The Use of Potassium Ferrocyanide for Preparing Standard Ferric Solutions for Volumetric Purposes. K. Schröder. (*Chem. Zeit.*, 1899, xxiii., 533, 540, 557.)—The author finds that potassium ferrocyanide is one of the best substances for preparing an iron solution for volumetric work. It has the advantage over iron filings and wire of being homogeneous, and over solutions (of Mohr's salt, etc.) of being unaffected by changes in temperature. It can be converted into a ferric salt quickly and with little trouble; and the usual destruction or removal of superfluous oxidizing material is avoided. Its purity need only be examined once, determining the proportion of water and that of iron by a gravimetric process; for it keeps indefinitely in brown or black bottles.

From the commercial article a pure product is obtained by rapid recrystallization from a boiling saturated solution, draining the crystals with the pump, drying them for twenty-four hours between paper, then digesting them with absolute alcohol, draining and drying for forty-eight hours as before. For use, 4 or 5 grammes are rinsed into a 500 c.c. flask of Jena glass, with 20 or 25 c.c. of sulphuric acid (specific gravity 1·84); the vessel is placed slantingly on a tripod, and is heated over a bare flame which does not touch the flask, till, after a few agitations, solution is affected. The flame is raised till the carbon monoxide is wholly driven off, then raised further until the liquid boils briskly (using a coil of platinum to prevent bumping). It was found by the author that the iron by this treatment was completely converted into the ferric state, the salt formed being, according to Fownes, ammonium-potassium-iron alum—

$$(NH_4)_2SO_4 + K_2SO_4 + 2Fe_2(SO_4)_3.$$

After thirty minutes it is cooled, 25 c.c. of water are introduced and mixed with the solution; 10 or 15 c.c. of 1.19 hydrochloric acid are next run in, and the whole is boiled for five or ten minutes. The liquid which contains all the iron in the ferric state is ready to be employed as a means of standardizing stannous chloride or (obviously) iodine, if an excess of tin be taken. The titration must not be carried out in flasks with a pronounced yellow tint, or the end-reaction will be difficult of observation. The figures quoted by the author respecting the composition of recrystallized potassium ferrocyanide show a satisfactory agreement with the formula $K_4Fe(CN)_6 + 3H_2O$. F. H. L.

Valuation of Persulphates. G. H. Mondolfo. (*Chem. Zeit.*, 1899, xxiii., 699.)—This process depends on the reaction:

$$M'SO_4 + KI = M'KSO_4 + I.$$

Two or three grammes of the sample are dissolved in 100 c.c. of cold water, 10 c.c. of the liquid are mixed with an excess (0·25 to 0·5 gramme) of potassium

iodide, and warmed for ten minutes to 60° or 80° C. The liberated iodine is titrated with decinormal thiosulphate and starch, 1 c.c. of the reagent corresponding to 0·0114 gramme of NH_4SO_4, or to 0·0135 gramme of KSO_4. F. H. L.

Estimation of Acids from the Volume of Hydrogen they evolve on Treatment with Metals. K. Ulsch. (*Chem. Zeit.*, 1899, xxiii., 624.)—The author has already described (*Zeits. anal. Chem.*, 1891, xxx., 175; 1892, xxxi., 392) a process of determining nitric acid by reducing it to ammonia with nascent hydrogen, and noting the deficit of gas liberated when an excess of iron and a known quantity of sulphuric acid are employed to generate the latter. It has been suggested that occlusion might interfere with the accuracy of the method; further experiments have therefore been instituted which disprove this objection, and show that the process is available for the gas-volumetric estimation of inorganic and many organic acids. To generate the hydrogen, 2·5 grammes of "ferrum pulveratum" and 10 drops of a 5 per cent. solution of platinic chloride are used, but within reasonable limits the exact quantities are immaterial. The volume of gas is read off after a few minutes' shaking, for although a little continues to be evolved for several hours, the reaction is practically completed at once. The strength of the acid may vary within wide limits, but it should not be too weak [apparently it should be about decinormal]. Owing to solubility and the presence of oxygen, the yield of hydrogen is always slightly below the theoretical: 20 c.c. of decinormal sulphuric acid evolve 22·05 c.c. instead of 22·34 c.c. As an example of the accuracy attainable, normal sulphuric acid was prepared by diluting strong acid according to the indications of the above process; 10 c.c. finally neutralized 28·65 c.c. of baryta-water, whereas 10 c.c. of normal acid standardized on sodium carbonate neutralized 28·70 c.c. Hydrochloric acid may be treated similarly, also phosphoric acid, but owing to the formation of ferric phosphate, the latter reaction is slower, and the same portion of iron cannot be used so often. Oxalic, acetic, and succinic acids give correct results; lactic acid (possibly by reason of impurity) comes out too low; tartaric and citric acids present certain difficulties, liberating too much gas. Further details are promised. F. H. L.

Tests for Boric Acid. V. Lenher and J. S. C. Wells. (*Journ. Amer. Chem. Soc.*, vol. xxi. [5], pp. 417-420.)—An improved method of performing the flame-test has been devised by the authors, the apparatus employed being a test-tube containing the substance and reagents, and closed by a cork fitted with a small glass tube drawn out to a fine jet. Heat being applied to the test-tube, and the alcoholic vapour ignited, the flame will show the presence of 0·1 per cent. of boron trioxide, the test thus being ten times as delicate as the ordinary flame-test. Copper and barium salts do not colour this flame.

The authors determined the limits of sensitiveness of the other tests in use, with the following results: Boric ether flame (old method), 1·0 per cent.; glycerin method, 0·1 per cent.; potassium fluoride and acid sulphate, 1·0 per cent turmeric paper, 0·01 per cent. C. S.

Valuation of Hydrogen Peroxide. A. Sonnié-Moret. (*Rép. Pharm.*, 1899, [3], xi., 289; through *Chem. Zeit. Rep.*, 1899, 224.)—Three or four c.c. of the solution are brought into a nitrometer filled with mercury, 1 or 2 c.c. of sodium hydroxide solution are added, and 0·3 or 0·4 gramme of finely powdered manganese dioxide is introduced into the liquid through the mercury by means of a glass tube. The volume of gas is then read off. F. H. L.

The Valuation of Basic Slag (Thomas Meal) on the Basis of its Percentage of Soluble Phosphoric Acid. P. Wagner. (Pamphlet published by Paul Parey, Berlin, 1899.)—So many changes have been made during the past few years in the treatment of Thomas slag, with the object of increasing the solubility of the phosphoric acid, that its composition now differs essentially from that formerly produced. The proportion of easily-decomposable calcium silicate now present is much greater than was formerly the case, with the consequence that the combined action of this and the free lime present is sufficient to so reduce the acidity of the official (German) citrate solution, as to affect its solvent action upon the phosphoric acid of the slag.

The author has carried out a series of experiments with the view of determining the relative manurial values of the slags now on the market, and of so modifying the official method as to adapt it to suit the altered circumstances. He finds that a citrate solution containing 2 per cent. of free citric acid is preferable to the official solution containing only 1·4 per cent. For testing pure slags, a simple aqueous citric acid solution may be used, but the acidified citrate solution has this advantage, that it affords a means of distinguishing between pure slags and those mixed with ground Redonda or Belgian phosphates. Thus, a Belgian phosphate treated with a citrate solution containing 2 per cent. of free citric acid showed a solubility of only 8 per cent., whilst the same phosphate treated with a 2 per cent. aqueous citric acid solution showed a solubility of 30 per cent. The following are abridged directions of the process recommended by the author:

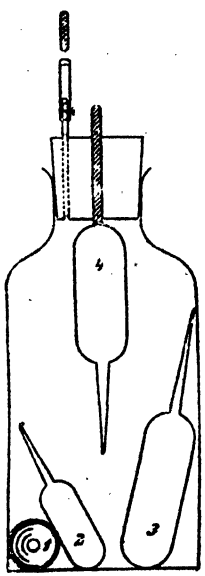
I. Solutions:

1. A 10 per cent. citric acid stock solution containing 5 grammes of salicylic acid per 10 litres.

2. The same diluted to a 2 per cent. strength.

3. Molybdate solution: 150 grammes of ammonium molybdate to be dissolved in 500 c.c. of water, 1 litre of nitric acid of 1·19 specific gravity, and 400 grammes of ammonium nitrate to be added, and the whole diluted with water to 2 litres. The solution to be allowed to stand for twenty-four hours at 35° C., and then filtered.

4. Magnesia mixture: 110 grammes of magnesium chloride and 140 grammes of ammonium chloride to be dissolved in 1,300 c.c. of water, and 700 c.c. of 8 per cent. ammonia added. The solution to be allowed to stand for several days, and then filtered.



5. Citrate-magnesia mixture: 200 grammes of citric acid to be dissolved in a 20 per cent. ammonia solution, and made up to a litre with the same solution. This solution to be then mixed with 1 litre of the magnesia mixture.

II. The determination is carried out as follows: 5 grammes of the Thomas

meal are placed in a half-litre flask containing 5 c.c. of alcohol, and the flask filled to the mark with dilute (2 per cent.) citric acid solution, at a temperature of 17½° C. The flask is then closed with a caoutchouc stopper, and shaken for thirty minutes in a rotating apparatus making thirty to forty revolutions per minute. The liquid is then filtered. Fifty c.c. of the filtrate are placed in a beaker, 80 to 100 c.c. molybdate solution added, the mixture warmed to 60° to 70° C., and allowed to cool. It is then filtered, the precipitate washed with 1 per cent. nitric acid solution, and dissolved in about 100 c.c. of 2 per cent. ammonia. Fifteen c.c. magnesia mixture are then added, the mixture allowed to stand for two hours, the precipitate filtered off, washed with 2 per cent. ammonia solution, dried, ignited, and weighed.

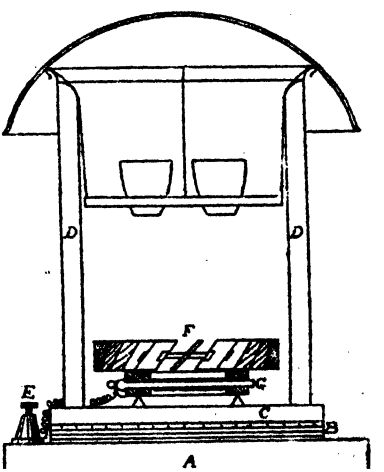
H. H. B. S.

Determination of Oxygen in Water. L. Mutschler. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 481-484.)—By means of the apparatus shown in the accompanying figure, the author adapts Mohr's method, for the determination of oxygen in water in situations where the accommodation of a properly-equipped laboratory is not available. The apparatus consists of a strong bottle of about 1 litre capacity with a wide neck, to which is fitted a double-bored caoutchouc stopper. The tubes 2, 3, and 4 are made of thin glass, so that they can be easily fractured by means of the glass or agate ball 1. They are filled with the reagents and sealed up. The tube 4 is for the sulphuric acid. It is of 15 to 20 c.c. capacity, and is fixed through the central hole in the stopper, as shown in the figure. The tube 2, of 5 to 8 c.c. capacity, is for the soda solution, and the tube 3, of 25 to 30 c.c. capacity, for a known quantity of ferrous ammonium sulphate solution. Through the second hole in the stopper a narrow-bore glass tube is fixed, flush with the under surface of the stopper, and projecting about 2 cm. above the top. On the projecting part is fixed a piece of caoutchouc tubing, which can be closed by means of a small piece of glass rod, thus providing a vent.

The determination is carried out as follows :

The bottle is filled with the water to be tested, the tubes are inserted, the stopper fixed in its place, and the vent-tube closed. The bottle is then carefully shaken so as to fracture and release the contents of the ferrous salt and soda tubes without breaking the sulphuric acid tube. The latter is left intact until after the return to the laboratory, when its contents are similarly discharged. The bottle is then allowed to stand for 10 to 15 minutes until the fluid clears, after which it is washed out with boiled water, and the unoxidized ferrous salt determined by titration.

H. H. B. S.



Action of a Hard Water on Certain Metals. J. L. Howe and J. L. Morrison. (*Journ. Amer. Chem. Soc.*, vol. xxi. [5], pp. 422-425.)—The water examined was found

to corrode brass fittings; it contained per 100,000 parts: Lime, 7·80, magnesia, 4·065, carbon dioxide, 30·196, sulphur trioxide, 0·2127 parts, chlorine a trace. Strips of brass, zinc, copper, iron, lead, and aluminium were immersed in the water during four months, with and without access of air, and duplicate tests were made with distilled water. The results of the subsequent examination of the metal and water lead to the conclusion that waters of the above class, free from chlorine, attack zinc more readily than distilled water does, and dissolve out this metal from brass; they should therefore not be conveyed through zinc-lined iron pipes. The hardness of this water does not prevent it dissolving lead, the action being more than half as great as that of distilled water when protected from the air. When air is excluded, the action on iron is relatively slight, and this water has no influence on aluminium or nickel.

C. S.

APPARATUS.

An Electrically-heated Drying Oven. T. W. Richards. (*Amer. Chem. Jour.*, 1899, xxii., 45.)—The general construction of this oven is shown by the annexed drawing. G is a frame composed of two parallel porcelain clamps, such as are used for securing electric wires, held together by means of glass rods passing through the screw-holes, and with larger glass tubes encircling the rods to act as distance pieces. Round the porcelain sides of the frame is wound a coil of platinum wire to act as the resistance. F is a stationary fan made by cutting radial slits in a circle of sheet tin or platinum, bending the sectors through an angle of 45°; or it may be constructed of mica vanes and a platinum centre, etc. Its object is to force the current of hot air to ascend in a spiral in order to produce a uniform temperature in all parts of the oven; this it does to within 2°. The walls, D, consist of two beakers with their bottoms cut off, the annular space being packed with asbestos, etc. The cover is either a clock-glass, a porcelain basin, or a tile. C is a porcelain tile, B layers of asbestos, A a wooden base. The quantity of wire on the resistance must obviously vary according to circumstances. Richards quotes for a 52-volt current, and prescribes 5 metres of No. 32 B. and S. [about No. 35½ S.W.G. = 0·008 inch, or 0·2 millimetre] platinum wire. This when heated has a resistance of about 25 ohms, requires, therefore, 2 ampères (which can safely be taken from a lighting circuit), and absorbs 100 watts—an amount of energy that is capable of heating an oven large enough for most analytical laboratories. If the current be obtained from 8-volt accumulators, from 5 to 15 ampères should be needed, according to the dimensions of the apparatus; in this case thin platinum foil would make the best resistance. The fixed resistance is adjusted to give the maximum temperature; lower heats are

produced by including other resistances outside, or by increasing the amount of air admitted.

An ordinary 16 candle-power glow-lamp fixed inside a paraffin-lamp chimney, the whole jacketed with a tin can, forms an efficient makeshift which will hold a crucible; it gives a temperature of 120° C. or 130° C. F. H. L.

The Incandescent Electric Lamp as a Source of Heat in Ether Extraction. C. G. Hopkins. (*Journ. Amer. Chem. Soc.*, vol. xxi. [8], pp. 645-647.)—For heating a battery of twenty Soxhlet apparatus, the author employs five ordinary 110-volt thirty-two candle-power lamps placed in an air-bath of galvanized iron, 36 × 3 × 6 inches, lagged with asbestos to prevent radiation, the removable cover being perforated by twenty 2-inch holes in two rows. The lamps are set 7 inches apart, under the centres of the squares formed by every four holes, thus equalizing the heat, which is sufficient to distil about 60 drops per minute in each apparatus. The usual temperature of the bath does not exceed 75° C., but since, when all the holes are covered, the heat may attain the ignition point of ether, it is advisable, for absolute security in case of breakage of any of the flasks, to immerse the lamp-bulbs in water. The economy of these lamps is high, about 96 per cent. of the electrical energy being converted into heat. C. S.

REVIEW.

A Treatise on Practical Chemistry and Qualitative Analysis. By Frank Clowes, D.Sc., Emeritus Professor in the University College, Nottingham; Chemical Adviser to the London County Council, etc. Seventh edition. London: Churchill, 1899.

This work, which has now reached its seventh edition, is so well known to students and teachers of chemistry, that any special review of it is almost unnecessary, and criticism is disarmed. It has, in fact, become a standard work, and may be regarded as one of the leading English text-books of Qualitative Analysis.

It has perhaps ever been a vexed question whether detailed directions to the student are on the whole better than a brief outline of the tests to be made by him, but the unqualified success of Dr. Clowes's work may be taken as a strong argument in favour of the former view; and always provided that the student can be induced to read, there can be no doubt that a conscientious study of this manual will insure a sound knowledge of the subject, while the time of the teacher will be largely saved.

The tables of differences constitute a very special feature, and in this and the later editions there is scarcely any branch of the subject which has not been more or less fully handled, notably many organic substances of importance, and the reactions of the rare metals.

There is perhaps only one regrettable omission—that of the theoretical explanations of analytical processes; these I venture to think might still find a place in a new edition. Dr. Clowes is not unconscious of this omission, and alludes to it in his preface. H. W. H.

THE ANALYST.

DECEMBER, 1899.

THE SALE OF FOOD AND DRUGS ACT OF 1899.

[62 & 63 Vic., Ch. 51.]

ARRANGEMENT OF SECTIONS.

Section

1. Precautions against importation of agricultural and other produce insufficiently marked.
2. Power for Local Government Board or Board of Agriculture to sample articles of food.
3. Power for Local Government Board or Board of Agriculture to act in default of local authority.
4. Power for Board of Agriculture to make regulations as to analysis of milk, cream, butter, or cheese.
5. Extension of Margarine Act, 1887, to margarine-cheese.
6. Marking of margarine and margarine-cheese.
7. Provisions as to manufacturers of and dealers in margarine and margarine-cheese.
8. Restriction on amount of butter fat in margarine.
9. Provision as to name and address of person selling milk or cream in a public place.
10. Division of samples taken in course of delivery or transit.
11. Provisions as to condensed, separated, or skimmed milk.
12. Notice of mixtures.
13. Amendment of 38 & 39 Vic. c. 63, as to samples.
14. Taking samples in course of delivery.
15. Amendment of 38 & 39 Vic. c. 63, as to registered parcels.
16. Obstruction of officer in discharge of his duties.
17. Penalties for offences under the Sale of Food and Drugs Acts.
18. Articles sold in tins or packets.
19. Time for proceeding and regulation as to summons.
20. Provisions as to use of warranty or invoice as defence, and proceedings against the warrantor.
21. Duty of court to send articles for analysis.
22. Provisions as to certificates of analysis.
23. Transfer of powers from Secretary for Scotland to Local Government Board.
24. Application to Ireland.

Section
25. Interpretation of terms.
26. Definition of "food."
27. Repeal of enactments in schedule.
28. Short title and commencement.
Schedule.

CHAPTER 51.

AN ACT TO AMEND THE LAW RELATING TO THE SALE OF FOOD AND DRUGS.
[August 9, 1899.]

BE it enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:

1.—If there is imported into the United Kingdom any of the following articles, namely:

(*a*) Margarine or margarine-cheese, except in packages conspicuously marked "Margarine" or "Margarine-cheese," as the case may require; or

(*b*) Adulterated or impoverished butter (other than margarine), or adulterated or impoverished milk or cream, except in packages or cans conspicuously marked with a name or description indicating that the butter or milk or cream has been so treated; or

(*c*) Condensed separated or skimmed milk, except in tins or other receptacles which bear a label whereon the words "Machine-skimmed Milk" or "Skimmed Milk," as the case may require, are printed in large and legible type; or

(*d*) Any adulterated or impoverished article of food to which Her Majesty may by Order in Council direct that this section shall be applied, unless the same be imported in packages or receptacles conspicuously marked with a name or description indicating that the article has been so treated;

the importer shall be liable, on summary conviction, for the first offence to a fine not exceeding twenty pounds, for the second offence to a fine not exceeding fifty pounds, and for any subsequent offence to a fine not exceeding one hundred pounds.

(2) The word "importer" shall include any person who, whether as owner, consignor, or consignee, agent, or broker, is in possession of, or in anywise entitled to the custody or control of, the article; prosecutions for offences under this section shall be undertaken by the Commissioners of Customs; and subject to the provisions of this Act this section shall have effect as if it were part of the Customs Consolidation Act, 1876.

(3) The Commissioners of Customs shall, in accordance with directions given by the Treasury after consultation with the Board of Agriculture, take such samples of consignments of imported articles of food as may be necessary for the enforcement of the foregoing provisions of this section.

(4) Where the Commissioners of Customs take a sample of any consignment in pursuance of such directions, they shall divide it into not less than three parts, and

send one part to the importer and one part to the principal chemist of the Government laboratories, and retain one part.

(5) In any proceeding under this section the certificate of the principal chemist of the result of the analysis shall be sufficient evidence of the facts therein stated, unless the defendant require that the person who made the analysis be called as a witness.

(6) If, in any case, the Commissioners of Customs are of opinion that an offence against this section has been committed, they shall communicate to the Board of Agriculture for their information the name of the importer and such other facts as they possess or may obtain as to the destination of the consignment.

(7) For the purposes of this section an article of food shall be deemed to be adulterated or impoverished if it has been mixed with any other substance, or if any part of it has been abstracted so as in either case to affect injuriously its quality, substance, or nature.

Provided that an article of food shall not be deemed to be adulterated by reason only of the addition of any preservative or colouring matter of such a nature and in such quantity as not to render the article injurious to health.

2.—(1) The Local Government Board may, in relation to any matter appearing to that Board to affect the general interest of the consumer, and the Board of Agriculture may, in relation to any matter appearing to that Board to affect the general interests of agriculture in the United Kingdom, direct an officer of the Board to procure for analysis samples of any article of food, and thereupon the officer shall have all the powers of procuring samples conferred by the Sale of Food and Drugs Acts, and those Acts shall apply as if the officer were an officer authorized to procure samples under the Sale of Food and Drugs Act, 1875, except that—

(*a*) The officer procuring the sample shall divide the same into four parts, and shall deal with three of such parts in the manner directed by section fourteen of the Sale of Food and Drugs Act, 1875, as amended by this Act, and shall send the fourth part to the Board, and

(*b*) The fee for analysis shall be payable to the analyst by the local authority of the place where the sample is procured.

(2) The Board shall communicate the result of the analysis of any such sample to the local authority, and thereupon there shall be the like duty and power on the part of the local authority to cause proceedings to be taken as if the local authority had caused the analysis to be made.

3.—(1) It shall be the duty of every local authority entrusted with the execution of the laws relating to the sale of food and drugs to appoint a public analyst, and put in force from time to time, as occasion may arise, the powers with which they are invested, so as to provide proper securities for the sale of food and drugs in a pure and genuine condition, and in particular to direct their officers to take samples for analysis.

(2) If the Local Government Board or Board of Agriculture, after communication with a local authority, are of opinion that the local authority have failed to execute or enforce any of the provisions of the Sale of Food and Drugs Acts in relation to any article of food, and that their failure affects the general interest of the consumer or

the general interests of agriculture in the United Kingdom, as the case may be, the Board concerned may, by order, empower an officer of the Board to execute and enforce those provisions, or to procure the execution and enforcement thereof in relation to any article of food mentioned in the order.

(3) The expenses incurred by the Board or their officer under any such order shall be treated as expenses incurred by the local authority in the execution of the said Acts, and shall be paid by the local authority to the Board on demand, and in default the Board may recover the amount of the expenses with costs from the local authority.

(4) For the purposes of this section an order of the Board shall be conclusive in respect of any default, amount of expenses, or other matter therein stated or appearing.

(5) Any public analyst appointed under the Sale of Food and Drugs Acts shall furnish such proof of competency as may from time to time be required by regulation framed by the Local Government Board.

4.—(1) The Board of Agriculture may, after such inquiry as they deem necessary, make regulations for determining what deficiency in any of the normal constituents of genuine milk, cream, butter, or cheese, or what addition of extraneous matter or proportion of water, in any sample of milk (including condensed milk), cream, butter, or cheese, shall for the purposes of the Sale of Food and Drugs Acts raise a presumption, until the contrary is proved, that the milk, cream, butter, or cheese is not genuine or is injurious to health, and an analyst shall have regard to such regulations in certifying the result of an analysis under those Acts.

(2) Any regulations made under this section shall be notified in the London and Edinburgh Gazettes, and shall also be made known in such other manner as the Board of Agriculture may direct.

5.—The provisions of the Margarine Act, 1887, as amended by this Act, shall extend to margarine-cheese, and shall apply accordingly, with the substitution of "margarine-cheese" and "cheese" for "margarine" and "butter," and provided that all margarine-cheese sold or dealt in otherwise than by retail shall either be inclosed in packages marked in accordance with the Margarine Act, 1887, as amended by this Act, or be itself conspicuously branded with the words "margarine-cheese."

6.—(1) Where under this Act or the Margarine Act, 1887, it is required that any package containing margarine or margarine-cheese shall be branded or marked, the brand or mark shall be on the package itself, and not solely on a label, ticket, or other thing attached thereto.

(2) The letters required to be printed on the paper wrapper in which margarine or margarine-cheese is sold shall be capital block letters not less than half an inch long and distinctly legible, and no other printed matter shall appear on the wrapper.

(3) The words "or with" in section six of the Margarine Act, 1887, shall be repealed.

7.—(1) Every occupier of a manufactory of margarine or margarine-cheese, and every wholesale dealer in such substances, shall keep a register showing the quantity and destination of each consignment of such substances sent out from his manufactory or place of business, and this register shall be open to the inspection of any officer of the Board of Agriculture.

(2) Any officer of the Board of Agriculture shall have power to enter at all reasonable times any manufactory of margarine or margarine-cheese, and to inspect any process of manufacture therein, and to take samples for analysis.

(3) If any such occupier or dealer—

(*a*) Fails to keep such a register, or

(*b*) Refuses to produce the register when required to do so by an officer of the Board of Agriculture, or

(*c*) Fails to keep the register posted up to date, or

(*d*) Wilfully makes any entry in the register which is false in any particular, or

(*e*) Fraudulently omits to enter any particular which ought to be entered in the register,

he shall be liable on summary conviction for the first offence to a fine not exceeding ten pounds, and for any subsequent offence to a fine not exceeding fifty pounds.

(4) The provisions of section nine of the Margarine Act, 1887, relating to registration of manufactories shall extend to any premises wherein the business of a wholesale dealer in margarine or margarine-cheese is carried on.

(5) The registration of a manufactory or other premises shall be forthwith notified by the local authority to the Board of Agriculture.

8. It shall be unlawful to manufacture, sell, expose for sale, or import any margarine the fat of which contains more than ten per cent. of butter fat, and every person who manufactures, sells, exposes for sale, or imports any margarine which contains more than that percentage shall be guilty of an offence under the Margarine Act, 1887; and any defence which would be a defence under section seven of that Act shall be a defence under this section, and the provisions of the former section shall apply accordingly.

Provided that nothing in this section shall apply to any margarine manufactured or imported in fulfilment of any contract made before the twentieth day of July one thousand eight hundred and ninety-nine.

9. Every person who, himself or by his servant, in any highway or place of public resort sells milk or cream from a vehicle or from a can or other receptacle shall have conspicuously inscribed on the vehicle or receptacle his name and address, and in default shall be liable on summary conviction to a fine not exceeding two pounds.

10. In the case of a sample taken of milk in course of delivery, or of margarine or margarine-cheese forwarded by a public conveyance, the person taking the sample shall forward by registered parcel or otherwise a portion of the sample marked, and sealed, or fastened up, to the consignor if his name and address appear on the can or package containing the article sampled.

11. Every tin or other receptacle containing condensed, separated, or skimmed milk must bear a label clearly visible to the purchaser on which the words "Machine-skimmed Milk," or "Skimmed Milk," as the case may require, are printed in large and legible type; and if any person sells or exposes or offers for sale condensed, separated, or skimmed milk in contravention of this section, he shall be liable on summary conviction to a fine not exceeding ten pounds.

12. The label referred to section eight of the Sale of Food and Drugs Act, 1875,

shall not be deemed to be distinctly and legibly written or printed within the meaning of that section unless it is so written or printed that the notice of mixture given by the label is not obscured by other matter on the label: Provided that nothing in this enactment shall hinder or affect the use of any registered trade mark, or of any label which has been continuously in use for at least seven years before the commencement of this Act; but the Comptroller-General of Patents, Designs, and Trade Marks shall not register any trade mark purporting to describe a mixture unless it complies with the requirements of this enactment.

13. In section fourteen of the Sale of Food and Drugs Act, 1875, the words "offer to" and the words "proceed accordingly and shall" shall be repealed.

14. The provisions of section three and section four of the Sale of Food and Drugs Act Amendment Act, 1879 (relating to the taking of samples of milk in course of delivery), shall apply to every other article of food: Provided that no samples shall be taken under this section except upon the request or with the consent of the purchaser or consignee.

15. In section sixteen of the Sale of Food and Drugs Act, 1875, the words "registered parcel" shall be substituted for the words "registered letter."

16. Any person who wilfully obstructs or impedes any inspector or other officer in the course of his duties under the Sale of Food and Drugs Acts, or by any gratuity, bribe, promise, or other inducement prevents, or attempts to prevent, the due execution by such inspector or officer of his duty under those Acts, shall be liable, on summary conviction, for the first offence to a fine not exceeding twenty pounds, for the second offence to a fine not exceeding fifty pounds, and for any subsequent offence to a fine not exceeding one hundred pounds.

17.—(1) Where, under any provision of the Sale of Food and Drugs Act, 1875, a person guilty of an offence is liable to a fine which may extend to twenty pounds as a maximum, he shall be liable for a second offence under the same provision to a fine not exceeding fifty pounds, and for any subsequent offence to a fine not exceeding one hundred pounds.

(2) Where, under any provision of the Sale of Food and Drugs Acts, a person guilty of an offence is liable to a fine exceeding fifty pounds, and the offence, in the opinion of the court, was committed by the personal act, default, or culpable negligence of the person accused, that person shall be liable (if the court is of opinion that a fine will not meet the circumstances of the case) to imprisonment, with or without hard labour, for a period not exceeding three months.

18. Notwithstanding anything in section seventeen of the Sale of Food and Drugs Act, 1875, where any article of food or drug is exposed for sale in an unopened tin or packet duly labelled, no person shall be required to sell it except in the unopened tin or packet in which it is contained.

19.—(1) When any article of food or drug has been purchased from any person for test purposes, any prosecution under the Sale of Food and Drugs Acts in respect of the Sale thereof, notwithstanding anything contained in section twenty of the Sale of Food and Drugs Act, 1875, shall not be instituted after the expiration of twenty-eight days from the time of the purchase.

(2) In any prosecution under the Sale of Food and Drugs Acts the summons

shall state particulars of the offence or offences alleged, and also the name of the prosecutor, and shall not be made returnable in less time than fourteen days from the day on which it is served, and there must be served therewith a copy of any analyst's certificate obtained on behalf of the prosecutor.

20.—(1) A warranty or invoice shall not be available as a defence to any proceeding under the Sale of Food and Drugs Acts unless the defendant has, within seven days after service of the summons, sent to the purchaser a copy of such warranty or invoice with a written notice stating that he intends to rely on the warranty or invoice, and specifying the name and address of the person from whom he received it, and has also sent a like notice of his intention to such person.

(2) The person by whom such warranty or invoice is alleged to have been given shall be entitled to appear at the hearing and to give evidence, and the court may, if it thinks fit, adjourn the hearing to enable him to do so.

(3) A warranty or invoice given by a person resident outside the United Kingdom shall not be available as a defence to any proceeding under the Sale of Food and Drugs Acts, unless the defendant proves that he had taken reasonable steps to ascertain and did in fact believe in the accuracy of the statement contained in the warranty or invoice.

(4) Where the defendant is a servant of the person who purchased the article under a warranty or invoice he shall, subject to the provisions of this section, be entitled to rely on section twenty-five of the Sale of Food and Drugs Act, 1875, and section seven of the Margarine Act, 1887, in the same way as his employer or master would have been entitled to do if he had been the defendant, provided that the servant further proves that he had no reason to believe that the article was otherwise than that demanded by the prosecutor.

(5) Where the defendant in a prosecution under the Sale of Food and Drugs Acts has been discharged under the provisions of section twenty-five of the Sale of Food and Drugs Act, 1875, as amended by this Act, any proceedings under the Sale of Food and Drugs Acts for giving the warranty relied on by the defendant in such prosecution, may be taken as well before a court having jurisdiction in the place where the article of food or drug to which the warranty relates was purchased for analysis as before a court having jurisdiction in the place where the warranty was given.

(6) Every person who, in respect of an article of food or drug sold by him as principal or agent, gives to the purchaser a false warranty in writing, shall be liable, on summary conviction, for the first offence to a fine not exceeding twenty pounds, for the second offence to a fine not exceeding fifty pounds, and for any subsequent offence to a fine not exceeding one hundred pounds, unless he proves to the satisfaction of the court that when he gave the warranty he had reason to believe that the statements or descriptions contained therein were true.

21. The justices or court referred to in section twenty-two of the Sale of Food and Drugs Act, 1875, shall on the request of either party under that section cause an article of food or drug to be sent to the Commissioners of Inland Revenue for analysis, and may, if they think fit, do so without any such request.

22.—(1) At the hearing of the information in any proceeding under the Sale of

Food and Drugs Acts, the production by the defendant of a certificate of analysis by a public analyst in the form prescribed in section eighteen of the Sale of Food and Drugs Act, 1875, shall be sufficient evidence of the facts therein stated, unless the prosecutor requires that the analyst be called as a witness.

(2) A copy of every such certificate shall be sent to the prosecutor at least three clear days before the return day, and if it be not so sent the court may, if it thinks fit, adjourn the hearing on such terms as may seem proper.

23. This Act shall apply to Scotland with the substitution for "the Local Government Board" of "the Local Government Board for Scotland," and all powers and duties vested in or imposed on the Secretary for Scotland in relation to the Sale of Food and Drugs Acts shall be transferred to, vested in, or imposed on the Local Government Board for Scotland.

24. This Act shall apply to Ireland with the substitution for "the Board of Agriculture" of "the Department of Agriculture and Technical Instruction for Ireland," and for "the Local Government Board" of "the Local Government Board for Ireland," and for "the London and Edinburgh Gazettes" of "the Dublin Gazette."

25. In this Act, unless the context otherwise requires—

The expression "margarine-cheese" means any substance, whether compound or otherwise, which is prepared in imitation of cheese, and which contains fat not derived from milk:

The expression "cheese" means the substance usually known as cheese, containing no fat derived otherwise than from milk:

The expression "local authority" means any local authority authorized to appoint an analyst for the purposes of the Sale of Food and Drugs Acts, and the expression "public analyst" means an analyst so appointed:

Other expressions have the same meaning as in the Sale of Food and Drugs Acts, and an offence under this Act shall be treated as an offence under those Acts.

26. For the purposes of the Sale of Food and Drugs Acts the expression "food" shall include every article used for food or drink by man, other than drugs or water, and any article which ordinarily enters into or is used in the composition or preparation of human food; and shall also include flavouring matters and condiments.

27. The enactments in the schedule to this Act are hereby repealed to the extent mentioned in the third column of that schedule.

28.—(1) This Act may be cited as the Sale of Food and Drugs Act, 1899, and the Sale of Food and Drugs Act, 1875, and the Sale of Food and Drugs Act Amendment Act, 1879, and the Margarine Act, 1887, and this Act may be cited collectively as the Sale of Food and Drugs Acts, 1875 to 1899, and are in this Act referred to as the Sale of Food and Drugs Acts.

(2) This Act shall come into operation on the first day of January one thousand nine hundred.

SCHEDULE.

ENACTMENTS REPEALED.

Session and Chapter.	Short Title.	Extent of Repeal.
38 & 39 Vic., c. 63.	The Sale of Food and Drugs Act, 1875.	In section two, the definition of the term "food." In section fourteen, the words "offer to," and the words "proceed accordingly and shall." Section fifteen. In section twenty-seven, the words from "Every person who shall give a false warranty in writing" to "a penalty not exceeding twenty pounds."
42 & 43 Vic., c. 30.	The Sale of Food and Drugs Act Amendment Act, 1879.	Section ten.
50 & 51 Vic., c. 29.	The Margarine Act, 1887.	In section six, the words "or with" and the words "not less than a quarter of an inch square."
54 & 55 Vic., c. 46.	The Post-Office Act, 1891.	Section eleven.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, November 1, in the Chemical Society's Rooms, Burlington House, the President (Mr. W. W. Fisher, M.A.) occupying the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of the following candidates were read for the second time: E. C. P. Barber, Chemist to the Anglo-Chilian Nitrate Railway Company, Toco, Chili; Frederick Davis, 51, Imperial Buildings, Ludgate Circus, London; William Francis, Chief Analyst to the Condensed Milk Company, of Ireland, Limerick; Alfred Lucas, Analytical Chemist, Public Works Department (Geological Survey Branch), Cairo; Edward Russell, B.Sc. (Lond.), F.I.C., Demonstrator of State Medicine, King's College, London; and F. L. Slocum, Ph.D., Pittsburgh, Pa., U.S.A. And in favour of the following candidates for the first time: John Alfred Foster, A.I.C., Assistant Chemist, Her Majesty's Dockyard, Portsmouth; J. B. P. Harrison, A.I.C., Assistant Analyst to the Aylesbury Dairy Company, London; and D. Lloyd Howard, of Messrs. Howard and Sons, Stratford.

Messrs. T. W. Glass, B.Sc., H. D. Hewitt, D. L. Thomas, and S. A. Woodhead, B.Sc., were elected members of the Society.

The PRESIDENT, referring to the subject of Food and Drugs legislation, said

that since the Society's last meeting the Sale of Food and Drugs Act, 1899, had received the Royal Assent, and would come into operation on January 1 next. It was satisfactory to note that the representations which the Society had made through its officers to the Government while the Bill was being considered had been favourably received, and for the most part adopted in the Act, which showed a considerable improvement when compared with the Bill as first proposed. With regard to the clause which empowered the Board of Agriculture to direct officers to take samples under certain circumstances, there had arisen, from the manner in which the clause was worded in the Bill, an uneasy feeling that it might be interpreted as an attempt to centralize the work of analysis. The Society, however, had been assured by the President of the Board of Agriculture that there was no such intention, and it had been made perfectly clear that such samples would be submitted to the public analyst for the district in which they were taken, and treated as part of his ordinary local work. The central idea which the Society had expressed in regard to any further legislation—viz., that something in the nature of a standing departmental committee of reference should be established—was not given effect to in the form in which it was suggested, but a nucleus had been established by the new Act, and it remained to be seen in the future how far it would be developed and made useful. The wording of the section relating to the proportion of butter-fat to be permitted in margarine has been modified in accordance with a suggestion made by the Council, and a proposal which the draft Bill contained, involving an alteration of the form of certificate, had been abandoned, the form of certificate remaining as it was. The provision that any legal proceedings must be taken within twenty-eight days of the time of purchase would probably not inflict any great hardship on public analysts, given a reasonable amount of consideration on the part of those whose duty it was to purchase and submit samples. Various new articles had been brought within the Act, and one of the most useful alterations was the amendment of the definition of the word "food," the necessity for which had been impressed strongly upon the Government. Altogether, a distinct amount of progress had resulted from the recommendations which the Council had laid before the Government. It might also be mentioned that a committee had been recently appointed by the Local Government Board to inquire into the use of preservatives and colouring matters in food, and had invited the Society's evidence on the subject, in the collection of which members had been asked to assist the Council by recording the results of their experience in a schedule which had been issued to them for the purpose.

A paper was read by Dr. J. Lewkowitsch on "The Meaning of the Acetyl Value in Fat Analysis."

THE MEANING OF THE ACETYL VALUE IN FAT ANALYSIS.

By J. Lewkowitsch, Ph.D.

(*Read at the Meeting, November* 1, 1899.)

The following lines are a continuation of a paper on "The Acetyl Value" which I read before the Society of Chemical Industry (1897, 503). Since that time the processes described have been very extensively used in my laboratory, and their accuracy has been confirmed, not only by different workers in my own laboratory, but also by other chemists. It may, however, be useful to add some explanatory directions.

The preparation of the acetyl product should be done as described previously. A number of experiments have shown that it is quite sufficient to wash the product three times. Prolonged washing beyond the stated limit causes slight dissociation of the acetyl product; of course, this would lead to too low acetyl values. It should be noted that dissociation of the neutral acetyl product takes place in course of time, and the splitting off of the acetyl group may be likened to the natural hydrolysis of the fats and oils. The outward sign of such hydrolysis having taken place is the more or less strong smell of acetic acid which the substance gives off on slight warming. On washing with water the latter acquires a distinct acid reaction. A measure of the amount of hydrolysis will be found in Column VIII. of Table No. I.

The weight of the acetylated product required for the determination of the acetyl value should preferably be increased to about 5 grammes, as for this quantity 1 c.c. of $\frac{N}{10}$ KOH corresponds with about one unit in acetyl value.

The distilled water used in determining the value by either the distillation or filtration process should be carefully freed from CO_2 by previous boiling, as otherwise serious errors may be made. Even the water used for generating steam in the distillation process should be brought to violent ebullition before the steam is passed into the distilling flask. This source of error may easily creep in in the case of very hard water. Check experiments with pure acetic acid will readily guide the operator, if necessary. In order to facilitate the separation of the insoluble fatty acids in the filtration process, it will be found useful to add a slight excess of mineral acid. Of course, this amount must be measured accurately and deducted from the alkali required for determining the dissolved acids.

A glance at the following tables will show that the two processes yield concordant results, especially in the case of those oils which contain but small amounts of volatile fatty acid.* Those fats and oils, however, which are characterized by a large proportion of fatty acids standing on the border line between easily soluble and insoluble fatty acids — such as cocoanut and palm-nut oils — are more conveniently examined by the distillation process; for in this case the fatty acids have a better chance of being well agitated with hot water. It is also necessary to collect at least 600 to 700 c.c. of the distillate (or filtrate, as the case may be) in

* Compare also my paper on the "Theory of Saponification," *Proc. Chem. Soc.*, 1899, 190.

order to obtain the total amount of volatile acids; but even at best it is a somewhat tedious operation to drive off all the fatty acids of cocoanut and palm-nut oils.

I now give in table No. I. a number of determinations made with various fats and oils. In Column V. are registered the acetyl values, as obtained by examining the acetylated products by the two processes described in my first paper. These values I have termed "Apparent Acetyl Values." Owing to the presence of volatile fatty acids, notably in the case of croton oil, palm-nut oil, cocoanut oil, and butter-fat, the apparent acetyl values would be found too high; it is therefore necessary, in order to arrive at the true acetyl value, to determine the amount of volatile fatty acids in the fat or oil before acetylation, and to deduct their amount from the apparent acetyl value. The former values are given in Column II., under the heading, "Total Volatile Fatty Acids per gramme, in terms of mgrms. KOH." They have been determined mostly by the distillation process, in some cases by the filtration process as well, in order to check the results. It is obvious in the case of the four last-mentioned fats that these values cannot be neglected. But even in the remaining cases they are not always negligible, and they even vary for one and the same fat, showing as they do the state of freshness of the samples (compare below). Taking cotton-seed oil as an instance, sample No. I., representing an indifferently refined oil, contains a notable amount of volatile fatty acids when compared with sample VII., the volatile fatty acids of which are almost negligible. (In passing, I may remark how erroneous it would be to draw conclusions from one sample of an oil only.) The difference between the apparent acetyl value and the total volatile fatty acids is given in Column VI., under the heading "True Acetyl Value." I have explained in my first paper (*Jour. Soc. Chem. Ind.* 1897, 504) why the difference of the saponification values of the original and the acetylated fats and oils should not be taken as the true acetyl value; and the same stricture might apply to the differences registered in Column VI. However, as the total volatile fatty acids in the case of castor oil are nil, and in all other cases, with the exception of the last four oils, very small, and, again, as in the last cases the acetyl values are not very high, no appreciable error is being committed.

As regards the difference of saponification values registered in Column VII. in the case of castor oil, which consists almost exclusively of glycerides of hydroxyacids, the incommensurability of the values of the original and acetylated oil becomes very pronounced, and therefore it is no longer permissible to look in this case to the difference as a guide. Yet in almost all other cases enumerated in the following tables this difference may be used as an approximate check of the determination of the acetyl value—in fact, on comparing the values in Columns VI. and VII., the agreement will be found satisfactory, with the exception, of course, of castor oil, as has been explained above. The agreement is satisfactory because the fats examined contained only small quantities of free fatty acids, which give rise to the formation of anhydrides (*cf.* "Proceedings Chemical Society," 1890; 71, 92), and therefore might have interfered with the reliability of the check. In natural fats which have not reached a very advanced state of decomposition (or hydrolysis)—and here we are only concerned with such—the amount of free fatty acids is as a rule small. Hence this question need not be pursued any further.

The acetyl value has been classed as a constant; one would therefore expect the *true* acetyl value to be constant. The table reveals the fact that this is not always the case, the deviations being much greater than the experimental error would warrant. Before discussing the question whether the acetyl value is a constant, or must be regarded as a variable, like the acid value of fats and oils, it will be advisable to inquire as to the substances, or classes of substances, which the acetyl value measures.

From the fact that castor oil, known to consist mostly of glycerides of hydroxylated fatty acids—hydroxyoleic or ricinoleic acid—possesses the highest acetyl value, viz., about 150, whilst the pure triglyceride of ricinoleic acid has the theoretical acetyl value of 159·1, it would appear that the acetyl value is a measure of hydroxylated fatty acids; indeed, originally the acetyl value was proposed to measure them, and has hitherto been regarded a measure thereof.

Alcohols in a fat or oil would, of course, also show an acetyl value; in this case the value is identical with the saponification value of the acetates. The amount of cholesterol and phytosterol in a fat or fatty oil rarely exceeds 1 per cent., hence the presence of these will hardly affect the acetyl value. In fact, as an easy calculation will show, the influence they exercise on the value will be found to be within the limits of the experimental errors of the method. This will be different in the case of waxes, which contain notable amounts of free alcohols.

In order to arrive at definite figures, I have determined the acetyl values of a number of waxes (see Table No. II.).

TABLE No. II.

Wool-wax alcohols ...	0·0	2·2	142·8–143·8		141·2	143·8	140·3	143·3

Speaking broadly, we find the same general outlines as in Table No. I. Whilst it is certain that in the case of carnauba wax, beeswax, and wool wax, the true acetyl values indicate the presence of free alcohols, further research must show whether the same can be said of the other waxes enumerated in the table. The last column shows that also in the case of waxes the difference of the saponification values of the original

and the acetylated substances may be taken as a rough check of the correctness of the direct determination of the true acetyl value, with the exception of carnauba wax, which, on account of the high proportion of free alcohols it is known to contain, affords a very good analogy to castor oil.

The blown oils give high acetyl values, and it therefore appeared desirable to examine them as well. Table No. III. gives the results of the examination of a number of blown oils prepared both on a commercial scale and in the laboratory; to these are added some boiled oils, as also blown oleic acid. Column IV. gives the apparent acetyl values; by deducting from them the amount of volatile fatty acids in the original oils, stated in Column II., we obtain the true acetyl values, registered in Column VII. It has been widely assumed that the blown oils and also boiled oils contain hydroxyacids. Some years ago Fahrion proposed a method for their quantitative determination, based on the insolubility of these acids in petroleum ether. I have, however, shown* that this method is valueless in the case of castor oil fatty acids, and mixtures thereof with non-hydroxylated fatty acids; I have therefore proposed for these insoluble acids the term "oxidized acids" pending further inquiry into their nature. The acetyl values given in Column VIII., Table No. III., further substantiate my objections; for if we were to assume for these hypothetical hydroxyacids the molecular weight of 300—which is, in fact, the molecular weight of hydroxystearic acid, $C_{18}H_{35}(OH)O_2$—it would be possible to calculate their amount. The calculation has been carried out by multiplying the true acetyl values by 0·55. The result is tabulated in Column IX. At the same time, the oxidized fatty acids have been determined quantitatively by Fahrion's method. They are set down in Column IV. With the exception of the commercial blown oils, these numbers greatly deviate from those given in Column IX., although they run parallel to them, as one would naturally expect. It is also remarkable that the difference of the saponification values (given in Column X.), which we have hitherto been able to use as a check, no longer performs the same duty.

In order to gain some further insight into this question, I have examined the oxidized fatty acids of solid oxidized linseed oil, carefully freed from fatty acids soluble in petroleum spirit. The acetyl value of these acids was found to be 130, which on multiplication by 0·55 gives 71·6 per cent. of oxidized acids, whereas theory would postulate 100 per cent. These oxidized acids possessed the acid value 168, and the saponification value 199. We must therefore assume the presence of lactonic substances, a measure of their amount being furnished by the difference 199–168 = 31.

It might be thought for a moment that the acetyl test would permit a distinction to be made between hydroxylated acids and lactones; but it must not be forgotten that true lactones cannot, according to our present views, assimilate acetic acid. Indeed, Geitel† has shown that stearo-lactone does not react with acetyl chloride.

In the case of commercial blown oils, the true acetyl value approximately agrees with the proportion of oxidized acids; hence we may safely conclude that the acetyl value is a measure of the oxidized acids.

But in all the other cases given in Table No. III. we find that the calculated oxidized acids (compare Column IX.) are very much higher than those found direct. What, then, are the substances which lead to the high acetyl values? Are they hydroxylated acids, which are soluble in petroleum spirit, in contradistinction to

* "Chemical Analysis of Oils, Fats, Waxes," etc., Edit. I., p. 157; Edit. II., p. 204.
† *Jour. Prakt. Chemie*, 1888 [37], 84.

the oxidized acids? We can hardly assume that they are polymerized fatty acids, such as we can obtain from castor oil; for we know that polymerization tends to reduce the capacity for assimilating acetyl groups. It is impossible in the present state of our knowledge to pronounce a definite opinion. One naturally looks round for analogies. Thus, pyromeconic acid, to which the somewhat doubtful formula,

$$\begin{matrix} CH\cdot O\cdot CO \\ \dot{C}H\cdot CO\cdot \dot{C}H_2 \end{matrix}$$

is ascribed, yields on boiling with acetyl chloride, acetylpyromeconic acid of the formula $C_5H_3(C_2H_3O)O_3$.

I may further point out that I have shown some years ago* that the mixed fatty acids from sawarri fat yielded an acetyl value of 14, whereas the fat itself has the acetyl value 6·6 (compare Table I.). I was able to show that these fatty acids contain lactonic substances. But as the *fatty acids* were experimented upon, the evidence is not quite conclusive, for reasons given below. Finally, I may state that I found in the crystals obtained by the action of concentrated sulphuric acid on oleic acid, and subsequent dilution with water, a neutral substance whose saponification value on boiling with alcoholic potash agreed fairly well with the number stearo-lactone would demand. Yet with acetic anhydride it yielded a product having an acetyl value and saponification value fairly corresponding with the numbers required for hydroxystearic acid. I am investigating all these points, and in the meantime, without committing myself to any definite opinion, propose to describe them as "unknown acids." Their presence is indicated by the acetyl values set out in Table No. III.

Further research will also be required to determine the oxidized acids in the presence of true hydroxylated acids and "unknown acids." An investigation with this object in view is being carried on. The separation of hydroxylated acids from the oxidized acids is possible by means of the different solubilities of their salts.

So far, then, it appears that an acetyl value indicates the presence of the following classes of substances:

(*a*) Hydroxyacids.
(*b*) Free alcohols.
(*c*) Oxidized fatty acids.
(*d*) "Unknown acids."

If fats contain mono- and di-glycerides, the presence of these would cause the fat to exhibit an acetyl value. And if the moisture of the atmosphere is capable of hydrolysing triglycerides, then it is not only possible, but, indeed, very likely that natural fats and oils which are not perfectly fresh will contain mono- and di-glycerides. I have shown in another paper,† in agreement with Geitel's researches, that mono- and di-glycerides do occur in partially hydrolysed triglycerides. Here it would only be necessary to examine the question whether fats and oils that have undergone *natural* hydrolysis exhibit notable acetyl values due to this cause. The

numbers given in Table I. supply an answer to some extent. Besides, I have examined several highly decomposed fats and oils containing a considerable proportion of free fatty acids. The latter were removed in the usual way, and the remaining neutral fats examined. They were expected to contain lower glycerides. The results are set out in Table No. IV.

TABLE No. IV.

Neutral Fat of Oil prepared from:	I.	II.	Acetylated Product. III.	IV.

(*b*) Insoluble in alcohol	195·9	94·62	5·4	203·8	7·4
	196·3	94·34			

The samples of maize oil given in Table No. I. have a very much lower acetyl value than the neutral oil prepared from the rancid maize oil, and both the acetyl value and saponification value of the acetylated oil seem to speak in favour of the presence of lower glycerides. Two samples of cocoanut oil, containing 3·9 per cent. and 13·25 per cent. free fatty acids, calculated as oleic acid, respectively, were also freed from the fatty acids, and the neutral oils, presumably containing lower glycerides, were treated with alcohol, in the hope of resolving them into two fractions which might show differences in saponification and Hehner values, as mono- and di-glycerides, being more readily soluble in alcohol than triglycerides, would pass into the alcoholic solution to a greater extent. The results given in the table do not speak against the presence of lower glycerides. Since, however, the triglycerides of the lower fatty acids occurring in cocoanut oil are also to some extent soluble in alcohol, too much weight must not be attached to the cocoanut oil experiment. No

such complication arises in the case of palm oil. Three samples of palm oil, containing 31·3 per cent., 23·8 per cent., and 9·67 per cent. respectively, were treated in a similar fashion. I give the results in Table No. IV. These certainly point to the presence of lower glycerides. Unfortunately, there was not enough of the portions soluble in alcohol left to determine the acetyl values.

A more complete series of experiments will be taken in hand shortly.

The presence of mono- and di-glycerides in natural fats would thus appear to deprive the acetyl value of its rank as a constant. The uncertainty caused thereby can be eliminated by saponifying the fats and determining the acetyl value of the fatty acids. One would naturally conclude that if the acetyl value of the original fat was due to mono- and di-glycerides, the fatty acids would have a considerably lower acetyl value; if not, the acetyl value of the fatty acids should be approximately the same as that of the original fats.

I have therefore determined the acetyl values of some mixed fatty acids prepared from fats whose acetyl values were known. The results can be gathered from Table No. I. In the following table, No. V., I place side by side the acetyl values of the fats and their mixed fatty acids:

TABLE No. V.

			Acetyl Value of		
			Fat or Oil.	Insoluble Fatty Acids.	Difference.
			I.	II.	I.-II.
1.	Cotton-seed oil...	I.	15·8	17·9	−2·1
2.	,, ,, ...	II.	11·7	14·1	−2·4
3.	,, ,, ...	III.	18·0	21·5	−3·5
4.	Tallow ...		4·55	3·3	+1·25
5.	Palm-nut oil ...	I.	9·7	13·4	−3·7
6.	,, ,, ...	II.	7·1	8·0	−0·9
7.		III.	8·36	2·19	+6·17
8.	Cocoanut oil ...	I.	6·9	5·6	+1·3
9.		II.	5·5	0·7	+4·8
10.		III.	7·91	−2·97	+10·88
11.		IV.	9·45	−0·9	+10·35
12.	Butter-fat ...	I.	5·8	0·0	+5·8
13.	,, ...	II.	8·55	16·7	−8·15
14.	Sawarri-fat ...		6·61	14·03	−7·42

At first sight it appears that they prove nothing, for Nos. 7, 9, 10, 11 and 12 would seem to speak in favour of the presence of lower glycerides in the original fat, whilst in Nos. 3, 5, 13, and 14 we notice a considerable increase in the case of the fatty acids. Finally, Nos. 1, 2, 4, 6, 8 would not prove anything, for the difference falls within the limit of experimental error. To explain the apparently capricious results, one appears to be driven to the assumption that in Nos. 7, 9, 10, 11, 12 the original oils and fats contained lower glycerides, whereas in the cases of Nos. 2, 3, 5, 13, 14 the fatty acids have become oxidized in the process of preparation, thus leading to acetyl values, as explained above.

It will be remembered that this very contingency was one of the reasons which induced me to determine the acetyl values in the fats and oils themselves in preference to the fatty acids.

If there is any truth in the above-made assumption, and if we further adopt the view supported by the best evidence that rancidity is due to the oxidation of the fatty acids, setting in subsequently to the natural hydrolysis of triglycerides by the moisture of the atmosphere, it does not appear improbable that the acetyl number might furnish a measure of the rancidity. The latter must not be considered as coterminous with acidity, for whilst the acidity is only a measure of the hydrolysis of the triglycerides, the acetyl value would not only indicate the dissociation of the triglycerides, but, over and above that, the amount of oxidation which has caused the fats to exhibit those properties which we comprise under the term "rancidity."

In order to put this reasoning to the test, a number of fats should be examined both in the fresh state and after exposure to the atmosphere. Only such fats and oils can be chosen as can be considered practically pure triglycerides, *i.e.*, such as have been freed from vegetable and animal tissue—in short, of organic substances the contact with which causes triglycerides to undergo a rapid decomposition, marked by the occurrence of a high proportion of fatty acids. Therefore, such vegetable oils as commercial palm oil, or unrefined seed oils, or olive oil expressed from the fermented pulp, would not be suitable for our purpose, inasmuch as the presence of putrescible or fermentable matter, or ferments themselves (lipases) induces hydrolysis. Nor would unrefined animal fats lend themselves to such an investigation; nor even butter, which contains legitimately organic non-fatty substances, whereas butter-fat would be more appropriate.

Hitherto I have been able to examine a few fats only. After they had been tested in the fresh state, they were exposed for some little time to the atmosphere. The numbers thus obtained are collated in Table No. VI. The differences given in

Column XV. show that the exposed or rancid fats possess higher acetyl numbers than the fats in the fresh state. In the case of cacao butter and curcas oil, at least, the increase in the acetyl value cannot be attributed to the presence of lower glycerides. Yet the number of experiments made is too small to be conclusive evidence in favour of the opinion that the acetyl value might be a better indication of rancidity than the doubtful colour reactions proposed recently. There is all the more reason to consider this an open question, as the results of the examination of the palm-nut and cocoanut oils made at different periods (*cf.* Table No. I.) are somewhat conflicting.

The view that rancid fats contain hydroxyacids has frequently been put forward, and was apparently supported by the high acetyl values given by several chemists for rancid tallow, butter-fat, etc. Since, however, those acetyl values referred to the fatty acids, and, moreover, as they were determined by a method which I have shown to lead to very unreliable results, they cannot be quoted as favouring my opinion. Recently, Gripper* has determined the acetyl values of a number of old rape oils by my method, but the results do not show any regularity, a fact which can only be explained by the assumption that hydrolysis as well as rancidity have each and severally contributed their quota to make up the acetyl value obtained. I expect that examination of a larger number of fats and oils concurrently with that of their mixed fatty acids will throw some light on this subject.

We have thus seen that to the four classes of substances enumerated above, under *a*, *b*, *c*, *d*, we must add :—(*e*) mono- and di-glycerides, (*f*) rancid fats. In the case of most rancid fats it will be difficult to discriminate between classes *e* and *f*, more elaborate methods of analysis being required than we possess at present. Should they be found, then we shall be in a position to discriminate by analytical methods between acid and rancid fats, and dispense with organoleptic methods.

It will be clear that a value which is a measure of so many different classes of substances, as the acetyl value is, cannot be considered a constant, but must be rather looked upon as a variable until we are in a position to differentiate by analytical methods between hydroxyacids, oxidized, and "unknown acids," and to allocate to each of these substances the respective quota which in their totality build up the acetyl value.

Experiments have been taken in hand to elucidate these points ; at present we must, unfortunately, resign ourselves to pronounce a *non liquet*.

The experiments detailed in the paper have been carried out by my assistants, Messrs. E. J. Read and C. D. Robertshaw. I wish to acknowledge here my indebtedness to them, and especially to Mr. Robertshaw, who has also prepared lantern-slides of the tables given.

Discussion.

The President having invited discussion,

Mr. Hehner said that the author's work in differentiating between the various reasons which caused a fatty body to have an acetyl number was very important. The total acetyl value, measuring as it did the hydroxyl, whether it be the hydroxyl

* *Journal Soc. Chem. Ind.*, 1899, p. 342.

in an alcohol or in an acid, was in his opinion but rarely of such value from a practical point of view as to repay the trouble of determining it, castor oil and blown oils being the most noteworthy exceptions. But from the differentiation of the various hydroxyl groups useful information would probably result. Some of the author's figures seemed to indicate that not only the unsaturated acids in a fat might spontaneously oxidize, but that oxidation might also take place in the saturated acids, since a fat, like cocoanut oil, for instance, which contained very little oleic acid had a moderately high acetyl value. It seemed to him a matter of great importance to ascertain if possible whether the unsaturated oil acids, of the constitution of which we were almost entirely ignorant, contained doubly, or perhaps trebly, linked carbon atoms. The difference in the properties of highly unsaturated oils might possibly be explained by different linking, such as he has suggested. Dr. Lewkowitsch had plainly shown that the so-called oxy-acids of Fahrion consisted of at least two classes of substances, one of which consisted clearly of hydroxylated bodies, whilst the others were not hydroxylated.

Mr. ARCHBUTT said that he had compared the acetyl values respectively determined by the original method of Benedikt and by Dr. Lewkowitsch's process, but without finding the labour involved by the latter (owing to the necessity of having to separately estimate and deduct the potash required to neutralize soluble fatty acids) commensurate, from a practical point of view, with the information obtained, and he had not become convinced that the original process did not answer all practical purposes in the technical analysis of oils for the detection of adulteration. In castor oil the acetyl values obtained by both methods were practically identical, but in samples of blown East India rape oil, blown Ravison oil, and blown cotton-seed oil, considerably higher figures were obtained by the new method (unless the soluble fatty acids were allowed for), as shown by the following figures:

Description of Oil.	Acetyl Value of the Insoluble Fatty Acids by Benedikt's Process.	Acetyl Value of the Glycerides by Lewkowitsch's Method, without allowing for the Soluble Fatty Acids present.
Castor oil	149·5	150·2
Castor oil (another sample)	150·8	150·7
Blown East India rape oil	56·8	80·9
Blown Ravison oil	53·7	79·7
Blown cotton-seed oil	69·6	98·3

If the anhydrides formed in Benedikt's process were not hydrolysed again on boiling with water, one would expect the results to be variable, but practically constant results were obtained by Benedikt's process on the blown oils referred to. Therefore, if it were required to use the acetyl value for differentiating between castor oil and blown oils, or for detecting adulteration of the former with the latter, a practically useful result would be obtained more easily by Benedikt's process. In washing the acetylated glycerides obtained from blown oils, there was a considerable tendency to emulsification on boiling with water, whereas there was not the slightest difficulty in boiling and thoroughly washing out the excess of acetic acid from the acetylated fatty

acids. From a scientific point of view the new process was no doubt the more perfect one, but from the purely practical point of view of the analyst it seemed that the original process supplied all that was needed.

Dr. LEWKOWITSCH, in reply, said he thought he might claim that his investigation was not wanting from the practical point of view. In processes connected with the resolution of partly converted fatty acids and fats—such as the products of sulphuric acid saponification—or in the case of castor oil and turkey-red oils, the acetyl value would be found to be of material assistance, and in fact sometimes the only means of unravelling the mysteries in which such matters were often enshrouded. He agreed that it was not at present possible to differentiate between the different classes of substances indicated by the acetyl value, but it was first of all necessary to ascertain what the acetyl actually indicated. Continental literature stated it to indicate the presence of hydroxylated fatty acids or oxy-acids, but acetyl values would be obtained in fats like cocoanut oil, and considerable confusion resulted from such values being reported as indicating the presence of hydroxylated fatty acids. With regard to the "unknown" acids, what he meant and understood was shown in Column IX. of Table III. Multiplying the true acetyl values by 0·55, values were obtained which were higher than the so-called oxidized fatty acids. The question might be asked, Were not such substances merely hydroxylated fatty acids, which were soluble in petroleum spirit? If they were, the matter was finished, but there was no evidence to support this. In what particular way the oxygen was combined he did not think it was possible at present to say. If in a true hydroxylated acid the hydroxyl group were split off, forming water with the hydrogen of the COOH group, there would result a true lactone which should not absorb acetic acid. Stearolactone had been isolated, and was stated not to react, but he had found another substance to which the same formula seemed to apply, but which gave high acetyl values. As a kind of analogy he had mentioned pyromeconic acid, which did not contain a hydroxyl group, but which yielded a well-defined acetylated product. There was a difference between the saturated and the unsaturated fatty acids as regards oxidation —between, for instance, stearic acid and oleic acid. In the case of stearic acid, hydroxylated acids were not obtained by blowing. In the case of oleic acid, the so-called oxidized fatty acids, insoluble in petroleum spirit, were practically very small in quantity, while those calculated from Column VIII. were much higher. The difference unquestionably pointed to the formation of some other bodies which were able to absorb acetic acid, and these, whatever they were, had been termed provisionally "unknown" acids. Most of the so-called acetyl values that were being passed into literature were merely values due to the oxidation or rancidity of the fats, having no quantitative meaning whatever as regards the original fats. In reply to Mr. Archbutt, he had been able to prove substantially that in Benedikt's process the fatty acids were really converted into their anhydrides when boiled with acetic anhydride, and that such anhydrides were not completely hydrolysed by boiling with water. In the case of blown rape oil, the so-called oxidized fatty acids did agree with those calculated from the acetyl value, which led to the conclusion that this class of substances was, amongst other things, indicated by the acetyl value.

FOODS AND DRUGS ANALYSIS.

Assay of Preparations containing Pilocarpine. H. A. D. Jowett. (*The Wellcome Chemical Research Laboratories Report*, No. 6, 1899, 1-7.)—The mixture of amorphous bases obtained from jaborandi or its preparations by any of the usual methods is dissolved in a small quantity of a saturated alcoholic solution of pilocarpine nitrate, the solution slightly acidified by means of a strong alcoholic solution of nitric acid (freshly prepared), and, after the addition of a crystal of pilocarpine nitrate, left for two hours to crystallize. The crystals are filtered off, washed with the saturated solution of pilocarpine nitrate with the aid of a filter-pump, dried and weighed.

In most cases the author states that the crystalline deposit may be assumed to be pilocarpine nitrate, but in very accurate estimations the melting-point and specific rotation of the substance should be determined.

Assuming that pilocarpine is the only impurity, and that Petit and Polonowsky's constants for the nitrate of that base are correct, the percentage of pilocarpine may be calculated from the specific rotation of the mixed nitrates by the formula

$$p = \frac{100}{43{\cdot}7}(x - 38{\cdot}5),$$

in which p represents the required percentage, and x the specific rotation of the mixture.

If the melting-point exceed 174° C., the substance may be regarded as pure pilocarpine nitrate; and if between 167° and 174° C., as containing from 80 to 90 per cent. of that salt. If the melting-point is lower than 167° C., the substance should be recrystallized from a small quantity of hot absolute alcohol, and the deposit weighed and examined as above.

The author shows that pure pilocarpine nitrate obtained from the small-leaved variety of jaborandi (*Maranham jaborandi*) has the same physical characters as that obtained from the true jaborandi, viz., melting-point, 178° C.; $[\alpha]_D + 82{\cdot}9°$; and solubility in water, 1 in 6·4 at 20° C.

A specimen of pure pilocarpine hydrochloride prepared in the usual way from the nitrate, and purified by repeated crystallization, melted at 204°–205° C., and had a specific rotation of $[\alpha]_D = +91{\cdot}74°$.

In examining these salts for medicinal purposes, the following characteristics and tests are recommended as indicating a sufficient degree of purity:

Pilocarpine Nitrate.—White distinct crystals, unaltered on exposure to the air. Soluble in 6 to 7 parts of water at ordinary temperatures in 146 parts of cold 95 per cent. alcohol, fairly soluble in boiling alcohol, nearly insoluble in ether or chloroform. Melting-point, 176° to 178° C. Specific rotation in aqueous solution, +81° to 83°. No residue on ignition. Gives no precipitate on adding to its concentrated aqueous solution ammonium hydroxide, or a solution of sodium or potassium hydroxide. Gives the characteristic tests for nitrates.

Pilocarpine Hydrochloride.—White crystals, which deliquesce in moist air. Soluble in less than its weight of water, and in 10 parts of absolute alcohol; almost insoluble in ether or chloroform. After being dried at 100° C., it melts at 200° to 204° C. Specific rotation in aqueous solution, +90° to 92°. No residue on ignition. On adding ammonium hydroxide to its concentrated aqueous solution there is no precipitate, while potassium or sodium hydroxide only precipitates a few oily drops, which soon redissolve, and it gives the tests for chlorides. C. A. M.

ORGANIC ANALYSIS.

Chlorine Compounds in Cotton Oil, and its Behaviour with the Phloroglucinol and Vanillin Test. P. N. Raikow. (*Chem. Zeit.*, 1899, xxiii., 769, 802.)—The fact that cotton oil gives a red colour with the author's phloroglucinol and vanillin test (ANALYST, 1898, xxiii., 244) has hitherto been explained, in accordance with Dupont's definite assertions, by the statement that the material contains an organic compound of sulphur. After examining four samples of cotton oil, however, obtained from Merck of Darmstadt, from Kahlbaum of Berlin, and commercially from France, Raikow finds that it is absolutely free from sulphur, and that the red colour is due to an ingredient containing chlorine. If a little cotton oil is burnt in the tubular torch already described (*loc. cit.*), and the flame is brought inside a beaker charged with a few drops of potassium hydroxide solution, which is held horizontally and slowly rotated so that its internal surface is wetted all over, the liquid will finally give the reactions of hydrochloric acid, but not those of sulphuric acid. Similarly, a repetition of Dupont's experiments (extraction of the oil with steam) has yielded distillates quite free from sulphuric acid. The chlorine compound in the original cotton oil is perfectly insoluble in water and alcohol, is not affected by treatment with steam at 100° C., but is slightly volatile in highly superheated steam; whether it can be entirely removed from the oil in this manner remains to be seen. Of the oils which give no colour with phloroglucinol and vanillin (*ut sup.*), olive and walnut contain neither sulphur nor chlorine; of those which do give a red colour, colza and rape contain sulphur but no chlorine.

According to Benedikt. the presence of chlorine in fats is due to carelessness in carrying out a bleaching process, but Kilgore has stated that American cotton oil is bleached without the use of halogen. The chlorine must therefore be a natural constituent, and if it exists in every variety of cotton oil, a characteristic test for the material is thus given. Either the phloroglucinol-vanillin reaction or the test with potassium hydroxide may be employed to seek for the halogen; but if only a little cotton oil be present in the sample under examination, it is necessary to burn several c.c. In such cases the flame is best held under a funnel, which is connected with a set of bulbs containing the alkali, and thence with a pump, a blank experiment being conducted at the same time to insure purity of the potash and absence of hydrochloric acid vapours in the laboratory atmosphere. Combustion of 1 c.c. of an olive oil mixed with 6 per cent. of cotton oil is sufficient to yield an indication of chlorine; if the former contains only 1 per cent. of the adulterant, 5 c.c. must be burnt.

As the whole of the chlorine or bromine in an organic body is converted by

ignition into hydrochloric or hydrobromic acid, the percentage of halogen in any combustible organic substance may be determined by operating in this manner.

F. H. L.

[No reference is made to Charabot and March's recent investigation (ANALYST, 1899, xxiv., 247), in which the existence in cotton oil of Dupont's volatile sulphur compound was corroborated, and in which also the analogous sulphur compound in olive oil discovered by Dupont and Charabot was again mentioned.—ABS.]

THE GOVERNMENT LABORATORY AND MINERAL MATTER IN TEA.

(*From the "Derby and Chesterfield Reporter," April* 28, 1899.)

CHARGE OF SELLING ADULTERATED TEA.

AT the Derby County Police Court on Friday morning, before Mr. S. Leeke (in the chair), Mr. W. Mallalieu, and Mr. E. S. Milnes, William Henry Woodward and Edgar Woodward, grocers, of Draycott, were summoned for selling 4 ounces of caper tea which was adulterated with at least 6 per cent. of ferruginous sand and small stones at Draycott on January 23. Mr. R. S. Clifford appeared to prosecute, and Mr. Bendle Moore conducted the case on behalf of the defendants.—Mr. Clifford said the formal portion of the evidence had been taken on February 24, and Mr. Moore then made an application that the third sample should be sent to Somerset House for analysis. The Somerset House analysis completely bore out the analysis of Mr. White, the County Analyst, viz., that there was 6 per cent. of mineral matter in the tea.—. . . Mr. E. Lewin, Superintendent Analyst at Somerset House, said . . . he did not agree with Dr. Bell's statement in his book on the subject of adulteration. *A point that could not be lost sight of in this case was the fact that the tea had passed the Custom House Inspector.* Mr. Lewin went on to explain the method of dealing with tea at the Custom House, adding that such particular attention was paid to that article by the inspectors and tea-tasters that it really was not worth the time of the Public Analyst to trouble about it at all. *The tea would have been deemed by the Custom House Inspectors to be commercial tea. He believed the inspectors after analysis would have deliberately passed the tea as fit for home consumption.* So long as tea passed the Customs he did not think the Public Analyst had much to do with it.—Cross-examined by Mr. Moore: Mr. Lewin said that the amount of silica and sand in the tea was either natural to the tea itself, or became mixed in the course of preparation. *The analyst at the Custom House had passed tea containing more mineral matter than was present in this case.*—After a legal argument as to the bearing of certain other cases upon this one the Bench retired. They returned after an absence of half an hour, and the Chairman said that the Bench were of opinion that the amount of extraneous matter which had been proved to have existed in the caper tea was, upon the evidence, unavoidably mixed in the process of collection, and therefore there would be no conviction.*

The following correspondence has passed between the Hon. Secretaries and the Principal of the Government Laboratory and the Secretary to the Customs:

[Copy.]

June 13, 1899.

DEAR DR. THORPE,

We are instructed by the Council of the Society of Public Analysts to call your attention to the statement made by Mr. Lewin in the course of his evidence in a case of alleged tea adulteration at Derby, to the effect that the analyst at the Customs House would pass as genuine tea containing even more mineral matter than the sample in question, which, according

* The fact that Mr. White found practically the same amount of total ash in the tea that Mr. Lewin did (13·6 per cent.) is not recorded in the above extract.—EDITOR.

to Mr. Lewin, gave 13·6 per cent. of total ash. As this allowance for extraneous matter is, as far as our knowledge goes, larger and more liberal than any hitherto sanctioned, we shall esteem it a favour if you will inform us what limit for total mineral matter, or for extraneous matter beyond the natural ash of tea, is authorised and adopted by the authorities of Her Majesty's Customs.

We herewith enclose a copy of the certificate of Messrs. Lewin and Davis, and a newspaper report of the proceedings.

We are, yours faithfully,
(Signed) E. J. BEVAN, A. C. CHAPMAN. } Hon. Secretaries.

Dr. T. E. THORPE, F.R.S.

GOVERNMENT LABORATORY, *June* 20, 1899.

DEAR SIRS,

I beg to acknowledge the receipt of your letter of the 13th inst.

As you are doubtless aware, the chemical examination of the tea imported into the United Kingdom is, by direction of Clause 30 of the 36 and 39 Vict., undertaken by persons appointed by the Commissioners of Customs, subject to the approval of the Treasury. I have not been called upon by the Commissioners to fix the limits for total mineral matter, or for extraneous mineral matter beyond the natural ash of tea, which determine when a sample of tea shall not be allowed to pass into consumption in this country.

I must, therefore, refer your Council to the Comissioners of Customs for information as to the limits which are adopted and authorized presumably by the Treasury.

Yours very truly,
(Signed) T. E. THORPE.

E. J. BEVAN, ESQ., A. C. CHAPMAN, ESQ., } Hon. Secretaries.

LONDON, *June* 28, 1899.

SIR,

We are instructed by the Council of the Society of Public Analysts to call your attention to a statement made in a recent case of alleged tea adulteration at Derby by Mr. Lewin of the Government Laboratory, to the effect that the Customs officials were in the habit of passing as genuine tea containing more than 13·6 per cent. of ash.

We shall esteem it a favour if you will kindly inform us if this statement is correct, and what is the limit adopted.

The matter is one of considerable importance to Public Analysts. We herewith enclose a newspaper report of the proceedings.

We are, your obedient servants,
(Signed) E. J. BEVAN, A. C. CHAPMAN, } Hon. Secretaries.

RICHARD T. PROWSE, ESQ., C.B.

CUSTOMS HOUSE, LONDON, *June* 30, 1899.

GENTLEMEN,

I have to acknowledge the receipt of your letter, dated the 28th inst., relative to the inspection of imported tea by officers of this Department, and to say that the subject shall have early attention, and a reply be sent to you in due course.

I am, Gentlemen, your obedient servant,
(Signed) R. T. PROWSE.

THE HON. SECRETARIES,
Society of Public Analysts.

CUSTOMS HOUSE, LONDON, *July* 5, 1899.

GENTLEMEN,

I am directed by the Board of Customs to acquaint you, with further reference to your

letter of the 28th ult., that they are informed by their official analyst for tea that the records for the past two and a half years have been carefully searched, with the result that no instance can be traced in which tea which has proved on analysis to contain as much as 13·6 per cent. of ash has been allowed to pass into consumption.

I am, Gentlemen, your obedient servant,

The Hon. Secretaries, (Signed) R. T. Prowse.
Society of Public Analysts.

July 19, 1899.

Sir,

We beg to thank you for your letter of the 5th inst.

We should feel still further obliged if you would kindly let us know, for the information of the Society, the limits for total mineral matter in teas adopted in the laboratory of Her Majesty's Customs, and if possible the time during which those limits have been in force.

We are, your obedient servants,

(Signed) E. J. Bevan, A. C. Chapman, } Hon. Secretaries.

Richard T. Prowse, Esq., C.B.

Customs House, London, *August* 9, 1899.

Gentlemen,

In reply to your further letter of the 19th ult., inquiring as to the limits applied in the laboratory here for total mineral matter in teas, and the time during which such limits have ruled, I am directed by the Board of Customs to acquaint you that, assuming your inquiry to relate to green teas and "capers," it is their general practice to admit such teas for home use when they are found to contain not more than 2 per cent. of facing matter, but that caper teas vary so much in quality and other characteristics that it has not been found practicable to fix a hard-and-fast line in respect of the ash or mineral matter they may be found to contain, each importation being treated on its merits, and that this has been the practice observed from the time when the duty of inspecting and analyzing imported teas was first imposed on the Department.

I am, Gentlemen, your obedient servant,

The Hon. Secretaries, (Signed) R. T. Prowse.
Society of Public Analysts.

Derby Tea Case.

4, New Court, *October* 24, 1899.

Dear Dr. Thorpe,

We have been instructed by the Council of the Society of Public Analysts to forward to you a copy of the correspondence we have had with the Customs authorities on the question of mineral matter in caper teas.

You will see that as far as Mr. Prowse's information carries us the statements made by Mr. Lewin are not supported.

We are, yours faithfully,

(Signed) Edward Bevan, Alfred C. Chapman, } Hon. Secretaries.

Dr. T. E. Thorpe, F.R.S.

Government Laboratory, *October* 27, 1899.

Gentlemen,

I am directed by Dr. Thorpe to acknowledge the receipt of your letter of the 24th inst., and I am to state that he is much obliged to you for the information you are so good as to send him.

Dr. Thorpe observes that the Board of Customs are of opinion that it has not been found

practicable to fix a hard-and-fast line in respect of the ash or mineral matter that caper tea may be found to contain.

He thinks, however, it would have been more pertinent to the point at issue if you had elicited from the Board of Customs whether the particular caper tea in question was or was not adulterated.

I am, Gentlemen, your obedient servant,

Messrs. BEVAN AND CHAPMAN, (Signed) F. J. REED.
Hon. Secretaries,
Society of Public Analysts.

4, NEW COURT, *November* 8, 1899.

DEAR DR. THORPE,

We are much obliged for your favour of the 27th ult., which was laid before the Council on the 1st inst.

We are instructed by the Council to say that so far as appears from the information given by the Customs authorities, Mr. Lewin's statement to the effect that the Customs were in the habit of passing teas containing 13·6 per cent. of total mineral matter is not warranted.

In view of the importance of the matter to Public Analysts, the Council proposes to publish the correspondence.

We are, yours faithfully, etc.

(Signed) E. J. BEVAN, A. C. CHAPMAN, Hon. Secretaries,

Dr. T. E. THORPE, F.R.S.

Mineral Matter in Tea.

LONDON, *November* 8, 1899.

SIR,

The information which you have been good enough to furnish us with on this subject has been laid before the Council, and we are instructed to inform you that in view of the importance of the matter to Public Analysts, it is proposed to publish the correspondence.

We are, yours obediently,

(Signed) E. J. BEVAN, A. C. CHAPMAN, Hon. Secretaries.

RICHARD T. PROWSE, ESQ., C.B.

CUSTOM HOUSE, LONDON, *November* 18, 1899.

GENTLEMEN,

I am directed by the Board of Customs to acknowledge the receipt of your letter of the 8th inst., and to state in reply that, so far as they are concerned, they do not offer any objection to the proposal to publish the correspondence referred to in that letter.

I am, Gentlemen, your obedient servant,

The HON. SECRETARIES, (Signed) R. T. PROWSE.

THE ANALYST.

JANUARY, 1900.

OBITUARY NOTICE.

THE LATE PROFESSOR HODGES, M.D., F.I.C., Etc.

It is with regret that we have to chronicle the death, on Dec. 13, 1899, at Belfast, of Professor Hodges, who had attained the venerable age of eighty-four years, and was a distinguished member of our society. He was born and educated at Downpatrick, and afterwards studied medicine at Dublin and Glasgow, qualifying at both places. During his stay at the latter city Mr. Hodges made the acquaintance of Professor Graham, who strongly advised him to devote his talents exclusively to chemistry. Mr. Hodges, however, preferred to adhere to his original intention, and commenced the practice of medicine at Newcastle, afterwards removing to Downpatrick. He there evinced much ability as a lecturer, and became so deeply interested in agriculture that this induced him to proceed to Giessen to study chemistry under Liebig, where his ability and diligence so interested the Baron that the two became intimate friends. At Giessen he took the degree of Doctor of Medicine. Dr. Hodges then returned to Downpatrick, and there delivered a lecture on agriculture, which attracted so much attention that one of its results was the formation of the Chemico-Agricultural Society of Ulster, in 1845, to which Dr. Hodges was appointed chemist. He removed to Belfast in 1844, and shortly afterwards was appointed Professor of Chemistry in the old Belfast College. On the foundation of a Chair of Agriculture in Queen's College, Belfast, Dr. Hodges was chosen as its first occupant, and also as Lecturer on Medical Jurisprudence there. Both of these positions he held to the day of his death. He was also Lecturer on Agriculture at the Glasnevin Agricultural School. Dr. Hodges wrote many treatises and papers, which had a wide circulation. He was one of the founders of the Royal College of Chemistry, London. He held many important offices. For a long time he was Government Analyst, also Public Analyst for Belfast, and for five Irish counties. He was a corresponding member of the Dublin Natural History Society, member of the Royal Academies of Agriculture of Sweden, and of Turin, and of the Imperial College of Gorygoretzt, Russia; also a Justice of the Peace for County Antrim.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, December 6, in the Chemical Society's Rooms, Burlington House, the President (Mr. W. W. Fisher, M.A.) occupying the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. J. A. Foster, J. B. P. Harrison and D. Lloyd Howard were read for the second time; and a certificate in favour of Mr. Bertram William John Warren, A.I.C., assistant to Mr. Otto Hehner, was read for the first time.

Messrs. E. C. P. Barber, Frederick Davis, William Francis, Alfred Lucas, Edward Russell, B.Sc. (Lond.), and F. L. Slocum, Ph.D., were elected members of the Society.

On the proposition of Mr. Ekins, seconded by Mr. Richmond, Mr. Benedict Kitto and Mr. Cecil H. Cribb, B.Sc., were appointed to act as auditors of the Society's accounts for the year 1899.

The following papers were read: "On some Analyses of Modern Dry Champagnes," by Otto Rosenheim, Ph.D., and P. Schidrowitz, Ph.D.; "Note on Asafœtida," by J. M. Martin, B.A., M.B., and C. G. Moor, M.A.; "On the Determination of the Iodine Value," by Dr. J. J. A. Wijs; "Treacle or Golden Syrup," by E. W. T. Jones; and "On a Method for distinguishing between Hops and Quassia," by Alfred C. Chapman.

NOMINATION OF OFFICERS AND NEW MEMBERS OF THE COUNCIL FOR 1900.

The following nominations were made by the Council at their meeting on December 6, 1899:

President.—W. W. Fisher, M.A. *Vice-Presidents.*—Charles E. Cassal, F.I.C.; E. W. T. Jones, F.I.C.; S. Rideal, D.Sc. *Hon. Treasurer.*—E. W. Voelcker, A.R.S.M. *Hon. Secretaries.*—E. J. Bevan, F.I.C., A. C. Chapman, F.I.C. *Other Members of the Council.*—L. Archbutt, F.I.C.; A. Ashby, M.B., F.R.C.S., F.I.C., G. Embrey, J. H. B. Jenkins, P. A. E. Richards, F.I.C., H. D. Richmond, F.I.C.

NOTE ON ASAFŒTIDA.

BY J. M. MARTIN, B.A., M.B., AND C. G. MOOR, M.A.

(*Read at the Meeting, December* 6, 1899.)

A SAMPLE of gum-resin of asafœtida having been found to yield a very much higher ash than the standard given by the British Pharmacopœia, a number of samples were examined to determine the general condition of the commercial article.

Twelve samples were examined as to:

1. Matter soluble in 90 per cent. alcohol.
2. Ash of the gum.
3. Portion of ash soluble in HCl.

In all the samples, on grinding, much mineral matter was found, in one case a stone weighing 3·4 grammes.

The percentage of the gum soluble in alcohol (90 per cent.) ranged from 14·8 to 39·8, instead of the 65 per cent. of the British Pharmacopœia.

The ash of the gum ranged from 63·1 to 26·4 per cent., the British Pharmacopœia figure being 10 per cent.

The solubility of this ash in 50 per cent. HCl varied from 15·7 to 57·9 per cent., but in one case reached 96·4 per cent., nearly the whole going into solution with much effervescence.

The British Pharmacopœia directions for making the tincture of asafœtida are to extract 200 grammes of the gum-resin with 1 litre of 70 per cent. spirit. Hence, supposing 65 per cent. of the gum were soluble, the tincture should contain 13·5 grammes per 100 c.c. of total solids. Seven tinctures were examined for total solids, and gave results ranging from 4·5 to 8·5 grammes per 100 c.c.

The results of the analyses made are as follows:

Sample.	Extract.	Ash of Gum.	Ash insoluble in HCl.
I.	31·9	38·6	82·5
II.	30·2	45·8	3·6
III.	14·9	62·1	77·8
IV.	20·2	56·3	84·3
V.	18·4	59·3	74·2
VI.	35·4	40·1	64·9
VII.	19·9	58·4	74·6
VIII.	23·0	52·9	78·2
IX.	14·8	63·1	83·9
X.	39·8	43·4	42·1
XI.	37·7	26·4	67·2
XII.	28·9	47·2	78·4

Tinctures.

I.	8·2 grammes per 100 c.c.	V.	5·3 grammes per 100 c.c.
II.	6·2 ,, ,,	VI.	4·3 ,, ,,
III.	4·5 ,, ,,	VII.	8 5 ,, ,,
IV.	7·6 ,, ,,		

It is, then, evident that commercial samples of the gum-resin of asafœtida are very far below the standard given by the British Pharmacopœia, and that they are probably intentionally weighted with worthless material. Consequently, preparations made from the gum-resin according to the British Pharmacopœia directions fall far below the presumed strength, and the medical profession are prescribing medicines of uncertain and variable composition.

A few other observers have noted this condition of commercial gum-resin of asafœtida, yet but little attention seems to have been given to their results.

Moerner (*Journ. Pharm. Chim.*, March 1, 1888, p. 24) examined a sample, and found 86 per cent. of mineral matter, and only 14 per cent. asafœtida. A large proportion, on fracture, proved to be alabaster coated with a thin layer of asafœtida resin.

Buckner (*A. J. P.*, 1890) found the ash in a number of samples to range from 19 to 56 per cent.

Lloyd (*P. J.*, i., 243, 1896) said "ash is often higher than the 10 per cent. required by the British Pharmacopœia." The *National Dispensatory* states that the ash of commercial samples is sometimes as high as 40 per cent.

A thirteenth sample was examined which had been specially prepared by a firm of chemists with a view to determining how far it was practicable attempting to produce a sample approaching British Pharmacopœia strength from this raw material. They succeeded in increasing the matter soluble in 90 per cent. alcohol to 57·5 per cent. (British Pharmacopœia, 65 per cent.). The ash of this was only 5·8 per cent.

Although asafœtida in its various preparations is now prescribed somewhat less than formerly, yet we certainly ought to have reliable material. The standard of the British Pharmacopœia is too high, unless means can be taken to prevent adulterated resin reaching the market. In this connection it may be remembered that a few years ago many samples of ginger were discovered with an abnormally low soluble ash, and that when attention had been drawn to this, and a few prosecutions followed, such ginger almost entirely disappeared from the market.

Discussion.

The President having invited discussion,

Mr. Chattaway said that the British Pharmacopœia, in addition to laying down certain regulations as to the proportion of ash, solubility in alcohol, etc., described the physical characters of the drug; and it would be interesting to know if the samples referred to were in accordance with the Pharmacopœia in this respect.

Mr. E. M. Holmes said that about a year previously, in his capacity as one of the referees in connection with the compilation of the present Pharmacopœia, he had had analyses made of several samples of asafœtida. He was aware that the commercial form of the drug was largely mixed with mineral matter, but, at the same time, the gum in the form of "tears" was almost pure, and he had experienced no difficulty in obtaining it. When the gum was being collected, a certain number of the tears were obtained pure, except for a small quantity of sand attached to their lower surface, where they fell on the ground; but there was a large quantity of more or less liquid asafœtida, which could not be collected in the ordinary way, and this was mixed by the collectors of the drug with a certain quantity of whatever soil might be obtainable in the neighbourhood in order to solidify it. Sulphate of lime, in the form of alabaster, was probably used as an adulterant, not only for asafœtida, but for benzoin, in which it could be used to represent white tears, a certain proportion of which was normally present in the lump form of the drug. In the samples which had been analysed for him the ash in no case exceeded 8 per cent., but in the crude material in lumps it often ranged from 20 to 60 per cent. He thought that, while for medicinal purposes a drug as pure as possible was desirable, a commercial article was admissible which could be used for drain-testing, or for denaturing tea in the manufacture of caffeine; and a normal standard might be laid down for the crude drug, quite apart from the medicinal point of view. The supply of asafœtida sufficiently pure for medicinal purposes was limited; but there was a fairly abundant supply of the ordinary form, in which a moderate proportion of mineral matter—say, from 20 to 30 per cent.—was for commercial purposes not of much consequence,

seeing that for such purposes the article would be bought on the basis of its percentage of active matter.

Mr. ALLEN said he felt some difficulty in agreeing with Mr. Holmes's suggestion to establish two qualities of the drug. The addition of calcium sulphate in the case of the lump asafœtida was an intentional adulteration, which it would, he thought, be dangerous to countenance. Even though the adulterated material were intended only for commercial purposes, he did not see why the purchaser should be supplied with calcium sulphate when he might imagine that he was getting pure asafœtida.

Mr. CRIBB said that he had found the ash in asafœtida to vary from 15 to 35 per cent., and the proportion soluble in alcohol was correspondingly low. The samples were purchased indiscriminately in London. As far as he could ascertain, the drug in the solid form was hardly ever asked for except in remote country districts, and it was now rarely employed in medicine in any form.

Mr. EKINS said that the drug was very seldom used in the solid form except for veterinary purposes, and the prescriptions in which the tincture appeared were very few.

Mr. MOOR said that the samples he had examined were all in the form of a hard concrete mass, which was the only form of the drug to which his experience extended. Regarding the tincture, which was the chief form in which the drug was used medicinally, it was perfectly easy to make the tincture up to the proper standard by taking a suitable quantity of asafœtida.

Dr. RIDEAL observed that in the Pharmacopœia it was directed that, in making the tincture and fetid spirit of ammonia, a certain quantity of the drug should be taken, and it seemed open to question whether the use of a less pure drug in larger quantity would be in strict conformity with the directions.

Mr. MOOR said that to sell a tincture of as nearly as possible the proper strength —even though it might be made from a larger quantity of the drug than the Pharmacopœia directed—would, he thought, be better than deliberately to sell a weak tincture, and accordingly he would suggest that the tincture itself should be standardized. It would be unreasonable, he thought, too strongly to insist on conformity with the British Pharmacopœia tests, and he would suggest that for the present asafœtida containing not more than 20 per cent. of ash, and not less than from 45 to 50 per cent. of matters soluble in alcohol, should be accepted.

Mr. CHATTAWAY said that the Pharmacopœia laid down that the drug should be in the form of tears—indeed, the actual size of the tears is specified; and he thought that the specimens referred to by the author, although they might be admissible commercially, could not be regarded as representing the British Pharmacopœia article, which frequently contained as little as 2 or 3 per cent. of ash.

Mr. HOLMES said that, while the British Pharmacopœia limit of ash was 10 per cent., a much smaller percentage was quite common in the drop or tear asafœtida. He thought that lump asafœtida would be admissible only provided that it contained less than 10 per cent. of ash. The question of purity was merely a question of the price given for the drug, which varied from about 45s. or 60s. for the lump, to 120s. per cwt. for the finest tears. Seeing that the Pharmacopœia intimated that only the pure drug should be used in medicine, he did not think it would be justifiable to use

the drug in an impure state in medicine, and in its purification some volatile active ingredients might be lost, and the British Pharmacopœia standard of strength would not be maintained.

ON SOME ANALYSES OF MODERN "DRY" CHAMPAGNE.

By Otto Rosenheim, Ph.D., and Philip Schidrowitz, Ph.D.

(*Read at the Meeting, December* 6, 1899.)

The authors have recently had an opportunity of examining a number of champagnes representative of the modern "dry" French product, and as there are practically no analyses of similar wines on record, we think it may be of interest to communicate the results obtained to the Society.

The figures obtained by the analysis of wines are to a great extent—as is the case with many other articles of food—dependent on the methods employed, and therefore we thought it advisable to use the standard methods officially adopted in Germany,* in order to be able to compare our results with the data on this subject already in existence. The official German schedule was drawn up as a guide in the analysis of still wines, and therefore no mention is made of the estimation of carbonic acid. We determined the same gravimetrically by absorbing the gas in soda lime after drying with sulphuric acid in the ordinary manner, the last trace being expelled by heating in a water-bath, and then passing a current of air through the liquid. In order to regulate the flow of gas and to prevent frothing over, we made use of one of the well-known hollow champagne corkscrews with an accurately-fitting tap.

On the opposite page is a table of the analytical results obtained.

With regard to the composition and manufacture of champagne, Grünhut (*Z. f. analyt. Chem.*, 1898, 231) recently put forward the suggestion—based solely on analytical figures—that this article in general bears the character of a "gallisised" wine—that is, a product which has been unduly diluted by the addition of a weak solution of sugar prior to fermentation, and that this is principally evidenced by the low percentage of ash. The figures we have obtained appear at first sight to corroborate Grünhut's conclusions, to which he came, however, by an erroneous method of reasoning. He compared his figures with averages obtained from a large number of analyses of German white wines, but there is no justification for this, as the methods of manufacture are so completely different that no strict comparison can be made between the two classes of wine. Practically all better-class champagne is made from blue grapes, and in order to meet the exigencies of the market, which demands a very light-coloured article, the grapes must not be subjected to any preliminary crushing or kneading, and special care is taken to ensure a rapid separation of the juice from the skins, pips, etc., in the press. This procedure, adopted for the purpose of obtaining a light-coloured must, necessarily tends to prevent the extraction of mineral matter from the skins, stalks and pips, and it is therefore to be expected that the finished article will contain a relatively small percentage of ash. In the manufacture of ordinary white wines a preliminary crushing takes place in the vineyard,

* German Wine Law, June 25, 1896.

* The readings were made in a Laurent half-shadow apparatus at 15° C.

† This wine is not actually a "champagne," but is made according to the methods of the Champagne from blue grapes in St. Émilion, Gironde.

and the separation of the juice from the marc is not hastened as in the preparation of champagne. In connection with the above remarks, we may add that similar views were expressed by Kulisch (*Z. f. angew. Chem.*, 1898, 573) in criticising Grünhut's paper.

With regard to our own results, it will be observed that both the extract and the ash generally are rather low (compared with Bordeaux or Rhine wines), with the exception of No. 4 (3·76 per cent.), which is due to the high percentages of sugar and glycerin. No. 3 shows a high percentage of ash. In regard to the sugar percentages, it will be seen that only Nos. 4, 9 and 12 are appreciably above 1 per cent. The relation of "reduced extract" to ash is considerably below 10 per cent. (that being the normal average deduced from a large number of analyses of still white wines), except in the case of Nos. 3 and 10. We have already given an explanation for this apparent anomaly, which constitutes an excellent illustration of the fact that it is in many cases extremely dangerous and ill-advised to judge the quality and value of an article of food solely in the light of the figures obtained by analysis.

No. 10 shows some features of interest; it is the only case in which the specific gravity falls below 0·99, but this is probably due to the high percentage of alcohol in relation to the low extract. The total acidity is small, but the volatile acid relatively large. This sample also showed the highest percentage (1·02) of carbonic acid.

Another noteworthy feature is the high lævo-rotation of No. 6, which indicates a preponderance of lævulose. The absence of cane-sugar was demonstrated by inversion, which did not alter the rotation. According to Neubauer (*Ber.*, x., 827) the proportions of dextrose and lævulose in a mixture can be calculated according to the following equations:

$$1.\ X = 0{\cdot}637S + 0{\cdot}342\alpha.$$

$$2.\ Y = S - X.$$

X = dextrose; Y = lævulose; S = total invert sugar found; α = rotation observed in 200 mm. tube.

Although the results obtainable from these equations are not absolutely correct (for reasons into which we cannot enter here), they are sufficiently exact to permit of the approximate determination of the proportion of dextrose to lævulose respectively. On applying the above formulæ to the case in point, it was found that the quantity of lævulose was 7·01, and of dextrose 2·87. In most cases the proportion is as 1 : 1, and this indicates that in No. 6 the fermentation of the sugar in the added liqueur ceased after the disappearance of the greater part of the dextrose.

Discussion.

The President observed that, speaking broadly, it seemed that the proportion of extract in those cases in which it was high rose with the proportion of sugar, which probably depended on the composition of the liqueur that was added to the grape-juice after fermentation. He presumed that there might still remain a certain quantity of unaltered cane sugar, though doubtless most of the sugar would be inverted during secondary fermentation.

Dr. Schidrowitz said that in those cases in which the determination had been

made the sugar present was found to be completely inverted. It would become inverted very quickly, chiefly owing to the acidity of the liquid in question.

Mr. RICHMOND remarked that in a liquid which had undergone fermentation by means of yeast it was unlikely that there would be any unaltered cane sugar present, complete inversion being brought about by an enzyme secreted by the yeast.

The PRESIDENT observed that before the liqueur was added primary fermentation would be over.

Mr. RICHMOND said that the enzyme would still be present in the yeast cells remaining in the wine, and the sugar in course of time must, he thought, surely become inverted.

Mr. CRIBB inquired where a description of the German official methods of analysis was to be found.

Dr. SCHIDROWITZ said that the official methods were embodied in the German Wine Law, dated June 25, 1896, and were to be found in the appendices to most German works on the subject (*e.g.*, Windisch, *Die chemische Untersuchung u. Beurtheilung des Weines*, p. 45 and *e*).

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Occurrence of Chromates as Preservatives in Milk. A. Leys. (*Journ. Pharm. Chim.*, 1899, x., 337-340.)—During the present year the author has frequently met with chromates associated with formaldehyde, most frequently in the proportion of 1 part in 100,000 of milk, though considerably larger quantities are of not unfrequent occurrence.

In order to detect traces of chromates the following tests are recommended: From 100 to 150 c.c. of the milk are evaporated to dryness, the residue ignited, and the ash extracted with a few c.c. of water, note being taken of the colour of the solution.

A reagent is prepared by adding a few drops of indigo carmine solution to concentrated hydrochloric acid until the liquid has the colour of Fehling's solution. On boiling 5 c.c. of this reagent with a few drops of the filtered aqueous extract of the ash, the colour is instantly discharged in the presence of the slightest trace of chromate.

A second test consists in adding some pure aniline and commercial toluidine to an excess of acetic acid free from furfural, filtering through purified animal charcoal, and diluting the filtrate to the tint of the extract of milk ash. On boiling equal parts of this reagent and the extract for two or three minutes, a cherry-red colour is produced after a short time in the presence of a chromate.

The two reactions described above are said to be much more sensitive than Schiff's guaiacum reaction for chromic acid, and point to the presence of an oxidizing agent. In order to identify this as a chromate Barreswil's hydrogen peroxide reaction may be employed. The aqueous extract of the ash is acidified with a few drops of dilute sulphuric acid and two or three drops of hydrogen peroxide added. The immediate formation of the fugitive blue tint of perchromic acid indicates the presence of a chromate. C. A. M.

On Fruit Juices and their Examination, with particular reference to Raspberry Juice. I. Detection of Foreign Colouring Matter. E. Spaeth. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1899, ii., 633-635.)—The author deals principally with the detection of artificial colouring matter in raspberry juice. One of the principal means of sophistication is by admixture with cherry juice, and though the lead acetate method is said to provide a means for the detection of even small quantities, the author cannot confirm this, nor is he able to indicate any method at present by which admixture with cherry juice can be detected with certainty. Other vegetable colouring matters used for the purpose are those of the whortleberry, red beet, red poppy, mallow, phytolacca and orseille. Cochineal is also used. Of these, orseille, phytolacca, beet and cochineal can be identified, whilst in a general way the addition of the juices of such other fruits, as the whortleberry, the blackberry, and the elderberry, can be detected, though in most cases it is impossible to say which of these has been added, their behaviour with reagents being so similar. Of the tar colours a large and ever-increasing number is made use of, such as rosaniline, fuchsin, eosin, etc.

The table opposite gives the principal reactions of the various colouring matters which the author has studied:

Tar colours dissolved by amyl alcohol can be distinguished from vegetable colours by the colour being removable by means of wool freed from fat. S. fuchsin, however, not being soluble in amyl alcohol, it is necessary also to submit the diluted juice itself to the wool test.

In the sophistication of lemon-juice, tar colours are always used, and the amyl alcohol test with the removal of the colour by wool is almost exclusively available. H. H. B. S.

The Detection of Saponin in Lemonade. Frehse. (*Journ. Pharm. Chim.*, 1899, x., 13-16.)—In a communication on the composition of the lemonade manufactured in Lyons in 1898, the author states that from time to time he has found saponin, but that its use is not general, owing to its being readily precipitated and causing a turbidity in the liquid.

It can be recognised by the persistent foam produced on shaking the bottle after the expulsion of the carbon dioxide, but its chemical identification is not easy in the presence of sugar and tartaric acid. The tests based on its conversion into

sapogenin by warming it with hydrochloric acid is uncertain in the case of lemonade. It was not found possible to precipitate it with lead subacetate and to liberate it from the precipitate with hydrogen sulphide, since in the presence of saponin the lead sulphide passed through the filter. Extraction of the lemonade with various solvents is useless, owing to the persistent emulsion produced in every instance, while the influence of the saponin prevents the use of fermentation to remove the sugar.

The only method by which the author could obtain relatively satisfactory results consisted in evaporating the lemonade to a paste and taking up the residue with acetic ether. On filtering this liquid, again evaporating and repeating the treatment with acetic ether, if required, a residue was obtained which gave a reddish-violet coloration with concentrated sulphuric acid, and which when boiled with dilute hydrochloric acid yielded a precipitate of sapogenin, with, as a rule, an odour resembling that of cedar wood. C. A. M.

The Addition of Liquorice Extract to Lemonade. Frehse. (*Journ. Pharm. Chim.*, 1899, x., 347, 348.)—According to the author, extract of liquorice or glycyrrhizin itself have recently been used to produce a persistent froth in lemonade. The reactions given by saponin (see preceding Abstract) are also given by glycyrrhizin, but the latter may be distinguished by its being precipitated in the cold by hydrochloric acid, and by the chlorides of sodium, calcium, and iron.

In the presence of sugar and of glycerin, which is a frequent constituent of foam headings, the reactions are frequently masked. In such cases subacetate of lead is added, and the precipitate filtered off, washed, and decomposed with hydrogen sulphide. In the presence of the tartaric acid of the lemonade the glycyrrhizin is left on the filter with the lead sulphide. The precipitate is washed with water slightly acidified with hydrochloric acid, then rapidly with water, and is taken up with alcohol, and finally with alcohol containing a little ammonia. On evaporating these solutions the glycyrrhizin is left as a yellow residue, readily identified by its odour and its reactions with hydrochloric and sulphuric acids. C. A. M.

ORGANIC ANALYSIS.

The Solubility of Volatile Oils and their Constituents in an Aqueous Solution of Sodium Salicylate. M. Duyk. (*Bull. de l'Acad. Royale de Belg.*, 1899, 503; through *Journ. Pharm. Chim.*, 1899, x., 353-359.)—The solvent power of an aqueous solution of sodium salicylate reaches its maximum when the liquid has a specific gravity of 1·240, and contains 1 part of the salt in 1 of water.

This reagent readily dissolves a large number of alcohols, aldehydes, ketones, and free terpene phenols. On dissolving 1 c.c. of the substance under examination in 4 c.c. of the salicylate solution, and adding water drop by drop, with continual agitation to the solution, the amount required to produce a permanent turbidity

varies considerably with different compounds. Thus, under these conditions, eugenol requires 3·5 c.c.; geraniol and benzaldehyde, 2·5 c.c.; carvol, 2·0 c.c.; citral, 1·7 c.c.; cineol and cinnamic aldehyde, 1·5 c.c.; and citronellone, 0·5 c.c.

Camphor, thymol, and menthol only dissolve in relatively large quantities of concentrated salicylate solution, although the same substances when present in their original oils are much more soluble.

The ethereal compounds of the soluble substances referred to above are not soluble, nor are terpene hydrocarbons, with certain exceptions, such as cymene, limonene, and menthene, which are slightly dissolved owing to the formation of traces of compounds between the terpene and the sodium salicylate.

The author gives the following classification of the principal alcohols, aldehydes, ketones, phenols, etc., of essential oils as regards their solubility in salicylate solution:

SUBSTANCES VERY SOLUBLE:

Alcohols.—Geranylic (rhodinol, geraniol); linalylic (dextro- and lævo-rotatory linalols); citronellic (citronellol); bornylic (borneols); menthylic (menthol).

Aldehydes.—Benzoic; salicylic; anisic; cinnamic; geranic (citral); cuminic; methylpyrocatechuic (vanillin); methylene-protocatechuic (heliotropin).

Ketones. — Carvone (carvol); methylheptenone; pulegone; methylnonylketone; menthone; thujone.

Camphor and cineol.

Phenols.—Eugenol; thymol; carvacrol.

(Menthol and ordinary camphor are soluble with difficulty.)

SUBSTANCES INSOLUBLE OR NEARLY SO:

Sesquiterpene Alcohol.—Santalol.

Phenol Derivatives.—Anethol; safrol; apiol.

Esters.—Bornylic; geranylic; linalylic; menthylic.

In applying this reagent to the examination of essential oils, the sample is shaken with a convenient quantity of the solvent and allowed to stand.

When the oil is composed exclusively of hydrocarbons, the mixture speedily separates into two layers, of which the upper consists of the unaltered hydrocarbon. Pure essence of terebenthene behaves in this way.

If the oil consist of a free oxygen compound, such as oil of bitter almonds (benzaldehyde, with traces of hydrocyanic acid), a clear and limpid solution is obtained.

When an essential oil of complex composition is treated with the reagent the oxygen compounds dissolve, while the esters and hydrocarbons separate out. Thus, in the case of oil of peppermint, the menthol and methone are dissolved, whilst the esters of menthol and menthene remain undissolved.

When the hydrocarbons or other insoluble constituents are only present in small proportion, they may be dissolved through the influence of the soluble oxygen compounds; but on adding an additional quantity of sodium salicylate, the solution becomes turbid, and the hydrocarbon eventually rises to the surface.

To extract the soluble portion of an essential oil by this means, as, for example,

carvol from oil of caraway, 100 grammes of the oil are shaken with 300 c.c. of the reagent for about fifteen minutes, and the mixture allowed to stand until the layers have completely separated, which requires about an hour. The lower layer is then withdrawn, filtered, and mixed with twice its volume of water in a separating funnel. The oily layer which separates is collected, and the aqueous layer concentrated to its original density on the water-bath, and again used for extracting the insoluble portion of the original oil, which will still contain a little carvol.

The carvol can also be recovered from its solution in the sodium salicylate by extraction with ether instead of precipitation with water.

In the case of oils, such as those of peppermint, bergamot, and geranium, which contain alcoholic compounds partly in the free state and partly in the form of esters, one portion of the oil is treated with the salicylate solution as described above to obtain the amount of free alcohols; a second portion is saponified with alcoholic soda, the product treated with water and the liberated oil washed, dried, and treated with the sodium salicylate solution as before to extract the total alcohols present.

In continuation of the subject (*Bull. de l'Acad. royale de Belg.*, 1899, 503; through *Journ. Pharm. Chim.*, 1899, x., 406-411) the author gives, as a first instalment, the following particulars of those essential oils found in the Pharmacopœias:

Oil of Bitter Almonds, which consists of benzaldehyde, with traces of hydrocyanic acid, is completely soluble in 4 volumes of the salicylate solution diluted with 2 volumes of water.

Oil of Absinthe.—The thujone (tanacetone) is readily dissolved; the insoluble residue should not exceed 60 per cent.

Oil of Anise (green).—This is nearly insoluble with the exception of traces of anisic aldehyde.

Oil of Bergamot.—The author found 12 per cent. of soluble constituents by direct treatment, and 35 per cent. after saponification.

Oil of Cajeput.—This is composed of cineol and hydrocarbons. A sample of undoubted purity yielded 53 per cent. of soluble products consisting of nearly pure cineol, whilst cumene was identified in the insoluble residue.

Oil of Cinnamon (Ceylon).—This is completely soluble in the concentrated solution, but is only partially soluble in a mixture of 4 volumes of the reagent with $1\frac{1}{2}$ volumes of water. The proportion of insoluble substances in an oil of good quality should not exceed 10 per cent.

Oil of Cinnamon (China).—On diluting the concentrated solution by one-fourth, the cinnamyl acetate and hydrocarbons are liberated. Their proportion should not exceed 25 per cent.

Oil of Caraway.—On treating this oil with a mixture of 4 volumes of the salicylate solution and 2 volumes of water, the portion dissolving consists of nearly pure carvol, whilst the insoluble part has the characteristics of limonene. The author has treated artificial mixtures of carvol and limonene in this manner, and has obtained results closely approximating to theory. Oil of caraway of good quality should contain at least 40 per cent. of soluble constituents.

Oil of Cedar, being composed of hydrocarbons, such as cedrene and cadinene, is insoluble in the salicylate solution.

Oil of Coriander.—The reagent dissolves the free linalool; the insoluble portion consists of limonene, pinene and linalylic esters.

Oil of Cumin.—The salicylate solution removes the cuminic aldehyde.

C. A. M.

The Action of Formaldehyde on Proteids. C. Lepierre. (*Bull. Soc. Chim.*, 1899, xxi., 729-738.)—The author has studied the action of formaldehyde on certain soluble proteid substances which do not coagulate on heating. From the results of his experiments he concludes that the action is one of dehydration and condensation, with the fixation of one or more CH_2-groups.

He finds that proto-albumoses (from muscle, fibrin, and egg albumin) are rendered completely insoluble, and the precipitate does not dissolve in hot water, in a 10 per cent. solution of sodium chloride (exclusion of hetero-albumoses), or in sodium carbonate solution. Deutero-albumoses are, in his opinion, not simple substances, but consist of a series of analogous bodies conveniently grouped together. Of these the members of higher molecular weight—*i.e.*, those approaching most nearly in composition to the proto-albumoses—become insoluble on treatment with formaldehyde, whilst those of lower molecular weight, approaching the true peptones, are converted into proto-albumoses, and only after a long-continued action of the reagent are the latter transformed into insoluble derivatives.

In like manner true peptones are said to be first converted into substances of a deutero-albumose nature, and these in turn into proto-albumoses.

The precipitates obtained from these different proteids are insoluble in cold or boiling water, but when heated for one or two hours in an autoclave at 110° C. are hydrated and rendered completely soluble, the solutions giving the characteristic reactions of the proteids from which the insoluble compounds were derived.

Contrary to the experience of Trillat, the author has found that proteids rendered insoluble are not altogether indigestible, but are dissolved by normal gastric juice, although more slowly than the untreated proteids.

With reference to the use of formaldehyde for the separation of gelatin from peptones in analytical work (ANALYST, xx., 44 and 247), it is stated that a certain amount of the peptones present are precipitated simultaneously with the gelatin, the proportion varying with the duration of the action of the formaldehyde and the nature of the peptones.

C. A. M.

Separation of the Products resulting from the Action of Pepsin on Albumin and other Proteids. J. Effront. (*Chem. Zeit.*, 1899, xxiii., 770 and 783.)—Tannin produces a precipitate in solutions of albumin, proteoses, or peptones; an excess of the reagent redissolves the peptone precipitate. If a solution of fibrin is treated with pepsin, and if to the mixture a solution of tannin, prepared exactly as below, is added, the precipitate contains nitrogen (practically) in proportion to the amount of fibrin originally taken. If the reaction between the fibrin and the pepsin is allowed to proceed for increasing periods of time, the weight of the precipitate yielded by

the tannin, and also the nitrogen in it, steadily diminishes, until, finally, no precipitation should take place. The precipitate from solutions of egg albumin with tannin contains constantly from 5·9 to 6·1 per cent. of nitrogen; it consists of 37·5 per cent. of albumin and 62·5 per cent. of tannin; extraction with water does not alter its composition; dilute alcohol removes some of the tannin, till about 45 per cent. is left. By treatment with 80 per cent. spirit, a few drops of hydrochloric acid, and ether, the albumin may be recovered pure; but the process is wasteful, and it is better to operate as follows: The precipitate is washed, dried between paper, suspended in water acidulated with a little hydrochloric acid, and dissolved by adding a sufficiency of absolute alcohol. Four or five volumes of water are introduced, followed by an excess of phosphotungstic acid. The new precipitate is collected, washed in dilute HCl, dried with paper, suspended in water, dissolved with ammonia, and thrown down with barium chloride. The filtrate is finally evaporated on the water-bath. A pure solution of albuminoids is thus produced, which, giving the xanthoprotein reaction, a precipitate with picric acid, and a deposit on saturation with zinc or ammonium sulphate shows that the original tannin-albumin mixture contained the proteoses. The filtrate from the tannin-albumin precipitate contains the peptones, and may be precipitated with phosphotungstic acid, whence treatment with barium chloride enables the peptones to be recovered pure. In their solution neither picric acid nor zinc or ammonium sulphate gives a precipitate; therefore they have been isolated.

To separate the various products of the peptonization of fibrin and albumin, two special reagents are needed. *Tannin solution:* 50 grammes of tannin are dissolved in 500 c.c. of water, 50 c.c. of normal sodium hydroxide are added, the mixture is diluted to 1 litre, and 15 c.c. of a 10 per cent. solution of tartaric acid are introduced. *Phosphotungstic acid:* A boiling 5 per cent. solution of sodium tungstate is boiled for 1 hour with 10 per cent. by volume of "medicinal" phosphoric acid;* and when cool, 15 per cent. by volume of strong sulphuric acid is added.

For analytical purposes, the original solution should contain between 5 and 10 per cent. of albumin.

(1) *Total nitrogen* is determined in 10 or 20 c.c. by the Kjeldahl process, slightly acidifying before evaporation to prevent loss of ammonia.

(2) *Total Albuminoids.*—5 or 10 c.c. of the solution are poured into 100 c.c. of the phosphotungstic acid. After twelve hours the precipitate is collected on a nitrogen-free paper, washed with semi-normal HCl, dried on the paper, and kjeldahled. In calculation the factor 6·25 is employed.

(3*a*) *Syntonins.*—From 20 or 40 c.c. of the solution, albumin is removed by coagulation under pressure. The liquid is neutralized with 1 : 10 sodium hydroxide; the precipitate brought on a small filter, washed with water, dried, and kjeldahled. More accurately, however (3*b*), the solution, freed from albumin as before, is precipitated with phosphotungstic acid (α) as it is, (β) after the insoluble products of neutralization have been filtered off. The difference gives a means of calculating the syntonins.

* The solution of phosphoric acid official in the Belgian Pharmacopœia contains 50 per cent. of H_3PO_4, and has a specific gravity of 1·35 (Squire).—ABS.

(4) *Proteoses.*—30 c.c. of the solution are freed from albumin and from syntonins with dilute soda; the volume is made up to 33 c.c. and filtered. To 11 or 22 c.c. of the filtrate are added 150 c.c. of the tannin reagent; after twelve hours the precipitate is collected on a nitrogen-free paper, washed five or six times with tannin, dried between paper, and kjeldahled.

(5) *Peptones.*—The filtrate from the proteose precipitate is mixed with 100 c.c. of phosphotungstic acid, allowed to rest for one hour; the precipitate is collected, washed with semi-normal HCl, dried between paper, and also kjeldahled.

In a liquid where peptonization has not proceeded far, saturation with zinc or ammonium sulphate and precipitation with tannin give nearly the same amounts of proteoses. The further the digestion has gone, the greater the difference between the yields, until, after seventy-two hours at 50° C., one process gives 50 per cent., the other only 33 per cent., of proteoses as the proportion of albuminoids in a solution originally containing 5 per cent. of fibrin. This anomaly is not due to the presence of peptones in the tannin precipitate, but apparently to the fact that some albumoses are thrown down by the sulphates, others not.

Phosphotungstic acid is a very untrustworthy reagent. If an almost unaltered fibrin solution, freed from albumin and syntonin, is kjeldahled, and if the phosphotungstic precipitate is also kjeldahled, the two results agree completely. If, however, digestion has proceeded far, the total nitrogen of the liquid (prepared as before) is no longer reproduced in the phosphotungstic precipitate. Experiments seem to show that "peptones" are bodies of two distinct kinds, some precipitable by the said acid, others not. The peptones themselves also appear to be attacked by pepsin. It follows that a determination of peptones from the difference between the total albuminoids and the syntonins plus proteoses does not always lead to correct figures, the error being the greater the longer the period of peptonization. Therefore, although tannin and sodium tartrate is a trustworthy reagent, and gives accurate results in the estimation of proteoses, the peptones can only be safely determined in fresh liquids; and accordingly the author's process, as a whole, is not satisfactory, if the original solution has been submitted to the action of pepsin for any considerable length of time. F. H. L.

The Use of Sozoiodol as a Reagent for Albuminous Substances in Urine. G. Guérin. (*Journ. Pharm. Chim.*, 1899, ix., 576.)—Sozoiodol, or di-iodo para-phenyl-sulphonic acid, is said to be a very sensitive reagent for abnormal albuminous substances in urine. On adding 10 to 15 drops of a 10 per cent. aqueous solution of this reagent to 8 or 10 c.c. of the filtered urine, a milky turbidity or white flocculent precipitate is produced in the presence of albuminous substances.

Alkaline urates and uric acid give no reaction; whilst albumoses, peptones, and the majority of alkaloids give a precipitate which is soluble on warming. On the other hand, nucleo-albumins give only a slight turbidity in the cold, but on heating become completely insoluble.

As the reagent undergoes alteration in the light, it should be preserved in orange-coloured bottles. C. A. M.

The Detection of Alcapton in Urine. **G. Denigès.** (*Bull. Soc. Pharm. Bordeaux*, June, 1899; through *Ann. de Chim. anal.*, 1899, iv., 312, 313.)—A urine containing alcapton is characterized by its optical inactivity (in the absence of sugar), by reducing ammoniacal silver nitrate, and by changing its colour spontaneously on exposure to the air.

The latter reaction, which is due to oxidation, has been rendered more intense by the author by treating the urine with an oxidizing agent, such as ammonium persulphate, manganese peroxide, or lead peroxide.

From 10 to 12 c.c. of the urine are mixed with 0·5 to 1·0 gramme of lead peroxide and 2 to 4 drops of a solution of sodium hydroxide, and the liquid filtered and shaken. In the absence of alcapton the filtrate remains yellow, but when that substance is present the colour varies from light to dark red.

With manganese peroxide used in the same proportion, the colour of the filtrate approaches brown, and with ammonium persulphate, of which a greater quantity is required, there is a similar coloration. C. A. M.

Analysis of Commercial Phenols. **S. B. Schryver.** (*Journ. Soc. Chem. Ind.*, 1899, xviii., 553.)—This process is based on the interaction of sodamide and bodies containing a hydroxyl group, which takes place according to the typical reaction:

$$NaNH_2 + C_6H_5OH = NaOC_6H_5 + NH_3.$$

A 200 c.c. wide-necked flask is fitted with a separating funnel, the tube of which passes to the bottom of the vessel, and an inverted condenser connected at its upper end with an absorbing vessel, and thence with an aspirator. About 1 gramme of sodamide is finely ground, washed two or three times with benzene by decantation, then introduced into the flask, and 50 or 60 c.c. of benzene (free from thiophen) added. The mixture is heated on a water-bath in a current of dry air freed from carbon dioxide for some ten minutes till the last traces of ammonia are expelled. About 20 c.c. of normal sulphuric acid are next placed in the receiver, and the phenol, dissolved in six times its weight of benzene, is brought into the funnel and allowed to drop into the flask. The funnel is rinsed with more benzene, and the current of air is maintained through the boiling liquid for one and a quarter hours. The excess of sulphuric acid is finally titrated with normal sodium carbonate and methyl orange. With phenol, cresol, and guaiacol (alone), the process gives correct results, provided (1) the apparatus and phenol are perfectly dry—sodamide acts upon water—(2) sufficient benzene is employed to hold the sodium salt in solution, (3) the benzene is free from thiophen, and (4) air is aspirated for a sufficient length of time. Toluene or xylene may replace the benzene, but in that case a sand-bath must be used instead of the water-bath.

The process is obviously not applicable to the determination of the relative proportions of more than two phenols; but it has been tested on mixtures of phenol and cresol, on wood-tar guaiacol, which is a mixture of guaiacol and creosol, on thymol in oil of thyme, and on eugenol in oil of cloves. Calling the number of c.c. of standard acid that are necessary to neutralize the ammonia given off when

1 gramme of a phenol (either simple substance or mixture) is treated with an excess of sodamide under the experimental conditions the "hydroxyl value"—which in the case of pure phenol is $\left(\frac{100}{9{\cdot}4} = \right) 10{\cdot}63$, and in that of pure cresol is $\left(\frac{100}{10{\cdot}8} = \right) 9{\cdot}26$, etc. —a table may be prepared for converting the hydroxyl value obtained when a mixture of two known phenols is operated upon directly into the relative proportion between the two ingredients, and the results calculated in this manner from the analysis of materials of the above-mentioned composition appear to be fairly satisfactory.

The method is equally available for determining the amount of water in any particular phenol, because the reaction between sodamide and water is analogous to that between the amide and a phenol. It also shows that fused sodium acetate is the best substance to remove the last traces of moisture from ordinary phenol. The process has an advantage over methods involving the use of bromine or iodine, as the results are not affected by the presence of hydrocarbons, for which reason it should be useful for estimating phenols in a large number of essential oils, etc. Sodamide acts upon ketones, amines, etc. (Titherley, *Journ. Chem. Soc. Trans.*, 1897, 460), but these bodies can be readily removed by various suitable reagents.

F. H. L.

A Critical Examination of the Methods of Quantitatively determining Salicylic Acid. **W. Fresenius and L. Grünhut.** (*Zeit. anal. Chem.*, 1899, xxxviii., 292-301.)—In their experiments on the extraction of salicylic acid by means of a solvent the authors dissolved 0·3017 gramme of pure sodium salicylate in 30 c.c. of water, and after the addition of sufficient sulphuric acid to liberate the salicylic acid, shook out the solution with four successive portions (25 c.c.) of chloroform. The united extracts were washed, evaporated at a low temperature, and the residue dried in the water-oven to constant weight. These amounts in percentages of the substance taken were: After 1 hour, 88·51; after 5 hours, 84·04; after 7 hours, 83·87; and after 9½ hours, 81·22. (Sodium salicylate contains theoretically 86·23 per cent. of salicylic acid). Thus, while the substance was still moist after 1 hour's drying, the results were too low when the drying was continued. From these results the authors conclude that it is impossible to obtain a constant weight in this way, and that only approximate determinations are possible.

Attempts were made to avoid this loss by dissolving the residue in ether before placing it in the water-bath and then employing a lower temperature. But even in this way it was not possible to determine the point at which all the solvent was expelled without any evaporation of the salicylic acid. The results thus obtained when the residue was dried at 100° C. were: After 1 hour, 85·83 per cent.; after 2 hours, 80·76 per cent.

As M. Saupe (*Pharm. Cent.*, xxxi., 314) obtained good results by drying fatty acids on the top of the water-oven instead of within it, the same process was tried with the salicylic acid, but even after the treatment with ether the residue still had an odour of chloroform, and was considerably too high.

In further experiments it was found that the drying could be effected with less

loss when a mixture of equal parts of ether and petroleum spirit was used in place of chloroform for the extraction of the salicylic acid, but that it was necessary to use the smallest possible quantity of solvent and to dry the residue on the top of the water-oven.

An iodometric method of estimating salicylic acid has been based on the observation of Messinger and Vortmann (ANALYST, xvi., 75; *Berichte*, xxii., 2312, and xxiii., 2753) that iodine acts upon phenols in alkaline solution, forming substitution products. In the case of salicylic acid the solution is heated to 50° to 60° C., and an excess of standard iodine solution added. On again warming the liquid to 50° to 60° C. a red precipitate is formed, which increases on acidifying with dilute sulphuric acid. When cold the liquid is diluted to a definite volume, and the residual iodine in an aliquot portion of the filtrate titrated with standard thiosulphate.

The authors point out that in the first communication by Messinger and Vortmann 4 atoms of iodine are said to take part in the reaction as in the equation,

$$C_6H_4\begin{matrix}OH\\COOH\end{matrix} + 4I = C_6H_3I\begin{matrix}OI\\COOH\end{matrix} + 2HI;$$

whereas in their second paper they state that the calculation must be based on the assumption that 6 atoms of iodine act upon 1 of salicylic acid, whilst Vortmann, in his *Anleitung zur Chem. Anal. organ. Stoffe*, gives the following explanation of the reaction:

$$C_6H_4\begin{matrix}OH\\COONa\end{matrix} + 3NaOH + 6I = C_6H_2I_2\begin{matrix}OI\\COONa\end{matrix} + 3NaI + 3H_2O.$$

The authors give the following results in illustration of their experience with this method, basing their calculations on the assumption that 6 atoms of iodine take part in the reaction:

	Sodium Salicylate Solution. c.c.	Normal Sodium Hydroxide Solution. c.c.	Iodine Solution added. c.c.	Acidified with Normal H_2SO_4. c.c.	Volume diluted to c.c.	Amount of Filtrate Titrated. c.c.	Thio-sulphate used. c.c.	Salicylic Acid found. Per cent.
1 ...	30	12·5	125·20	15·0	250	100	14·30	64·71
2 ...	25	12·5	126·71	15·0	250	100	16·30	74·36
3 ...	20	12·5	125·08	15·0	250	100	19·60	81·61
4 ...	20	12·5	125·02	15·0	250	100	33·89	92·70
5 ...	20	12·5	100·00	15·0	250	100	24·30	90·30

In the first three determinations the amount of sodium salicylate used was 1·0110 gramme dissolved in 100 c.c.; in the last two 1·0094 gramme in 100 c.c. In the former 1 c.c. of the iodine solution contained 0·0123215 gramme of iodine, and in the latter 0·025600 gramme of iodine.

From these results the authors conclude that this method cannot yet be relied upon to give even approximately correct results, and that the exact conditions under which it can be used as a quantitative method have yet to be determined.

The bromine method proposed by Freyer (*Chem. Zeit.*, xx., 820) has been found by them to be the most satisfactory of all the methods tried. This is based on the

facts that, on mixing a solution of salicylic acid with bromine-water in excess, a yellowish-white precipitate is formed,

$$C_6H_4\begin{matrix}OH\\COOH\end{matrix} + 8Br = C_6HBr_3{\cdot}OBr + 4HBr + CO_2;$$

and that, on adding a solution of potassium iodide, not only does the excess of bromine liberate an equivalent amount of iodine, but the tribromphenol bromide also reacts as in the equation :

$$C_6HBr_3{\cdot}OBr + 2KI = C_6HBr_3{\cdot}OK + KBr + 2I.$$

Hence, in calculating the results, only 6 atoms of bromine correspond to one of salicylic acid.

Freyer stated that an excess of about 100 per cent. of bromine was necessary, but the authors have proved that an excess of from 75 to 80 per cent. is sufficient. They have tested the method with concentrated bromine solutions, using considerable quantities of sodium salicylate, and have obtained as satisfactory results as Freyer himself. They give the following details of their method of working, in which, like Freyer and Koppeschaar, they used solutions of potassium bromate and bromide, and liberated the bromine by the addition of hydrochloric acid. The required quantity of the bromine salts solution is diluted with 300 c.c. of water, and decomposed with 30 c.c. of dilute hydrochloric acid (specific gravity 1·10). Into this mixture is introduced with continual stirring a solution of about 1 per cent. in strength of the substance under examination. A white precipitate is immediately formed, and, after this has been allowed to stand for about five minutes with occasional agitation, 30 to 40 c.c. of a 10 per cent. solution of potassium iodide are introduced and the separated iodine titrated with $\frac{N}{10}$ thiosulphate.

In the most successful results the bromide solution contained 2·5 grammes of potassium bromate, and about 10 grammes of potassium bromide in a litre of water. Twenty-five c.c. of this solution corresponded with 25·49 c.c. of thiosulphate solution, and 1 c.c. of the latter to 0·01097505 gramme of iodine or 0·00199111 gramme of salicylic acid.

The percentage of salicylic acid thus found in the same sample of sodium salicylate as used before varied in four determinations from 86·21 to 86·43 per cent.

This method is not applicable to the analysis of tabloids composed of starch and sodium salicylate. In such cases the substance should be dissolved in 90 per cent. alcohol, the solution brought to a definite volume, filtered from the undissolved starch, and an aliquot part of the filtrate used for the analysis. In a mixture of 90·91 cent. of sodium salicylate and 9·09 per cent. of starch, the authors found in this wa 89·97 per cent. of the former.

In the analysis of wines which contain sulphurous acid, aldehyde sulphurous acid, and other substances which act upon bromine, the best method of determining salicylic acid, when present, is to make the liquid alkaline, concentrate it, render it acid, and extract it with a mixture of ether and petroleum spirit. The extract thus obtained is shaken with alkaline water, which removes the salicylic acid, and this aqueous solution can then be used in the bromine method.

As regards the colorimetric method of estimating salicylic acid by means of iron

chloride, the authors state that it can only be used when the amount of salicylic acid is less than 2 milligrammes. C. A. M.

Electrolytic Recovery of Copper, Zinc, and Tin from Preserves. Hilger and L. Labaud. (*Chem. Zeit.*, 1899, xxiii., 854.)—The organic matter of the sample is best destroyed by heating with sulphuric acid, as in the Kjeldahl-Halenke method; but for the estimation of copper, treatment with 25 per cent. nitric acid is satisfactory. Zinc is deposited from an alkaline solution of its phosphate with a current of 0·2 to 0·3 ampere at about 4 volts. Tin is preferably recovered from a solution of ammonium thiostannate, or it may be thrown down with sulphuretted hydrogen, the precipitate dissolved in ammonium sulphide, and the latter liquid electrolyzed. F. H. L.

INORGANIC ANALYSIS.

Separation and Determination of Arsenic and Antimony in Ores. O. C. Beck and H. Fisher. (*School of Mines Quarterly*, 1899, xx., 372.)—This article describes an investigation into the various methods proposed for estimating arsenic and antimony in ores, which was instituted to discover the quickest and most accurate process. For the determination of the arsenic, Pearce's method—fusion of the ore with sodium carbonate and nitrate, precipitation of the arsenic with silver nitrate, and titration of the solution in nitric acid with standard ammonium thiocyanate, using ferric alum as indicator—gives slightly low results. Evaporating the ore three times to dryness with fuming nitric acid before fusing it, as above, also showed loss of arsenic (probably) by volatilization. Fusing the ore similarly in a crucible coated with fused potassium nitrate gave correct results, but the process is too long. Fischer's distillation method—decomposing the ore in hydrochloric acid and potassium chlorate, distilling the arsenic in presence of ferrous sulphate, and precipitating the distillate with sulphuretted hydrogen—is accurate, but too lengthy. Pattinson's process—solution in hydrochloric acid and chlorate, reduction of the arsenic with stannous chloride, and precipitation with sulphuretted hydrogen—is accurate and rapid, especially if the arsenious sulphide is titrated with iodine; weighing the sulphide is less satisfactory, owing to the free sulphur. For the determination of the antimony, sulphide processes come out too high; oxide processes too low, owing to mechanical loss when the sulphide is treated with nitric acid. Jannasch's method of converting the sulphide into oxide is better, but takes much time, and introduces a large amount of sulphur which must all be oxidized before ignition. Weller's process—fusion of the ore (according to Rose) with sodium hydroxide, solution of the sodium hydrogen metantimoniate in hydrochloric acid and chlorate, precipitation with sulphuretted hydrogen, re-solution of the sulphide as before, addition of potassium iodide, and titration of the excess with thiosulphate and starch—and Mohr's method—reduction of the antimonic chloride, prepared, as in Weller's process, with sulphurous acid, and titration with decinormal iodine in presence of sodium tartrate and sodium bicarbonate—gave figures which agreed closely one with another. F. H. L.

Separation of Gold from Metals containing Platinum. E. Priwoznik. (*Oesterr. Zeits. Berg. u. Hüttenw.*, 1899, xlvii., 356; through *Chem. Zeit. Rep.*, 1899, 233.)—The sample is reduced to filings, and digested with nitric acid (specific gravity, 1·199) as long as silver is dissolved. The liquid is poured off, the metal washed, and an aqua regia composed of 100 c.c. of strong hydrochloric acid, 43 c.c. of strong nitric acid, and 143 c.c. of water (which hardly attacks platinum) is added. When the surface is coated with silver chloride the acid is run off, and the deposit dissolved in weak ammonia. Six alternations between the acid and the ammonia leave pure platinum behind. The gold solutions are evaporated with hydrochloric acid till the chloride crystallizes; it is then dissolved in water, and the platinum thrown down with ammonium chloride. The gold is finally precipitated with ferrous sulphate, etc.

True alloys of gold, silver, copper, and platinum are first fused with three times their weight of lead, or preferably zinc. The melt is granulated in water, digested with sulphuric acid, and further treated as already described. F. H. L.

Separation of Copper from Tellurium. F. Stolba. (*Casopis pro prumysl chemicky*, 1899, ix., 11; through *Chem. Zeit. Rep.*, 1899, 233.)—The author's process depends on the fact that invert sugar precipitates the copper from an alkaline solution of copper below 100° C., whereas tellurium is only thrown down on boiling.

F. H. L.

Separation of Iron from Chromium, Zirconium, and Beryllium by Volatilization. F. S. Havens and A. F. Way. (*Zeits. anorg. Chem.*, 1899, xxi., 389.)—Gooch and Havens have recently shown that from a mixture of ferric oxide and alumina the iron may be completely volatilized as ferric chloride by treatment with a current of hydrochloric acid gas containing free chlorine at a temperature of 180° C. (ANALYST, 1899, xxiv., 307). The same process is available for separating iron from any of the metals mentioned in the title. In order to avoid danger of mechanical losses, the operation is best conducted at not exceeding 200° C., at which temperature 0·1 gramme of iron may be driven off in one hour, but the heat may be raised for a few minutes at the end of the process to remove the last traces of iron. The gaseous mixture is conveniently prepared by allowing sulphuric acid to drop into strong aqueous hydrochloric acid containing common salt and a little manganese dioxide. F. H. L.

Volumetric Estimation of Manganese in Permanganates by means of Arsenious Acid. C. Reichard. (*Chem. Zeit.*, 1899, xxiii., 801.)—This process depends on the fact that permanganates are reduced by an alkaline solution of arsenious acid in the cold, or by a neutral solution of the same reagent at about 50° C. The reaction proceeds according to the equation:

$$4KMnO_4 + 5As_2O_3 = 5As_2O_5 + 2K_2O + 4MnO.$$

The method possesses a double advantage: as arsenious acid can be obtained in a state of chemical purity, it serves as a means of standardizing permanganate solu-

tions, and the precipitated oxide can be treated gravimetrically to serve as a check on the titration. The liquid containing the permanganate to be analysed is mixed with an excess of standard solution of arsenious acid, heated till the manganous hydroxide falls, and then filtered; the precipitate is washed, the filtrate neutralized with hydrochloric acid, sodium bicarbonate is added, and the whole is titrated with iodine and starch. It is not even necessary to filter off the precipitate, for the manganous hydroxide can be dissolved in sulphuric acid immediately it is reduced, and the liquid titrated with a permanganate solution which has been previously standardized on arsenious acid in the presence of sulphuric acid. The examples quoted are satisfactory.

F. H. L.

Gas-Volumetric Estimation of Nitric Oxide. G. v. Knorre and K. Arndt. (*Ber.*, 1899, xxxii., 2136.)—When nitric oxide and hydrogen are led over red-hot palladium-asbestos, two reactions take place:

(*a*) $2NO + 5H_2 = 2NH_3 + 2H_2O$ (2 vols. + 5 vols. = 0 vol. + 0 vol.)
(*b*) $2NO + 2H_2 = N_2 + 2H_2O$ (2 vols. + 2 vols. = 2 vols. + 0 vol.)

The former does not take place quantitatively; therefore the amount of ammonia, or the contraction in volume, is not under control. But if the gases are passed slowly through Drehschmidt's platinum capillary tube (*Ber.*, 1888, xxi., 3245), heated to bright redness, any ammonia which may be produced is instantly decomposed, and the total reaction proceeds according to *b*. Similarly, nitrous oxide and hydrogen react as follows:

$N_2O + H_2 = N_2 + H_2O$ (1 vol. + 1 vol. = 1 vol. + 0 vol.)

The composition of a mixture containing x c.c. of nitric oxide and y c.c. of nitrous oxide can therefore be calculated thus:

$$x + y = V$$
$$1{\cdot}5\,x + y = C \text{ (contraction)}$$
$$\text{whence} \quad x = 2\,(C - V)$$

The process may be checked by measuring the hydrogen required or the nitrogen produced, so that gases composed of $NO + N_2O + N$, $NO + N$, $N_2O + N$, $N_2O + O$, etc., are all amenable to treatment.

F. H. L.

Estimation of Sulphuric Acid in Presence of Iron. G. Lunge. (*Zeits. anorg. Chem.*, 1899, xxi., 194.)—This article is mainly polemical, being a second reply to Küster and Thiel, and a discussion of the opinions advanced by those authors, by Herting, and by Meineke (*cf.* ANALYST, 1899, xxiv., 137, 164; *Zeits. anal. Chem.*, xxxvi., 209). Lunge observes that he has never recommended his process for the analysis of burnt pyrites; it was devised for the valuation of the raw ore only. He also makes the point that in Küster and Thiel's method it is difficult to tell when the proper amount of barium chloride has been added, because the suspended ferric hydroxide renders the liquid opaque; moreover, a complete extraction of the hydroxide from the barium sulphate is more troublesome and lengthy than represented by those authors.

In order to determine the relative merits of the different processes when

applied to burnt pyrites, the whole question has been reinvestigated by Lunge's assistant Bebie, who has obtained the results shown in the annexed table. The methods employed were: (A) the original Watson-Lunge process (*Zeit. angew. Chem.*, 1892, 449); (B) Meineke's process of attacking the material with sodium carbonate and potassium chlorate, precipitating the sulphur with barium; (C) solution in aqua regia, followed by Lunge's ammonia method; (D) solution in aqua regia, followed by Küster and Thiel's plan; and (E) solution in aqua regia, and reduction of the ferric chloride with zinc (Meineke).

Process.	I.	II.	III.	Mean.	Time occupied.
A	1·98	2·03	1·88	1·96	1½ hours
B	1·98	2·00	2·01	2·00	8 or 9 hours
C	1·94	1·96	1·92	1·94	,, ,,
D	1·92	1·97	1·95	1·94	,, ,,
E	1·90	1·93	1·92	1·92	6 hours

F. H. L.

[Lunge does not refer to Heidenreich's note (ANALYST, 1899, xxiv., 193); but Meineke's process (E above) appears to be identical therewith, except that the former author has written of raw pyrites, while Meineke dealt with the burnt substance. (See also following abstract.)—ABS.]

A Review of the Methods for Estimating Sulphur in Iron, Pyrites, Slags, Coal, Coke, Asphalt, Caoutchouc, and Gas-purifying Material. O. Herting. (*Chem. Zeit.*, 1899, xxiii., 768.)—It is already well known that processes for determining sulphur in iron which depend on treatment with acids and absorption of the sulphuretted hydrogen are incorrect, for part of the sulphur is evolved as an organic compound (methylic sulphide), and this portion is not oxidized by bromine and hydrochloric acid or by hydrogen peroxide. Phillips, however, has proved that ignition in presence of hydrogen and carbon dioxide is quite efficient to convert the organic sulphur into sulphuretted hydrogen; and, based on this observation, Campredon has proposed absorbing the products of combustion in zinc acetate acidified with acetic acid, titrating the zinc sulphide with normal iodine and thiosulphate; while Schulte prefers to use acid cadmium acetate, converting the cadmium sulphide into copper sulphide, and weighing the latter in the form of oxide. Both methods are satisfactory; Campredon's is somewhat quicker in operation. For the determination of total sulphur in iron, Blair has described a process (ANALYST, 1897, xxii., 279) which is very suitable for occasional employment, and where great rapidity is not essential. For routine purposes the author is engaged in elaborating a colorimetric method with cadmium in Wiborgh's apparatus, details of which will follow. It is not possible by carrying out these absorption processes without the intermediate combustion tube, and calculating from the sulphuretted hydrogen so evolved, to ascertain the amount of "organic sulphur" in iron. Schulte's results have shown that the proportion of "organic sulphur" varies within very wide limits even in the same grades of metal.

To determine sulphur in raw pyrites Lunge's process is quite properly employed. Küster and Thiel's modification (ANALYST, 1899, xxiv., 137), according to Herting, is

"worthy of notice." For practical purposes the plan outlined in Heidenreich's preliminary note (ANALYST, 1899, xxiv., 193) is more serviceable; but the beaker should be kept well covered and in the dark while the barium sulphate is settling. The method has been improved by Lehnardt, who adopts stannous chloride instead of metallic zinc as the reducing agent, thus saving considerable time. For burnt pyrites fusion processes with alkali carbonates and nitre are the best. Slags from the puddling furnace should be treated like iron ores; blast-furnace slags by solution in bromine and hydrochloric acid. In the latter case the silica should be removed and the sulphuric acid precipitated directly, for the percentage of iron in such materials is generally low. The sulphur in blast-furnace slags may be estimated volumetrically by rubbing down 0·5 gramme in an agate mortar, adding 150 c.c. of warm water and a little starch, then introducing an excess of decinormal iodine and 20 c.c. of hydrochloric acid, agitating for one minute, and titrating with thiosulphate.

For coal, coke, and asphalt Eschka's process as improved by Hundeshagen is the most suitable, the absorbing material being magnesium oxide mixed with equal parts of sodium and potassium carbonate, or with potassium carbonate only. For indiarubber Unger's method is to be recommended: 0·5 gramme in very small pieces is carefully ignited with 12 grammes of copper oxide and 2 grammes of sodium carbonate. The melt is taken up in aqua regia, evaporated to remove the antimony, filtered and precipitated with barium chloride; the barium sulphate is fused with sodium carbonate, and the sulphuric acid thrown down a second time.

Estimation of sulphur in spent oxide by extraction with carbon disulphide yields results which are too high owing to the presence of tar, etc. The substance should be dried at 75° C., for six hours, ground till it will pass through a sieve of 400 meshes per square centimetre, then exposed to air for one hour. One gramme is next extracted with carbon disulphide, and the dried extract is oxidized with 25 c.c. of warm 1·19 hydrochloric acid and a few crystals of potassium chlorate; the excess of chlorine is driven off, and the sulphuric acid determined as usual. F. H. L.

Determination of Oxygen in Water. F. Zetsche. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 696, 697.)—The author has had considerable experience with Winkler's method for the open-air determination of oxygen in water, and regards it as the most practicable of any method devised for the purpose. His mode of working is as follows:

Apparatus and Chemicals Required.—(*a*) A number of glass-stoppered flasks (according to the number of samples to be taken), measuring from 250 to 300 c.c. capacity, and each containing ten to fifteen small porcelain balls. (*b*) A saturated solution of manganous sulphate (say 50 c.c.). (*c*) A solution containing 48 grammes of sodium hydrate and 15 grammes of potassium iodide in 100 c.c. of water. (*d*) 500 c.c. of concentrated hydrochloric acid. (*e*) Three pipettes, to deliver 1, 2, and 5 c.c. respectively. The capacity of each of the flasks must be accurately determined after the introduction of the balls.

Procedure.—The flasks are filled to overflowing with the water to be examined, and 1 c.c. of the manganous sulphate solution and 2 c.c. of the alkaline potassium

iodide solution are run in to the bottom of each by means of pipettes. The flasks are then closed and briskly shaken, the movement of the balls insuring complete mixing. When the brown precipitate produced has settled, the flasks are opened and 5 c.c. of hydrochloric acid run in (also to the bottom of the flasks). The flasks are then closed and again shaken, and as soon as the precipitate in each has dissolved, the liquid is transferred to a beaker, and the liberated iodine titrated with $\frac{N}{100}$ sodium thiosulphate solution. In calculating the results, allowance must of course be made for the 3 c.c. of reagents added. H. H. B. S.

The Cleaning of Crucibles. F. Wirthle. (*Chem. Zeit.*, 1899, xxiii., 803.)—Platinum crucibles in which vegetable substances have been incinerated are far more easily cleansed by melting borax in them than by the use of the favourite potassium bisulphate. Porcelain crucibles soiled with silver chloride, lead sulphate, stannic oxide, etc., are readily cleansed by filling them with acid and adding a fragment of zinc; after a short time the reduced metals can be completely removed. The author suggests that this electrolytic method of decomposing insoluble precipitates should perhaps be quicker in qualitative analysis than the usual plan of fusing them with various fluxes. F. H. L.

REVIEW.

THE CHEMISTRY OF ESSENTIAL OILS AND ARTIFICIAL PERFUMES. By ERNEST J. PARRY. London: Scott, Greenwood and Co. Price 12s. 6d. net.

Owing to the vigorous manner in which the study of the essential oils has been prosecuted during recent years, and to the enormous number of valuable, and in many cases brilliant, researches which have during that short period been brought to a successful conclusion, we have fully arrived at the point at which the services of a painstaking and careful gleaner become extremely desirable, and this service Mr. Parry has rendered in compiling and issuing to the world the volume under review.

Seeing that no work covering similar ground exists in the English tongue, British chemists will be quite ready to confirm the author in his belief that its appearance demands no apology.

Chapter II. deals with the properties of those compounds which are found in essential oils, but does not treat the subject as exhaustively as one could have wished, seeing that a work of this character must necessarily appeal rather to the chemical specialist than to the general chemist. It is with the analytical portion of the book that I am now chiefly concerned, but I may remark in passing that cymene is para-methyl-iso-propyl-benzene, and not the normal propyl compound, and that thymol and carvacrol are likewise iso-propyl derivatives. Further, I do not notice any reference to the open chain hydro-carbons which have been found in some oils, and which are of considerable interest.

When one remembers the very large trade interests involved, and the ease with which the sophistication of valuable oils could until quite recently (and in some cases

can still) be practised, the need of analytical processes capable of detecting, and so of preventing, these sophistications becomes at once apparent.

Moreover, it has to be borne in mind that most essential oils vary in composition within certain limits, and that the most variable constituent is often that upon which the value of the oil chiefly depends.

Analytical processes are therefore necessary for the evaluation of these oils as well as for the detection of adulteration.

Mr. Parry has devoted one chapter to a discussion of certain methods, which are generally applicable to essential oils, dealing with the processes for the estimation of certain special constituents in later sections of the book, an arrangement which certainly makes for convenience.

In the general section some details in regard to the determinations of specific gravities are given, the use of a bottle being recommended for this purpose, a sprengel tube being only employed when the volume of oil at the analyst's disposal is too small for the former method. But surely it is in the case of liquids, like the majority of essential oils, having high co-efficients of expansion and great mobility, that the superiority of the sprengel tube over the bottle is so evident. We are next treated to the inevitable dissertation on the polarimeter, its construction and use. Both these matters might well have been omitted, seeing that every chemist concerned in the analytical examination of essential oils might well be supposed to be conversant with them. On the other hand, many analysts would doubtless have welcomed some information in regard to the simplest and most convenient apparatus for distillation under reduced pressure. It is the process which has to be carried out prior to the scientific investigation of practically all essential oils, and one that can often be resorted to with great advantage in their analytical examination. A few hints in regard to forms of receivers, distillation in an atmosphere of carbonic acid gas, and other points, might have been of service to many chemists. In this section no mention is made of the "methyl number," a useful determination in some cases.

The special analytical processes are clearly and carefully described, and the book will undoubtedly prove of considerable value to all chemists who are engaged in the examination of these oils.

Mr. Parry has evidently spared no pains in selecting from the enormous masses of recorded results those to which the greatest amount of probability attaches, and he has given numerous references to the original papers when they are likely to be of value to the reader. The book is well printed, and possesses a good index.

In many places, however, the wording is a little loose. One would like to know for example what is meant by the expression "excretionary functions" as applied to essential oils. Presumably it should refer to the cell. The words "under reduced pressure" should be substituted for "in vacuo," in speaking of distillation, and "rotatory" for "rotary."

There are many little blemishes of a literary character which, whilst in no way detracting from the real value of the book, yet tend to diminish the pleasure with which one reads it. These would doubtless disappear in a future edition.

A. C. C.

THE ANALYST.

FEBRUARY, 1900.

OBITUARY NOTICE.

THE LATE MR. GEORGE JARMAIN.

We regret to have to chronicle the death, at the age of seventy-three years, of an old member of our Society, Mr. G. Jarmain, F.I.C., F.C.S., which took place at Huddersfield on January 16. Mr. Jarmain held the post of Public Analyst to the Huddersfield Corporation since the institution of that office. He was a native of York, and received his education at the Training College there. He first adopted the scholastic profession, but relinquished it for the study, and subsequently for the practice, of chemistry. He lectured at the Huddersfield Technical College for about forty years, resigning his post there only five or six years ago. His name is associated with several elementary works on chemistry, including his well-known and, for beginners, valuable little book on "Qualitative Analysis."

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

The annual general meeting of the Society was held on Wednesday, January 24, in the Chemical Society's Rooms, Burlington House. The President (Mr. W. W. Fisher, M.A.) occupied the chair.

The minutes of the previous meeting were read and confirmed.

A certificate of proposal for election to membership in favour of Mr. B. W. J. Warren, A.I.C., was read for the second time; and certificates in favour of Messrs. Norman Parr Booth, assistant to Mr. Wm. Chattaway, Apothecaries' Hall, London; John Macallan, A.R.C.S.I., F.I.C., chief assistant to Sir Charles A. Cameron, Municipal Buildings, Dublin; and C. T. Tyrer, Works Manager and Analytical Chemist, Stirling Chemical Works, Stratford, were read for the first time.

Messrs. J. A. Foster, J. B. P. Harrison and D. Lloyd Howard were elected members of the Society.

The Hon. Treasurer (Mr. E. W. Voelcker), in presenting the accounts of the Society for the past year, said that the balance of receipts over expenditure during 1899 was considerably less than had been the case in the previous year. In 1898 he successful, with only one exception, in collecting all the subscriptions that

were due, including nine outstanding from earlier years. Of the 1899 subscriptions nine remained in arrear at the end of the year, while there had only been one outstanding subscription to collect, and the balance of income for 1899 had been affected accordingly. The expenditure during the year had been carefully kept down. The cost of the ANALYST was slightly less than in the previous years. The expenses of meetings were somewhat higher, owing to the fact that one more general meeting and three more council meetings had been held. In petty disbursements, postage, and expenses of a similar class, a considerable saving was shown, while in the case of printing and stationery there was an increase of about £3. A somewhat unusual item of expenditure appeared, namely, law charges, which had been incurred for the benefit of a member whose interests had been in danger of being prejudicially affected by the action of a certain County Council. In the early part of 1899 the Society's investments had been increased by the purchase of £100 2½ per cent. annuities. The securities held by the Society comprised £300 Consols and £200 2½ per cent. annuities, as against only £150 Consols at the end of 1894, an increase which, made as it had been in the short space of five years, might be regarded with considerable satisfaction.

On the motion of Mr. G. EMBREY, seconded by Mr. P. A. E. RICHARDS, the accounts were unanimously adopted.

Votes of thanks to the Hon. Treasurer and Auditors were unanimously passed.

The President then delivered his annual address.

A vote of thanks to the President for his address was proposed by Mr. HEHNER, with the request that he would allow it to be published. This was seconded by Dr. DYER, and carried unanimously.

The PRESIDENT, having responded, announced that the list of officers and members of Council nominated for the ensuing year had been without any exception accepted, and expressed his thanks to the Society for again placing him in the position of President. He felt that in that position he owed a great deal to the officers of the Society, and especially to the Hon. Secretaries as well as to the senior members of the Council.

A vote of thanks was unanimously passed to the President and Council of the Chemical Society for permission to use their rooms during the past year.

OFFICERS AND MEMBERS OF COUNCIL FOR 1900.

President.—W. W. Fisher, M.A.

Past-Presidents.—M. A. Adams, F.R.C.S., Alfred H. Allen, Sir Chas. A. Cameron, C.B., M.D., F.R.C.S., A. Dupré, Ph.D., F.R.S., Bernard Dyer, D.Sc., Otto Hehner, Alfred Hill, M.D., J. Muter, M.A., Ph.D., Thos. Stevenson. M.D., F.R.C.P.

Vice-Presidents.—Charles E. Cassal, E. W. T. Jones, S. Rideal, D.Sc.

Hon. Treasurer.—E. W. Voelcker, A.R.S.M.

Hon. Secretaries.—E. J. Bevan, Alfred C. Chapman.

Other Members of Council.—L. Archbutt, A. Ashby, M.B., F.R.C.S., G. Embrey, J. H. B. Jenkins, Arthur R. Ling, C. A. Mitchell, B.A., James Nimmo, Thomas A. Pooley, B.Sc., P. A. E. Richards, H. Droop Richmond, R. T. Thomson, Rowland Williams.

ANNUAL DINNER OF THE SOCIETY OF PUBLIC ANALYSTS.

THE annual dinner was held at the Criterion Restaurant after the annual meeting, under the chairmanship of the President (Mr. W. W. Fisher, M.A.). There were present over seventy members and guests, among the latter being Mr. R. T. Prowse, C.B., Secretary H.M. Customs Establishment; Prof. T. E. Thorpe, F.R.S., President of the Chemical Society; Dr. Thos. Stevenson, F.R.C.P., President of the Institute of Chemistry; Dr. Stocker, Master of the Society of Apothecaries; Mr. W. Martindale, President of the Pharmaceutical Society; Mr. F. M. Mercer, Master of the Wheelwrights' Company; Mr. C. E. Groves, F.R.S.; Prof. Frank Clowes, D.Sc.; Dr. Henry E. Armstrong, F.R.S.; Dr. F. D. Chattaway; Mr. E. Rigg, M.A.; Mr. Edward Holmes; Mr. E. M. Holmes, F.L.S.; Mr. W. J. Fisher; Mr. W. P. Squire; and Mr. Aubrey W. Rake.

The following toasts were proposed: "The Queen," by the President; "The Navy, Army and Reserve Forces," by the President, responded to by Major Cassal; "The Institute of Chemistry," by Mr. Otto Hehner, responded to by Dr. Stevenson; "Kindred Societies," by Dr. Armstrong, responded to by Prof. Thorpe; "The Society of Public Analysts," by Prof. Frank Clowes, responded to by the President; "The Guests," by Dr. Bernard Dyer, and responded to by Mr. R. T. Prowse, C.B.

ON THE DETERMINATION OF THE IODINE VALUE.

BY DR. J. J. A. WIJS.

(*Read at the Meeting, December* 6, 1899.)

I READ with great pleasure the paper by Dr. Lewkowitsch on this subject recorded in the ANALYST, p. 257, and am desirous of making the following observations on the subject-matter of it:

I. *Iodine Values found for Allyl Alcohol.*—I fully agree with Dr. Lewkowitsch that allyl alcohol is not a substance specially suitable for deciding the respective values of the different methods for determining iodine values. The rapidity with

which the addition process takes place in allyl alcohol being less than that of the oil which has the smallest rapidity (linseed-oil), allyl alcohol demands a greater additive force on the part of the liquid than is necessary in its ordinary application.

From some experiments published in my first paper (*Zeits. f. Anal. Chem.*, 1898, 277), Dr. Lewkowitsch calculates for allyl alcohol the iodine value 392. These experiments are, however, unsuitable for this purpose. The whole series was made merely with a view to determining the splitting off of acid from the ICl-addition product, and in order to have this splitting-off process as uncomplicated as possible, and not affected by the formation of acid which always takes place when a Hübl solution is allowed to stand for any length of time, the duration of the reaction was kept very short (quarter to half-an-hour). The iodine values calculated from these experiments are therefore much too low, particularly for substances such as allyl alcohol, linseed oil, or cholesterol, which possess a small rapidity of addition.

Dr. Lewkowitsch obtained with ICl-acetic acid liquid for a sample of allyl alcohol iodine values of 419-420, and with the Hübl method 421-422, whereas I found with the same sample with ICl-acetic acid liquid 429, and for another sample by Hübl's method 425. The difference between the results obtained with the same method depends, as is evident from a letter I received from Dr. Lewkowitsch, upon a different method of working, *i.e.*, having a different excess of iodine present. I always used an excess of about 75 per cent. of the quantity originally added, whereas Dr. Lewkowitsch writes that he also in every case employed an excess of 75 per cent., and in most cases considerably more, approximating to 100 per cent. It is evident that this can only have been 75 to 100 per cent. of the quantity of halogen absorbed, *i.e.*, only 43 to 50 per cent. of the quantity originally added. It is, therefore, not at all a matter of surprise that Dr. Lewkowitsch obtained lower iodine values than mine.

II. *Effect of Time on the ICl-acetic Acid Liquid.*—Dr. Lewkowitsch finds that a solution of iodine chloride in 95 per cent. acetic acid is much more liable to alteration (decrease) than a solution in an acid of 99 per cent. When the acid is pure and especially free from oxidizable matters, there is, theoretically, no possibility of any decrease. Dr. Lewkowitsch found that a solution in 95 per cent. acid, after sixty-four hours, had decreased 4 per cent. of its value; whereas I had stated (*Berichte d. deutsch. Chem. Ges.*, xxxi., 750) the decrease to be 0·3 per cent. in ninety-six hours. I can find no other explanation for this difference than the assumption that Dr. Lewkowitsch's 95 per cent. acid was not so pure as mine.

III. In the third place, Dr. Lewkowitsch writes that the iodine determinations made with Hübl solution lead to correct results provided that the Hübl method is applied in a proper manner, and further on he says that the solution should not be allowed to act longer than six or seven hours on the fat under examination. I must add here that this limitation to seven hours only bears reference to those cases in which, in the first place, fresh (*e.g.*, sixteen-hours-old) iodine solution is used; and, secondly, where an excess of about 75 per cent. of the added iodine is employed. When treating oils of a high iodine value (*e.g.*, linseed oil) with a Hübl solution that is not fairly fresh, say about five days old, twenty-four hours are required.

It is clear that what I call a proper application of the Hübl method is but little

different from the usual one carried out in the case of oils with a low iodine value; whereas in the case of oils with a high iodine value the difference is greater.

I was therefore convinced that the iodine value of linseed-oil especially required a revision, and I made one (*Revue ü. d. Fett- und Oelindustrie*, 1899, 29). This paper not having appeared in the ANALYST in abstract form, I give a short account of it.

I determined the iodine values of eighty-six samples of guaranteed pure linseed-oil, all from seeds of known origin; sixty-nine were pressed from unmixed seeds, and seventeen from mixed. The results were as follows:

	Iodine Values.	
Dutch linseed oils	From 191·5 to 201·8	
North Russian (Baltic) oils ...	,, 192·1 ,, 200·0	(only one had a value 188·5)
South Russian oils	176·3 186·3	
Indian oils ...	182·2 187·5	
La Plata oils ...	174·7 182·7	
North American oils	177·8 188·5	

The more rapidly-drying varieties (Dutch and North Russian), which are only used for paints and varnishes, have higher iodine values than those used solely for soap-making. I also determined the specific gravity at 15° C. of twenty-four of these samples, and found the following relation between this constant and the iodine value:

	Iodine Values.	Specific Gravity.
One sample	Higher than 200	... 0·9352
Mean of four samples ...	... Between 195·0 and 200·1 ...	... 0·9339
,, ,, ,, ...	... ,, 190·0 ,, 195·1 ...	... 0·9329
,, ,, ,, ...	... ,, 185·0 ,, 190·1 ...	... 0·9322
,, six ,, ...	... ,, 180·0 ,, 185·1 ...	... 0·9317
,, five ,, ...	Lower than 180·1	... 0·9310

DISCUSSION.

Dr. LEWKOWITSCH said that although Dr. Wijs and himself were more or less in agreement on this subject, there were one or two points raised in the paper which seemed to require correcting or amplifying. He was very glad that after all Dr. Wijs agreed with him in thinking that allyl alcohol was not a suitable substance to decide the question at issue. It had, in fact, been introduced by a third party, and it was this that had led him (the speaker) to calculate, from one of Dr. Wijs' former papers, the number 392. He quite accepted the author's remarks on this point. Dr. Wijs thought that he could explain the divergence in the iodine numbers of the same sample of allyl alcohol examined by both (viz.: Wijs, 426; Lewkowitsch, 420), by the fact that different excesses of the reagent had been used. There was, indeed, some misunderstanding as to the excess to be employed. Dr. Wijs considered that if from 100 parts of iodine added 25 were absorbed, an excess of 75 per cent. was used, whereas he (the speaker) should call that an excess of 300 per cent. However, he had started a number of experiments for the purpose of settling this point. The following figures showed that the variations between different observations were sometimes greater than those due to differences of excess, and it would seem that it did not really much matter whether one worked with an excess—in Wijs' sense—of

75 per cent. or 43 per cent. (or, as he would call it, 300 per cent. and 100 per cent. respectively):

Substance.	Iodine Value.	Excess of Iodine in W.'s sense. Per cent.	Excess of Iodine in L.'s sense. Per cent.
Allyl alcohol	413·2	73·7	281·2
,, ,, ...	416·0	52·8	89·3
,, ,, ...	416·0	52·8	89·3
Linseed oil	179·8	77·6	347
,, ,, ...	180 9	76·0	315
,, ,, ...	179·3	57·2	133
,, ,, ...	178·6	52·5	110
Candle-nut oil	163·4	73·6	278
... ...	163·4	72·99	270·3
... ...	162·1	53·4	115·0
.. ..	159·1	49·5	97·9
... ...	163·9	77·5	308·9
... ...	163·9	77·5	308·9
... ...	162·1	51·6	106·8
... ...	162·1	51·6	106·8
Oleic acid	82·9	76·1	319·9
,, ,, ...	83·25	73·9	283·2
,, ,, ...	82·81	52·7	115·5
,, ,, ...	82·82	50·0	100·4

As a rule, the excess he used was not calculated beforehand, but left more or less to chance, and varied generally between, say, 100 per cent. and 150 per cent. (in his own sense). But even making the largest possible allowance, the difference of about 1 per cent. in the value of allyl alcohol did not explain the difference of Dr. Wijs' own figures for allyl alcohol. He thought, therefore, that the matter might fairly be allowed to drop there, accepting the conclusion that it did not really matter whether the excess was 300 per cent. or half of that, because, according to the law of mass action, secondary reactions were bound to occur with the possible formation of substitution products, thus probably introducing greater errors than those due to differences in the excess. The temperature variations had only a very slight influence, as Dr. Wijs himself had shown. The explanation Dr. Wijs had given for the somewhat rapid decomposition of the speaker's solution, prepared with 95 per cent. acetic acid—viz., that the acid had been impure—did not hold good, it having been prepared from pure glacial acetic acid, it was the same sample from which the 100 per cent. glacial acid solutions were made later on. With regard to the figures given by Dr. Wijs for the various linseed oils, these numbers were very valuable as far as they went, but they ought not to be taken as indicating the order in which the oils derived from the various countries ranked in quality (or purity). He himself had examined some Indian linseed oils, the iodine value of which came up to 193, tested by the old Hübl process, allowing the solution to act from four to six hours. The specific gravity table showed the regularity one would expect, as the higher the iodine value, *i.e.*, the larger the quantity of linolic and linolenic acid present, the higher the specific gravity must be, since the specific gravities of linolic and linolenic acids were higher than

that of oleic acid. But it would not be permissible to allow the rule shown by the table to pass into literature as a general one.

Mr. A. MARSHALL said that, in his experience, solution made even with perfectly pure acetic acid, although it lost very little strength during the first few days, showed on keeping for some months a considerable decrease in strength, and became much darker, probably owing to chlorination of the acetic acid and reconversion of the iodine chloride into iodine.

Dr. LEWKOWITSCH said that in Dr. Wijs' process long hours of standing were not permissible at all. The author, in his fourth paper, had proved pretty accurately the occurrence of side reactions after a certain time, which affected the result in a reverse direction. This was well known to every observer, for if after titration of the iodine the solution were allowed to stand it became blue again. One of the chief points in Wijs' work was in showing that the importance which had been attached to a standard time for exposure was well founded, and that it was necessary to adhere strictly to a certain period, sufficiently long to insure the reaction coming to an end. He (Dr. Lewkowitsch) had been able to show that Hübl's method gave identical results with that of Wijs', but in the case of the latter the solution would keep for at least half a year, so that a blank determination was not absolutely necessary, and actually less time was required for a test than for a determination of the saponification value. It was so easy in preparing the Wijs' solution to hit exactly the point when the titer was doubled that there seemed to be no necessity for having an excess of either chlorine or iodine. He considered that a point had been reached when the discussions on, and the endless modifications of, the Hübl process might with advantage cease.

ON A METHOD FOR DISTINGUISHING BETWEEN HOPS AND QUASSIA.

BY ALFRED C. CHAPMAN, F.I.C.

(*Read at the Meeting, December* 6, 1899.)

IN the course of an investigation of the resinous constituents of hop-flowers, the results of which have been published elsewhere, I observed that these substances, when extracted from the hops by means of ether, yielded a somewhat considerable quantity of valeric acid on oxidation with an alkaline solution of potassium permanganate.

It occurred to me at the time that this fact might serve as the basis of a method for distinguishing between hops and quassia in fermented and other beverages, and the following experiments which I have since made show that such is the case.

In the first place, quassia-chips themselves were extracted with dry ether, and the small quantity of extract so obtained was submitted to the action of alkaline permanganate solution, but no valeric acid was obtained.

In order to arrive at the best conditions for the application of this method, fermented liquids of various kinds, bittered with hops on the one hand and with quassia on the other, were prepared in the laboratory in the following manner:

Cane-sugar solutions and malt-worts were prepared, containing in some cases 5 per cent., and in others 10 per cent., of dry solids. Each of these was divided into two portions, hops being added to the one at the rate of 10 grammes per 500 c.c. of the solution, whilst 2·5 grammes of quassia chips were added to the other. For equal weights, the quassia wood has roughly four times the bittering power of good strong hops, and if used to replace the latter, the quantity to be employed would probably be calculated on this basis. Both solutions were then boiled gently in covered beakers for one hour. At the end of this time they were filtered, yeast was added after cooling, and the solutions were allowed to ferment for several days.

The "artificial beverages" so prepared were then submitted to the following treatment: 500 c.c. were evaporated on a water-bath in a porcelain basin, fine recently-ignited sand being added towards the end of the operation, and the mass constantly stirred with a steel spatula to prevent it from adhering strongly to the surface of the dish. The residue was then transferred to an air-oven, and when quite dry was finely powdered in a mortar. This powder was next digested for some time with ether in a stoppered bottle, and the ethereal extract filtered into a flask, the ether being recovered by distillation. The flask was placed on a water-bath to drive off the last traces of ether, and the small quantity of residual matter oxidized by the careful addition of an alkaline solution of potassium permanganate, containing 40 grammes of parmanganate and 10 grammes of caustic potash per litre. This solution should be added in very small quantities at a time, the flask being vigorously shaken, and if necessary warmed. When the permanganate ceased to be readily reduced, a few drops of a hot solution of oxalic acid were added to complete the reduction, and the colourless liquid was filtered from the oxides of manganese into a glass dish, in which it was evaporated to dryness. The dry residue was then acidified with dilute sulphuric acid, when the odour of valeric acid in the case of the hop-bittered liquid became at once apparent, being rather accentuated by the carbon dioxide liberated at the same time from the potassium carbonate formed during the oxidation.

I may say that the smell observed is not that of pure valeric acid, but of valeric acid plus some other odorous compound, which serves to render it more characteristic.

In the case of the quassia experiment the liberated acid is chiefly acetic, with, of course, carbon dioxide, and only in a few cases was there any marked odour, which, however, was altogether different from that obtained from hops.

In the above experiments old hops responded as readily to this test as new hops.

Experiments were next made with beer itself. One litre of the beer was evaporated with sand, and the residue from the ethereal extraction treated as described above. In one or two samples of mild ale the indication was uncertain, but in all the samples of bitter beer and in the majority of the mild ales and porters examined this valeric smell was unmistakable.

Camomile extract behaves in a similar manner to hops, but chiretta yields no valeric acid.

This method is readily applicable to the examination of hop-bitter preparations (of a medicinal character), hop extracts, and similar products. It is also capable of furnishing additional evidence in the case of fermented beverages which have been

examined according to the systematic schemes in vogue, and which have yielded results of an uncertain nature.

In applying this method, it is important not to carry the oxidation of the ether residue too far. At first the permanganate solution is reduced readily, the mixture becoming warm, but towards the end it is usually necessary to heat slightly. With a very little experience there is no difficulty in arriving at the proper conditions, which cannot be definitely laid down, since the matter extracted by the ether varies both in character and quantity, and it must therefore be left to the operator to decide when the oxidation has been carried sufficiently far.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

The Detection of Formalin in Milk. A. Leys. (*Ann. de Chim. anal.*, 1899, iv., 338-342.)—The author describes the tests used in the Municipal Laboratory in Paris. The one principally relied upon is that of Jorissen (ANALYST, xxii., 282), in which 25 c.c. of the milk are shaken with 10 c.c. of a solution of phloroglucinol (1 gramme per litre), and subsequently with 5 to 10 c.c. of a solution of potassium hydroxide (1 of the ordinary laboratory solution with 2 of water).

It has been found, however, that in the proportion in which formalin is frequently met with in milk in Paris (1 : 10,000) there is a possibility of the colour being mistaken for that given by the potassium hydroxide alone with milk which has previously been boiled or artificially coloured with annatto, turmeric, or chrysoin yellow, and to eliminate these chances of error the following preliminary tests are made :

Ten c.c. of the milk are shaken with 20 c.c. of Adams' ammoniacal mixture of alcohol and ether. If after a few seconds the lower layer is completely opaque instead of being semi-transparent, the milk is regarded as having been boiled, thus altering the nature of the casein. When the lower layer is of a greenish tint and slightly fluorescent, annatto is indicated, and may be identified as described by the author in former papers (ANALYST, xxiii., 174 and 230). A red coloration of the lower layer points to the presence of turmeric, whilst chrysoin causes the upper layer to be golden yellow, and the milk itself gives a reddish-brown tint on treatment with potassium hydroxide.

When, in the absence of these substances, formalin has been detected by Jorissen's reagent, confirmatory evidence is obtained by distilling the milk and testing the distillate with Gayon's reagent (0·1 per cent. aqueous solution of fuchsin, 1,000 c.c. ; sodium bisulphite solution, 30° Bé., 10 c.c.; and concentrated hydrochloric acid, 10 c.c.). The milk itself is also tested by Denigés' method (ANALYST, xxi., 285).

C. A. M.

Chemical Composition of Butter Fat. C. A. Browne, jun. (*Journ. Amer. Chem. Soc.*, vol. xxi. [10], pp. 807-827.)—The quantities of mixed acids and corresponding triglycerides determined in the butter examined are:

	Acid. Per Cent.	Triglyceride. Per Cent.
Dioxystearic	1·00	1·04
Oleic	32·50	33·95
Stearic	1·83	1·91
Palmitic	38·61	40·51
Myristic	9·89	10·44
Lauric	2·57	2·73
Capric	0·32	0·34
Caprylic	0·49	0·53
Caproic	2·09	2·32
Butyric	5·45	6·23
	94·75	100·00

The unsaponifiable matter, amounting to only about 0·1 per cent., was not further investigated.

An elementary analysis of the fat gave results very closely according with the theoretical calculation from the above table, the values being:

	C. Per Cent.	H. Per Cent.	O. Per Cent.
Actual	75·17	11·72	13·11
Theoretical	74·86	11·71	13·43

C. S.

New Method of Estimating Starch. D. Crispo. (*Ann. de Chim. anal.*, 1899, iv., 289, 290.)—This is a rapid process, based on a polarimetric examination of an alkaline solution of the starch; a 10·1732 per cent. solution of starch examined in a 200 mm. tube, read at 100 Soleil-Ventzke-Scheibler divisions. 3·391 grammes of the sample are triturated with a little water, 50 c.c. of a 6 per cent. solution of potassium hydroxide added, and the liquid, after being diluted to about 140 c.c., kept for an hour on a boiling water-bath with constant agitation. When cold it is made up to 200 c.c., filtered, and examined with the polarimeter in a 200 mm. tube. The number of divisions, multiplied by 6, gives the percentage of anhydrous starch.

The following results were thus obtained in the analysis of specimens of different commercial starches:

	Potato Starch.			Maize Starch.	Rice Starch.
Starch by polarization ...	81·3	80·7	81·9	85·45	85·05
Ash	0·3	0·3	0·3	0·31	0·75
Proteid substances	0·2	0·2	0·2	0·38	0·50
Water	17·9	17·9	17·9	14·42	14·56
	99·7	99·1	100·3	100·56	100·86

It has not yet been determined whether this method can be used for the determination of starch in cereals, but the lævorotatory products formed by the

action of the potassium hydroxide on the gluten and other nitrogenous substances in the grain would probably be a source of error. C. A. M.

Estimation of Starch in Yeast. D. Crispo. (*Ann. de Chim. anal.*, 1899, iv., 220, 291.)—This is an application of the author's general polarimetric method (see preceding abstract). Fifty grammes of the yeast, which must be left until it has become soft, brown, and viscous, are stirred up in about 2 litres of water, and allowed to settle for from ten to twenty minutes. The supernatant liquid is siphoned off, and the deposit again washed four or five times in the same way, until the washings are almost clear. Finally the deposit is transferred to a graduated flask, where it is mixed with water in the proportion of about 100 c.c. to each 1 to 2 grammes of starch. A solution of potassium hydroxide is then introduced, with continual agitation, so that for each gramme of starch there is 1 gramme of alkali. The flask is filled to about three-fourths with water, heated on the water-bath for an hour, and the resulting solution examined with the S.-V.-S. polarimeter in a 200 mm. tube.

The number of divisions, multiplied by 0·10173, gives the percentage of anhydrous starch in 100 c.c. of the solution. The amount may be calculated on the moist yeast on the assumption that the latter contains on the average 18 per cent. of water. The mean correction for the starch removed during the washing has been determined experimentally by the author to be 11 per cent.

The following analyses of test mixtures of yeast and starch were made by five different chemists, using this method :

Starch added per cent.	13·8	5·66	1·96	3·85	6·00	4·00	2·00	10·0	5·0
,, found ,,	13·0	6·4	2·29	4·35	6·50	4·00	2·02	10·32	4·97

C. A. M.

The Detection of Sawdust in Flour. G. A. Le Roy. (*Ann. de Chim. anal.*, 1899, iv., 212, 221.)—After making experiments with various reagents used for the detection of woody fibre in paper, the author has obtained the most satisfactory results with an acid solution of phloroglucinol.

This is prepared by mixing 1 gramme of phloroglucinol with 15 c.c. of 90 to 95 per cent. alcohol, 15 c.c. of water, and 10 c.c. of phosphoric acid syrup.

In examining a flour, 1 or 2 c.c. of this reagent are placed in a porcelain capsule, a pinch of the sample introduced, and the liquid warmed very slightly. After a few seconds any particles of sawdust present assume a rose tint which gradually darkens to carmine, whilst the cellulosic substances of the flour only become coloured subsequently, and usually very slightly.

The coloration given by maize and potato flour is much less pronounced than that of wood flour.

Attempts to make this reaction quantitative have only given uncertain results.

C. A. M.

Wines containing Citric Acid. R. Kunz. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 692.)—Samples of so-called "wine composition" or "wine essence" examined at the Government Laboratory at Vienna were found to contain, besides tartaric acid, large quantities of citric acid. It is believed that these preparations are used not only in the production of artificial wines, but also for adulterating natural wines, and this opinion is strengthened by the fact that many wines, particularly those of Italian origin, have been found to contain considerable quantities of citric acid. The detection of citric acid in wines having thus become a matter of importance, the following method is proposed as being reliable and free from possible objections: 50 c.c. of the wine are mixed with 5 c.c. of a 20 per cent. solution of lead acetate. The precipitate is filtered off, washed, stirred up with 50 c.c. of water, and 3 c.c. of a 20 per cent. solution of sodium sulphide added to separate the lead. Should any turbidity be produced, a few drops of acetic acid may be added. The lead sulphide is then removed by filtration, the filtrate evaporated to dryness, the residue washed with the smallest possible quantity of water into a beaker, ammonia added to slight alkaline reaction, double the volume of ammonium chloride solution added, and the tartaric acid thrown down by calcium chloride. The large excess of ammonium chloride present hinders the precipitation of the citric acid. On now evaporating the filtrate from the calcium tartrate precipitate, the citric acid, if present, separates out in the form of crystals of calcium citrate. Or the filtrate from the calcium tartrate can be mixed with alcohol, the precipitate produced washed with alcohol, dissolved in a little hydrochloric acid, the solution made alkaline with ammonia and heated to boiling. This procedure has the advantage over the former that the removal of the ammonium chloride facilitates the precipitation of the calcium citrate. In either case the crystals of calcium citrate are identified by means of the microscope. H. H. B. S.

Estimation of Succinic Acid in Fermented Liquids. J. Laborde and L. Moreau. (*Ann. de l'Inst. Pasteur*, 1899, xiii., 657; through *Chem. Zeit. Rep.*, 1899, 283.)—Girard's process, though accurate, is tedious owing to the low temperature and slow speed of evaporation. If the temperature be raised, losses ensue, not because the succinic acid volatilizes, but because some of it combines with glycerin and does not take part in the final titration. The substance is preferably evaporated to dryness on the water-bath in presence of sand or fine shot, and the solid matter extracted with ether. The solvent is driven off, and in the dry extract free acid is estimated (1) by titration, (2) by saponification with an excess of potassium hydroxide. By adding the two yields together, the proportion of succinic acid is found; but the results are generally 0·1 to 0·2 gramme too high per litre of sound wine. Proper correction, however, can be made by determining the volatile acids. Free tartaric acid may pass into the ether; it must be converted into tartrate, estimated and deducted. If the original liquid contains more than 1 per cent. of sugar, extraction of the dry residue with ether is not complete; the sample must be evaporated only to a syrup, mixed with alcohol in amount corresponding with the

proportion of sugar, and then precipitated by the gradual addition of ether, repeating the whole process several times. F. H. L.

The Limits to the Detection of Malt Substitutes in Beer. E. Prior. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 697-701.)—Experiments were made with the following mixtures: Forty-five grammes of malt and 5 grammes of potato starch, 45 grammes of malt and 5 grammes of rice, 40 grammes of malt and 10 grammes of potato starch, and 40 grammes of malt and 10 grammes of rice. Each mixture was mashed in the manner customary in making malt analyses, the mash filtered, the grain washed with hot water, and the wort boiled with 0·5 gramme of hops. After cooling and filtering, the proper quantity of yeast was added, and the liquid fermented. At the expiration of four days the beer was filtered and analysed. In order to saccharify the added starch and rice as completely as possible, both were boiled to paste, and the rice in addition was steamed for three hours at 3 atmospheres' pressure. The results are given in the following tables:

Analyses of the Potato Starch and Rice.

	In the Natural State. Potato Starch. Per cent.	In the Natural State. Rice. Per cent.		In the Dry State. Potato Starch. Per cent.	In the Dry State. Rice. Per cent.
Water	18·63	12·74	Water	—	—
Starch	77·30	74·00	Starch	95·00	84·80
Nitrogenous matter	—	8·25	Nitrogenous matter	—	9·91

Analyses of the Malts.

	Malt.	Malt + 10% Starch.	Malt + 20% Starch.	Malt + 10% Rice.	Malt + 20% Rice.
Time of saccharification ...	20-25 min.	45-50 min.	60 min.	40 min.	40-45 min.
Condition of the wort ...	clear	cloudy	cloudy	clear	clear
Maltose in the extract ...	67·11%	67·43%	69·03%	67·15%	68·30%
Nitrogen in the extract ...	0·645%	0·547%	0·279%	0·630%	0·650%

Analyses of the Beers.

	Malt.	Malt + 10% Starch.	Malt + 20% Starch.	Malt + 10% Rice.	Malt + 20% Rice.
Maltose in the extract ...	13·91%	17·29%	25·61%	15·20%	14·90%
Nitrogen in the extract ...	1·032%	0·955%	0·940%	1·33%	1·35%
Degree of fermentation ...	66·34%	65·30%	63·25%	66·98%	67·18%

The following conclusions were arrived at:

The time occupied in saccharifying is increased by the addition of starch or rice. With 20 per cent. of starch erythro-dextrin was still found at the expiration of an hour.

The percentage of maltose and achroo-dextrin in the unfermented extract is not

increased by the substitution of 10 per cent. of starch or rice, but is somewhat increased by a 20 per cent. substitution.

The percentage of nitrogen in the unfermented wort extract is perceptibly reduced by the substitution of 10 per cent. of starch, and is reduced by more than half by the substitution of 20 per cent. Ten or 20 per cent. of rice does not reduce the proportion of nitrogen in the unfermented wort extract.

The degree of fermentation of the beer is somewhat reduced by the substitution of 10 per cent. of starch, and more so by the substitution of 20 per cent. On the other hand, rice occasions a slight increase.

The percentage of maltose and achroo-dextrin in the beer extract is increased by starch or rice, especially by the former.

The nitrogen of the beer extract is reduced but little below 1 per cent., and certainly not below 0·9 per cent., by the substitution of even as much as 20 per cent. of starch. Rice increases the proportion of nitrogen in the beer extract.

The Distinction of True Extract of Vanilla from Liquid Preparations of Vanillin. **W. H. Hess.** (*Journ. Amer. Chem. Soc.*, vol. xxi. [9], pp. 719-723.)

1. *Dilution Test.*—A small quantity of the tincture, agitated with two volumes of water, should furnish a flocculent reddish-brown precipitate, but only slight turbidity, since milkiness indicates foreign resin, as does also more than a slight turbidity ensuing on the addition of hydrochloric acid drop by drop to the diluted sample. If alkali has been used in preparing the extract, the turbidity is greater than otherwise, and the colour fades on addition of acid.

2. *Testing the Resin.*—Twenty-five c.c. of the extract under examination are evaporated on the water-bath to eliminate alcohol, and then made up to the original volume with water. The true resin forms an amorphous, flocculent, red to brown residue, separating out entirely on acidifying the solution with a little hydrochloric acid. It is soluble in caustic potash, giving a deep red solution, and is reprecipitated by acid. Unlike most other resins, this one gives little or no colour reaction with ferric chloride or hydrochloric acid in alcoholic solution.

3. *Colouring Matter.*—(*a*) Caramel: A portion of the filtrate from the resin is concentrated on the water-bath until about as dark as the original tincture. Caramel, when present, will be thrown down as a flocculent, yellowish-red precipitate on adding a few drops of strong hydrochloric acid and applying gentle heat. The precipitate is insoluble in water, strong alcohol, or ether, but soluble in dilute caustic potash, glacial acetic acid, or dilute alcohol. (*b*) Azo dyes: A portion of the filtrate is treated with ammonia—which deepens the colour of the true extract—and digested with zinc dust. If natural, the colour will revert to its original tint, or nearly so; but azo dyes will be decolorized, the colour returning on exposure to air, or on addition of hydrogen peroxide.

A portion of the original solution from the resin is tested for tannin, which should be present in small quantity only.

Organic acids and extractives are contained in considerable quantity in the pure

extract, and their precipitation by lead acetate forms a decisive test of the genuineness of the sample.

Coumarin, due to adulteration with Tonka extract, is detected by the method given in *Journ. Amer. Chem. Soc.*, vol. xxi., p. 256. C. S.

Estimation of Essential Oil in Cinnamon-Water. M. Duyk. (*Ann. de Chim. anal.*, 1899, iv., 223, 224.)—The method employed consists in treating the preparation with phenylhydrazine and weighing the insoluble cinnamyl hydrazone formed.

The cinnamon-oil of Ceylon and China consists almost entirely of cinnamic aldehyde, the proportion being as high as 90 per cent. in the Ceylon product.

The phenylhydrazine solution is prepared by dissolving 1 gramme of phenylhydrazine hydrochloride and 1·5 gramme of potassium acetate in 10 c.c. of water.

A sufficient quantity of this reagent is added to the cinnamon-water to cause complete precipitation of the cinnamic aldehyde at the ordinary temperature, and the precipitate collected on a filter, washed, dried on a porous plate under a clock-glass, and weighed.

In a test experiment the author dissolved 0·1 gramme of cinnamic aldehyde in 100 c.c. of water, and obtained 0·162 gramme of the hydrazone as against the theoretical amount 0·167 gramme. In an officinal sample the weight of the precipitate was 0·175 gramme, corresponding with rather more than 0·10 gramme of cinnamic aldehyde.

The distilled waters of certain other essential oils, such as peppermint, rose, orange flowers, and camomile, do not yield any precipitate with phenylhydrazine, but the method is applicable to the estimation of benzaldehyde in cherry-laurel-water.

As a general rule the presence of small amounts of alcohol in the waters do not interfere with the determination. C. A. M.

Estimation of Santonin. J. Katz. (*Arch. Pharm.*, 1899, ccxxxvii., 245; through *Chem. Zeit. Rep.*, 1899, 233.)—The author rejects the processes hitherto employed, and proposes the following: Ten grammes of coarsely powdered santonica are extracted with ether in a Soxhlet for two hours. The solvent is distilled off, and the residue is cohobated for fifteen or thirty minutes with a solution of 5 grammes of crystallized barium hydroxide in 100 c.c. of water. After cooling, the liquid is saturated with carbon dioxide till it has an acid reaction, filtered quickly, and the carbonate washed twice with 20 c.c. of water. The filtrate is concentrated on the water-bath to about 20 c.c., mixed with 10 c.c. of 12·5 per cent. hydrochloric acid, and heated for another two minutes. The liquid is brought into a separating funnel, the crystals in the basin being dissolved in 20 c.c. of chloroform; and basin, funnel, and filter are washed twice with 20 c.c. of the same solvent. The liquid is evaporated, and the residue boiled under a vertical condenser for ten minutes with 50 c.c. of 15 per cent. alcohol; the solution is filtered into a tared flask, and the insoluble matter treated twice again with 10 c.c. of boiling 15 per cent. spirit. After standing twenty-four hours, the flask and its contents are weighed, the alcohol is filtered

through a weighed paper, flask and paper being rinsed with 10 c.c. of the same spirit (which is not included in the subsequent calculation). The filter is finally dried and weighed; and to the weight of santonin so obtained a correction of 0·006 gramme is added for every 100 grammes of filtrate. F. H. L.

The Assay of Cacodylates. H. Imbert and A. Astruc. (*Journ. Pharm. Chim.*, 1899, x., 392-395.)—The fact that cacodylic acid—$AsO\begin{matrix}OH\\CH_3\\CH_3\end{matrix}$—behaves as a neutral body with the indicator helianthine A, but is monobasic with phenol-phthalein, affords a rapid method of estimating it.

Thus, in the case of sodium cacodylate, which is the salt most frequently met with in commerce, 1 molecule of acid should be required to render the salt neutral to helianthine. But in practice the authors have found that the samples they have met with have not the theoretical neutrality to phenol-phthalein, but are, on the contrary, markedly acid. This they consider is probably due to the dissociation of the salt by water in a manner analogous to that of bimetallic glycerophosphates.

In making an assay 1·6 gramme of sodium cacodylate is dissolved in 100 c.c. of water, giving a solution containing one-tenth of the molecular weight per litre. Ten c.c. of this liquid are neutralized with standard alkali, with phenol-phthalein as indicator, and then titrated with decinormal acid with helianthine as indicator. The number of c.c. required multiplied by 10 gives the percentage of pure sodium cacodylate in the salt.

In different commercial samples the authors found by this method from 75·20 to 92·80 per cent. of pure sodium cacodylate, and from 9·66 to 27·60 per cent. of free cacodylic acid.

Cacodylic acid and cacodylates do not give the characteristic reactions of arsenates. C. A. M.

ORGANIC ANALYSIS.

The Detection of Acetylene by Means of an Ammoniacal Solution of Copper and Hydroxylamine. L. Ilosvay and N. Ilosvay. (*Berichte*, 1899, xxxiii., 2697-2699.)—The colourless solution obtained by reducing an ammoniacal solution of cupric sulphate with hydroxylamine can be used as a reagent for acetylene, and the author has made experiments to determine under what conditions it is most sensitive and yields a copper acetylide of constant colour.

He finds that the sensitiveness of the liquid is dependent on the amount of ammonia and hydroxylamine it contains. If the proportion of ammonia be only just sufficient to dissolve the copper salt and the hydroxylamine only sufficient to just decolorize the liquid, the precipitate formed by acetylene is at first yellowish-brown and subsequently green. If, on the other hand, the ammonia be in considerable excess, and a correspondingly large amount of hydroxylamine present, the colour of the precipitate varies between a light and dark onion red. If there be too

little ammonia, a light yellow pulverulent substance (probably copper suboxide or cuprous hydroxide) is formed on the surface. This, however, does not destroy the sensitiveness of the reagent.

As a general rule, the solution should contain from 2·5 to three times the amount of ammonia absolutely necessary, and from fifteen to eighteen times the quantity of hydroxylamine required to reduce the copper compound.

The author gives the following directions for preparing the reagent (50 c.c.) from the chloride, nitrate, or sulphate of copper:

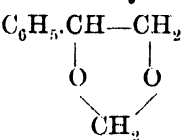
1. Cupric chloride ($CuCl_2\,3H_2O$), 0·75 gramme; ammonium chloride, 1·5 gramme; ammonium hydroxide (20 to 21 per cent. NH_3), 3 c.c.; and hydroxylamine hydrochloride, 2·5 grammes.
2. Cupric nitrate ($Cu(NO_3)_2.5H_2O$), 1 gramme; ammonium hydroxide, 4 c.c.; and hydroxylamine hydrochloride, 3 grammes.
3. Crystalline cupric sulphate, 1 gramme; ammonium hydroxide, 4 c.c.; and hydroxylamine hydrochloride, 3 grammes.

In each case the copper salt is dissolved in a little water, the ammonium hydroxide added, then the hydroxylamine hydrochloride, and the solution shaken and made up to 50 c.c.

The solutions remain stable for about three days, but on the fourth day become less sensitive, and subsequently begin to deposit a light red precipitate, whilst after fourteen days the metal is rapidly reconverted into the cupric state.

The presence of acetylene in coal-gas can be readily demonstrated by means of these solutions. A few c.c. of the reagent are placed in a 500 c.c. stoppered cylinder, the gas passed in until the liquid becomes rose-coloured, and the cylinder then closed and shaken, an immediate red precipitate being formed. C. A. M.

Estimation of Invert Sugar in Presence of Cane-Sugar. H. Jessen-Hansen. (*Meddelelser fra Carlsberg Lab.*, 1899, iv. [4], 314; through *Résumé in French, ibid.*, p. 193.)—Bruhns has recently objected (ANALYST, 1898, xxiii., 297) to Kjeldahl's method of estimating invert and other sugars with alkaline copper solutions (ANALYST, 1895, xx., 227), on the ground that it is incorrect when cane-sugar is simultaneously present, for the latter precipitates a large and variable amount of copper, which vitiates the results of the analysis. Jessen-Hansen remarks that Kjeldahl was not dealing in his original communication with such materials as may contain cane-sugar, therefore the criticism is somewhat unjust; but in order to render Kjeldahl's process available when reducing sugars are mixed with large quantities of cane-sugar, he has reinvestigated the whole question. He finds that when 30 c.c. of Fehling's solution, prepared according to Kjeldahl's directions, but containing double the usual amount (10·4 instead of 5·2 grammes) of Rochelle salt are used, and when the time of boiling in a current of hydrogen is limited to five minutes, the weight of copper thrown down by 10 grammes of cane-sugar is lowered from between 102 and 114 milligrammes to about 14 milligrammes, so that if the period of ebullition is governed exactly by means of a watch having a second-hand, concordant results can always be obtained. It follows, therefore, that the figures given by Kjeldahl (ANALYST, 1895, *ubi sup.*) for



invert sugar require modification in presence of cane-sugar; and the present author accordingly appends to his paper a lengthy table for converting the weight of copper deposited into invert sugar (*a*) when the latter exists alone, and (*b*) when it is mixed with different proportions of cane-sugar. The figures for pure invert sugar also are not quite the same as those already recorded. F. H. L.

The Odoriferous Principle of Jasmine Flowers. A. Verley. (*Bull. Soc. Chim.*, 1899, xxi., 226-232.)—Numerous attempts have been made to isolate the essential oil of jasmine flowers by distillation with steam, but these have been unsuccessful owing to the quantity of oil being very small, and to the fact that it is completely decomposed on boiling with acidulated water.

The author has obtained it by *enfleurage* in the cold. The fat saturated with the perfume was beaten with vaseline-oil, and the latter extracted with acetone. On evaporating the acetone under reduced pressure a clear reddish-brown oil was left.

A fractional distillation of 35 grammes of this substance under reduced pressure yielded 19 grammes between 70° and 180° C. under 15 mm. pressure, and a residue of 14 grammes of resinous matters. These 19 grammes on re-fractionation under 12 mm. pressure gave the following fractions: 70° to 100° C., 2 grammes; 100° to 101° C., 11 grammes; 101° to 110° C., 3 grammes; and 110° to 180° C., 2 grammes. The fraction distilling at 100° to 101° C. was a very mobile, slightly yellow liquid, with an intense odour of jasmine. It had a density of 1·1292 at 0° C., and a composition corresponding with the formula $C_9H_{10}O_2$.

To this substance, which was not quite pure, the author gave the name "jasmal. From its reactions it appeared to be the methylene acetal of phenylglycol.

This conclusion was confirmed by the synthetical preparation of that acetal. Fifty grammes of phenylglycol, 300 grammes of water, 125 grammes of sulphuric acid, and 100 grammes of formaldehyde were heated together on the water-bath, and the resulting clear supernatant oil removed by ether and rectified under reduced pressure. It boiled at 100° C. under 12 mm. pressure, and at 218° under the ordinary pressure. Its density was 1·334 at 0° C. In the pure state it had the characteristic odour of jasmine, and all the properties of the natural jasmal. When boiled with acidulated water phenylglycol and formaldehyde were regenerated.

Homologous compounds were obtained in the same manner, another aldehyde of the fatty acid series being substituted for formaldehyde, but these had not so pronounced an odour of jasmine. C. A. M.

Essential Oil of Jasmine Flowers. A. Hesse and F. Müller. (*Berichte*, 1899, xxxii., 565-574 and 765-779.)—The authors state that for some time past they have extracted the essential oil of jasmine by a method analogous to that described by

Verley (see preceding abstract), but have found that it is preferable to purify the oil by distillation in steam rather than under reduced pressure.

In this way they have determined the amount and characteristics of the oil recovered from numerous samples of jasmine pomade from the harvests of 1896 and 1897, and give the results of ten representative cases.

In these the amount of ethereal oil obtained from 1 kilo of pomade varied from 3·95 to 5·95 grammes, and had the following characteristics:

Specific gravity at 15° C., 1006—1018; optical rotation, +2° 30′ to +3° 30′; ester content in terms of linalyl acetate, 90·3—95·4 per cent.; in terms of benzyl acetate, 69·1—73·0 per cent.

One of the authors showed in a paper some years ago that the high percentage of esters in ethereal jasmine-oil was to be attributed to the presence of large quantities of benzyl acetate.

Since Verley has stated that the odoriferous principle in jasmine-oil is phenylglycol-methylene acetal, the authors have examined products obtained in exactly the same manner as described by Verley. Phenylglycol-methylene acetal prepared by the condensation of phenylglycol and formaldehyde, by means of dilute sulphuric acid, is not acted upon by alkalies; but on treatment with oxalic acid it is decomposed, with the liberation of phenyl glycol, which can readily be identified by its characteristic crystalline form, and the formation of phenyl acetaldehyde on heating it with dilute sulphuric acid.

Having proved that in this way it was possible to detect small quantities of the acetal in the presence of linalol and of benzyl acetate (in large excess), the authors tested the different fractions yielded by the distillation of 60 grammes of jasmine-oil under reduced pressure, but in none of them could any trace of phenylglycol-methylene acetal be detected.

The odoriferous principle was found to be due in the main to two substances, which together only amounted to 5 per cent. of the total volatile oil, and neither of which was Verley's acetal.

In order to determine the amount of the various constituents in jasmine-oil, a method based on the behaviour of these substances towards permanganate was devised.

It was proved experimentally that linalol, when thus oxidized, yielded carbonic and acetic acids, but no solid acid. Benzyl alcohol, however, was converted into benzoic acid, and in a test experiment 94·5 per cent. of the theoretical quantity was obtained. Crude linalyl acetate, prepared by boiling linalol with acetic anhydride and sodium acetate, behaved in an analogous manner to free linalol, and yielded carbonic and acetic acid and a small amount of an oily, soluble acid, but no solid acid. Benzyl acetate, in the absence of alkali, was not attacked by permanganate.

As a test of the applicability of this method to the examination of jasmine-oil, a mixture was prepared consisting of 30 per cent. of benzyl alcohol, 50 per cent. of benzyl acetate, 10 per cent. of linalol, and 10 per cent. of crude linalyl acetate (containing about 59 per cent. of that acetate). This mixture had a saponification value of 201, the calculated value being 200·2.

The mixture during oxidation was kept as neutral as possible by the addition of dilute sulphuric acid, and the temperature was maintained at from 15° to 20° C. by

adding ice. The permanganate was added at first in a 3 per cent. solution, and subsequently in the form of a fine powder, which was introduced little by little, with constant agitation, until the colour remained permanent for about an hour.

The excess of permanganate was removed with bisulphite, and the oxidized liquid extracted three or four times with ether. The acid oxidation-products were removed from the ethereal extract by shaking the latter with a dilute solution of sodium hydroxide. The residual ethereal layer was washed with water, dried with calcium chloride, and evaporated to dryness at 40° C. in a weighed and exhausted flask. The residue was benzyl acetate.

The alkaline extract was added to the original residue from the ethereal extraction, the mixture rendered slightly alkaline, filtered, the filtrate concentrated by evaporation and freed as far as possible from inorganic salts by the addition of alcohol, and the benzoic acid determined by rendering the liquid acid and filtering.

In this way, from 20 grammes of the above mixture, 9·8 grammes of benzyl acetate (= 98 per cent. of the theoretical amount) and 6·6 grammes of benzoic acid (97·5 per cent. of the theoretical quantity) were obtained. From these results the authors concluded that the method was capable of determining the amount of these substances within 2 to 4 per cent. of the real quantity.

Having proved qualitatively that the different fractions obtained in the fractional distillation of essential oil of jasmine consisted chiefly of linalol, linalyl acetate, benzyl acetate, and benzyl alcohol, the authors employed the oxidation method described above for a quantitative estimation, in which the percentage of linalyl acetate was calculated from the difference between the ester content of each fraction, and the amount of benzyl acetate actually found.

From the results obtained in the examination of the fractions and of the original crude substance, they came to the conclusion that the essential oil of jasmine flower contains in round numbers:

Benzyl acetate, 65; linalyl acetate (and other terpene alcohol esters), 7·5; benzyl alcohol, 6; other odoriferous constituents, 5·5; and linalol (and other substances), 16 per cent.

Hesse (*Berichte*, 1899, xxxii., 2611-2620) has continued the research on this subject commenced by himself and Müller. He finds that, in addition to the oxygen compounds described in the former papers, certain nitrogenous compounds are present and have a considerable influence on the nature of the perfume.

Of these the more important is indol ($C_8H_{17}N$), which can be isolated by precipitation with picric acid. It amounts to about 2·5 per cent. of the crude oil.

The author also states that the constituent of the oil which reacts with picric acid and the "aldehyde" of jasmine-flower-oil isolated by means of sodium bisulphite are identical.

The methyl ester of anthranilic acid ($NH_2.C_6H_4.CO_2.CH_3$) is also present in small amount (not exceeding 0·5 per cent.). This ester, which has also been found by Walbaum and Erdmann in neroli-oil, gives in dilute solution the blue fluorescence of jasmine-flower-oil. When present in greater quantity than 1 per cent., it can be precipitated as a sulphate by adding a mixture of sulphuric acid and ether. Its influence on the jasmine perfume is much less than that of the indol.

A third new constituent has been isolated from the fraction of the jasmine-oil distilling between 105° and 107° under 5 mm. pressure. This is a ketone of the formula $C_{11}H_{16}O$, to which the author has given the name of *jasmone*. It is a light yellow oil, becoming darker on keeping, and having an intense odour of jasmine. It has a specific gravity of 0·945 at 15° C., and boils at 257° to 258° C., under a pressure of 755 mm. It can readily be isolated as a semi-carbazone, which when purified by one crystallization from boiling alcohol melts at 204° to 206° C. The pure jasmone oxime ($C_{11}H_{16}NOH$) crystallizes from dilute alcohol in fine needles which melt at 45° C., and are volatile in a current of steam.

From the results of the investigations described in this and in the former papers, the author gives the following as the composition of the ethereal oil of jasmine flowers:

Jasmone, 3·0; indol, 2·5; methyl ester of anthranilic acid, 0·5; benzyl acetate, 65·0; linalyl acetate, 7·5; benzyl alcohol, 6·0; and linalol, 15·5 per cent.

C. A. M.

Bishop's Reaction for Sesamé Oil. H. Kreis. (*Chem. Zeit.*, 1899, xxiii., 802.)—In 1892 Ambühl mentioned that on testing an old rancid sample of sesamé with the Baudoin reaction, he obtained a blue colour instead of the usual red, a peculiarity which has not hitherto been explained. Quite recently the present author, examining a saccharine secretion from larch needles with sesamé and hydrochloric acid in order to test for sugar, obtained a blue-violet colour when the oil was rancid, but the normal red tint when a fresh specimen of sesamé was substituted. It seemed, therefore, that this blue might be a mixture of the Baudoin red with the green, which, as Bishop discovered (*Journ. Pharm. Chim.*, 1889, [5], xx., 244), is produced when old sesamé oil is shaken with 1·19 hydrochloric acid; and experiments showed that, by mixing together the coloured acids from the two tests, Ambühl's blue could be imitated in its various shades. The blue colour with rancid sesamé appears more distinctly when sugar is used than with furfural. Bishop's test gives at first a yellowish-green tint, which gradually changes to bluish-green, while the oil finally becomes pale violet. In the presence of resorcinol or phloroglucinol, Bishop's acid turns violet or orange-red, but other phenols exert no influence on the colour.

Bishop recommended his test as a means of judging the age of sesamé oil, but as the reaction seems to be caused by oxidized products, substances similar to which may be present in other oils, it is not surprising that an analogous green colour is produced when certain other rancid fats mixed with fresh sesamé are agitated with strong hydrochloric acid. For instance, an old olive oil (acid No. 5) gave no colour on shaking with acid, but after being mixed with an equal volume of a sesamé oil, which itself yielded no reaction, the whole immediately produced a green tint. The same phenomena were observed with old butter (acid No. 6) and lard (acid No. 2); neither coloured the acid alone, but with indifferent sesamé oil both gave the Bishop reaction. The investigation of this subject is being continued; in the meantime, it seems that Bishop's reaction is shown most strongly by those oils which still possess a normal acid number, but which are shown to be rancid by their taste. F. H. L.

Some New Reactions for Sesamé Oil. F. Breinl. (*Chem. Zeit.*, 1899, xxiii., 647.)—The furfural test for sesamé (ANALYST, 1896, xxi., 135) appears not only in presence of strong hydrochloric acid, but also if other dehydrating agents are used, such as sulphuric acid diluted with water, or preferably with glacial acetic acid. Other aldehydes—presumably all the aromatic compounds—give similar reactions; but the exact colours vary with the reagent employed. Benzaldehyde and cuminol yield an orange; *o*-nitrobenzaldehyde, an orange-yellow; *p*-nitrobenzaldehyde, a yellow; cinnamic aldehyde, *o*- and *p*-hydroxybenzaldehyde, vanillin, and piperonal all give a violet-red tint. Neither formaldehyde nor acetaldehyde produces a colour with sesamé oil; but as cinnamic aldehyde does, it would seem that unsaturated fatty aldehydes should behave analogously. Crotonic aldehyde, even in very dilute solution, yields an orange coloration.

As these colours are very similar to those given by furfural, etc., with albuminous substances, it would appear probable that the actual cause of the reaction might be a nitrogenous albumin-like body in the sesamé oil. Evidence of this cannot be obtained; nevertheless, repeated extraction of sesamé with strong hydrochloric acid removes from the oil the power of yielding colours, while the aqueous liquid shows a noteworthy colour. The acid extracts also contain a minute trace of nitrogen. Inasmuch as animal fats have been shown to contain albuminoids, it is not improbable that vegetable fats, especially those which have not been refined with strong acids, should contain proteids; and as albuminoids give the above-mentioned furfural reaction, it is not surprising that some samples of olive and castor oils have responded to the Baudoin test. A few specimens of the latter have also reacted with piperonal and vanillin; but the colours were so faint as to be overshadowed by the addition of 1 per cent. of sesamé.

Experiments have been made to determine the comparative delicacy and general utility of the several aldehydes as reagents for sesame oil; and seeing that many fats give red or brownish colours on shaking with strong hydrochloric acid alone, those substances are preferable which yield tints bluer than that produced by furfural. On the whole, *p*-hydroxybenzaldehyde, vanillin, and piperonal are to be recommended; and their alcoholic solutions have the advantage of being permanent for months when exposed to light. On account of their higher molecular weights, however, they should be used as 3 per cent. solutions. F. H. L.

Two New Colour Reactions for Sesamé Oil. J. Bellier. (*Ann. de Chim. anal.*, 1899, iv., 217-220.)—On shaking equal parts of this oil and a reagent consisting of sulphuric acid, 100 c.c.; water, 50 c.c.; and formaldehyde (40 per cent.), about 10 c.c., an emulsion is obtained which gradually assumes an intense and stable bluish-black colour; whilst with olive, cottonseed, earthnut, poppy, and nut oils the emulsion formed is of a more or less pronounced yellow. By this means it is possible to detect as little as 1 per cent. of sesamé oil in olive oil even in the case of Tunis oils, which give a relatively dark coloration with hydrochloric acid and furfural, but behave like other pure olive oils with this reagent.

The following is said to be an equally characteristic test: Two c.c. of the oil are

shaken with 2 c.c. of crystallizable benzene saturated with resorcinol, and 2 c.c. of nitric acid free from nitrous vapours (specific gravity 1·38).

With sesamé oil the mixture assumes an intense bluish-violet colour almost immediately, and the acid which separates has an intense bluish-green colour which lasts for five or ten minutes.

In the case of olive oil the mixture sometimes remains colourless, but generally, and especially with Tunis oils, has a more or less pronounced violet tint, while the acid which separates is at first pale yellow and finally orange yellow.

Earthnut, cottonseed, poppy, nut, and linseed oils yield an intense violet-blue mixture, but, unlike sesamé oil, do not give a green-coloured acid on the layers separating. With olive oil containing 1 per cent. of sesamé oil the green colour of the acid layer is still marked after several minutes. C. A. M.

INORGANIC ANALYSIS.

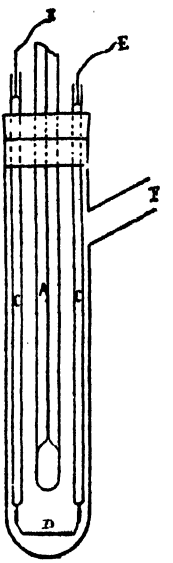
Solubility of Lead Sulphate in Ammonium Acetate. J. C. Long. (*Amer. Chem. Journ.*, vol. xxii. [3], pp. 217, 218.)—A series of experiments made show that the maximum solvent effect is exerted on lead sulphate when the ammonium acetate solution is of 31 to 37 "volume per cent." (29 to 34·3 per cent.) strength; therefore, to dissolve this lead salt, it should be boiled in 10 c.c. (for 1 gramme) of a 33 per cent. solution of the acetate (specific gravity 1·07), and filtered promptly. It is found that, in recovering the lead sulphate, the evaporation and expulsion of the ammonium acetate without loss is greatly facilitated by an addition of 0·5 gramme of sulphuric acid. C. S.

Analysis of White Metal. H. Nissenson. (*Chem. Zeit.*, 1899, xxiii., 868.)—Under the name of "metallic packing" for engine glands, etc., two classes of alloys are frequently to be met with, containing about 80 per cent. of lead with (*a*) 6 per cent. of antimony and 12 per cent. of tin, or (*b*) with 12 to 15 per cent. of antimony and 3 to 5 per cent. of tin. To analyse them, 1 gramme of the sample is mixed with 2 to 4 grammes (4 grammes for class *a*, 2 grammes for class *b*) of tartaric acid, 12 c.c. of water, and 4 c.c. of 1·4 nitric acid, warming till solution is effected. Four c.c. of strong sulphuric acid are then added to precipitate the lead, evaporating in such fashion that the nitric acid is driven off but the tartaric acid not decomposed. To attain this object, the liquid is heated in an Erlenmeyer flask as long as the red vapours are produced; and in order to watch the process conveniently, the nitrous acid is blown out of the vessel with a bent piece of tubing periodically. Immediately the fresh bubbles of gas are white, the flame is removed; a little water is introduced, and the lead sulphate is collected. The filtrate is made alkaline with sodium hydroxide, 50 c.c. of a cold saturated solution of sodium sulphide are run in (any copper thrown down being removed), and the whole is electrolysed at 80° C. with a current of 1·5 ampères at 3 volts. The liquid is poured off from the antimony, which is rinsed in a little water and dried. The sodium sulphide in the solution is next converted into ammonium sulphide by treatment with 25 grammes of ammonium

sulphate, and the tin is deposited with the same current, and at the same temperature as before. F. H. L.

Determination of Chromium in Steel. R. W. Mahon. (*Journ. Amer. Chem. Soc.*, vol. xxi. [11], pp. 1057-1060.)—A modification of McKenna's method gives good results, 3 grammes of the substance being dissolved in 50 c.c. of concentrated hydrochloric acid, and boiled down to a moist cake. This is boiled for a few minutes in 50 c.c. of concentrated nitric acid, and, after cooling in the dark, is treated with 4 grammes of potassium chlorate, and concentrated to 25-30 c.c. After dilution to 300 c.c. with water, 15 c.c. of ammonia, specific gravity 0·90, are stirred in, and the (cool) solution passed through a ribbed double filter-paper to remove oxides of manganese. The filtrate and (cold water) washings are made up to about 450 c.c., and titrated with standard ferrous ammonium sulphate and potassium permanganate, preferably standardized by standard potassium bichromate. If the removal of hydrochloric acid has been completely effected by nitric acid, about 2 grammes of potassium chlorate will suffice to oxidize the chromium present; but this salt is a more convenient agent than nitric acid for eliminating the final traces of hydrochloric acid. The solution must be dilute and cold, as well as free from too great an excess of nitric acid, in order that reduction of the chromic acid by the filter-paper may be prevented.

The manganese oxides on the filter may be utilized for the gravimetric determination of this metal, the precipitate being dissolved in hydrochloric acid, the iron thrown down as basic acetate, and the manganese as manganous ammonium phosphate.

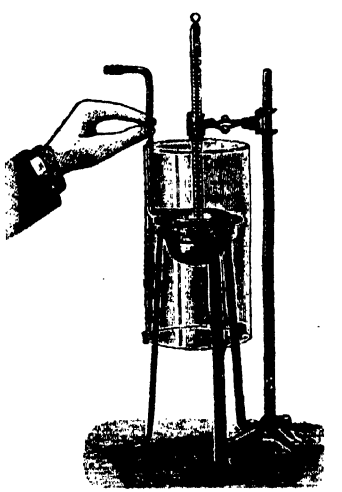


C. S.

Estimation of Chromium in Iron and Steel. E. Döhler. (*Chem. Zeit.*, 1899, xxiii., 868.)—When a hydrochloric acid solution of iron is precipitated with barium carbonate, not all the chromium is thrown down the first time; if the sample contains much chromium (4 per cent.), even a third treatment is necessary to recover it all. 2·5 to 5 grammes of the iron are dissolved by heating with 30 c.c. of 1·19 hydrochloric acid and 100 c.c. of water in a 750 c.c. flask closed with a valve-stopper. The liquid is diluted to about 600 c.c. with cold water, and a cream of barium carbonate is added until, after half an hour's standing, an excess is still noticeable. The precipitate, which should be slightly yellow owing to traces of iron, is allowed to rest in the well-closed flask for twelve hours, then filtered off through a covered funnel, and the filtrate is treated again with barium carbonate precisely as before. The mixed precipitates are ignited in porcelain with alkali carbonates and potassium nitrate, at first over a Bunsen flame, and finally for half an hour before the blowpipe. The mass is extracted with hot water, filtered from iron and barium, freed from silica by evaporation with hydrochloric acid, again filtered, and the chromium and aluminium separated as usual. Neither silver, nickel, nor platinum crucibles must be used, and a fresh porcelain one should be employed each time. Too large an excess of barium carbonate is to be avoided, and the substance should be very finely subdivided.

F. H. L.

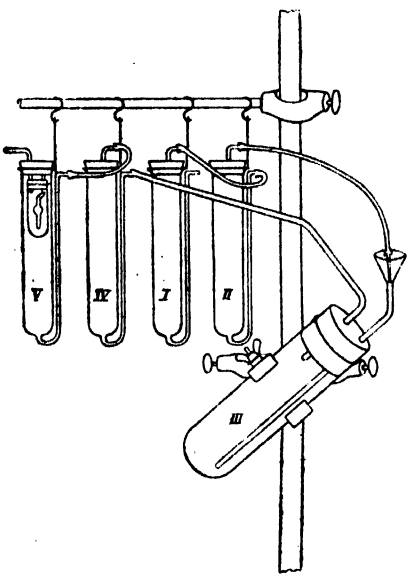
APPARATUS.



A Simplification of Beckmann's Boiling-point Apparatus. **S. L. Bigelow.** (*Amer. Chem. Journ.*, vol. xxii. [4], pp. 280-287.)—The substitution of electric heating for gas enables the sealed platinum wire, the glass beads, asbestos stove, outer jacket, and its attached reflux condenser, of the Beckmann apparatus to be dispensed with, and also obviates danger arising from breakage and fire in the case of inflammable solvents.

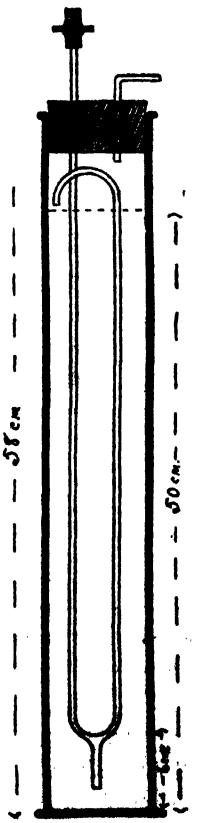
In the drawing, A represents the thermometer, and C,C two mercury tubes for conveying current to the platinum coil D, which is made of 0·1 millimetre wire wound to a diameter of about 1 millimetre, and measures 1½ to 2 centimetres in length, the free ends being preferably sealed into the mercury tubes. To replace the outer jacket employed by Beckmann, the vessel may be immersed in a battery jar well lined with felt; a Dewar vacuum jacket would, however, be preferable, to facilitate inspection.

A current of about 1·8 ampères from an incandescent lamp circuit will boil 30 c.c. of water in five minutes; and 3 cells of a storage-battery furnished the author with good results in the case of readily volatile solvents. Care is necessary to avoid any great perpendicular length of wire at the ends of the coil, or the wire may become enveloped in vapour and grow red-hot. C. S.



Apparatus for determining the Flash-point of Lubricating Oil. **R. Kissling.** (*Chem. Zeit.*, 1899, xxiii., 800.)—As shown in the illustration, this apparatus consists of a copper basin, 50 millimetres deep and 70 millimetres wide, filled with sea-sand, and containing a porcelain crucible to hold the oil, 45 millimetres deep and 40 millimetres in diameter. The crucible is sunk into the sand till it projects 10 millimetres, and it is charged with oil to the same level. The shade is made of heat-resisting glass, 250 millimetres high and 100 millimetres in diameter; it protects the apparatus from draughts, and prevents the igniting flame from being blown out by sudden gusts of air. The main burner is of such power that the oil rises about 2° in temperature in thirty seconds, and tests are made at the same intervals of time, commencing as soon as the sample reaches 20° or 30° below its expected flashing-point. A copper lid, provided with a slit for passing over the thermometer stem, and with a handle, is used to extinguish the flame of the burning oil.

F. H. L.



An Asbestos Filter-Tube. O. Lohse. (*Ber.*, 1899, xxxii., 2142.)—This consists of a piece of combustion tubing 12 centimetres long and 15 millimetres in diameter, expanded for about one-quarter of its length to a diameter of 20 millimetres, and closed like a test-tube at the end of its narrower portion with a hemispherical bottom, which is perforated with a number of small holes. It is charged with asbestos and fixed to a tube funnel for filtrations in the same manner as a Gooch crucible, while the shoulder enables it to be supported safely in a desiccator provided with a suitably perforated tray. The tube can be fitted with a glass stopper, if so desired, and by applying a cork and leading tube to its mouth the contained precipitate can be ignited in a current of gas. The author also describes various desiccators of somewhat obvious design, one of which holds caustic potash as well as calcium chloride. F. H. L.

An Improved "Potash-bulb," and a Simple Apparatus for estimating Carbon Dioxide by Absorption. R. Schaller. (*Zeits. angew. Chem.*, 1899, 878.)—The kind of vessel employed by the author to absorb carbon dioxide is shown by the tube marked V in the annexed illustration. He claims for it that useful space is raised to a maximum, that useless space is reduced to a minimum; that the tube has very little external surface, but a high absorbing power. The wide limb of the U is half filled with hollow round glass balls about 2 millimetres in diameter, and it contains about 10 c.c. of 50 per cent. potassium hydroxide. At the top, suspended by means of the tube through which the air passes out of the complete apparatus, hangs a small test-tube 8 centimetres long, filled with 1 c.c. of strong sulphuric acid; the tube whereby the air enters the latter is formed as shown, and extends to just below the level of the liquid. The carbon dioxide enters through the narrow limb of the U, and travels upwards through the moistened bulbs. The illustration as a whole represents apparatus for determining carbon dioxide by treating carbonates with acid in the vessel III. I and II, filled like V, free the current of air from carbonic acid; IV is a drying tube similarly filled with sulphuric acid. For exact work V is used in duplicate. The joint at the funnel is made with a tapering glass tube which enters the parallel funnel-tube; it is rendered air-tight by a water-seal. The current of air is aspirated rather than driven through the apparatus; and to ensure regularity of passage, either the final exit tube or both the exit and the first admission tubes are contracted to a fine point. The manipulation is obvious. F. H. L.

Platinum Gauze as a Cathode for Electrolytic Analysis. C. Winkler. (*Ber.*, 1899, xxxii., 2192.)—A piece of platinum gauze 10·5 centimetres long by 5·5 centimetres wide, composed of wires 0·12 millimetre in gauge, and with 250 meshes per square centimetre, has its edges bent over for a width of 2 or 3 millimetres so as to strengthen it, and is then coiled into an open (C-shaped) cylinder 5 centimetres high by 3·5 centimetres in diameter, leaving a slit 5 millimetres wide for the insertion of the anode. This form of cathode weighs only 13 grammes, and is capable of bearing its own weight of copper without any danger of the deposit falling off when washed. Much higher current-densities can be employed than formerly, reducing the time required to electrolyse a solution to about one-quarter of its usual length. Copper may be safely thrown down from its sulphate with a current of 0·5 ampère (density, $D_{100} = 5·1$ ampères), and 13 grammes can be deposited in sixteen or eighteen hours. Very gratifying results have also been obtained with silver, nickel, cobalt, zinc, and antimony. F. H. L.

A Dissolver. A. J. Hopkins. *Amer. Chem. Journ.*, vol. xxii. [5], pp. 407-410.)—An ordinary glass cylinder of suitable capacity may be used, that shown in the figure holding 2,200 c.c. A straight 6-millimetre tube is passed through one hole in the stopper, and connected below with a Y-tube, the other upper limb of which is connected to an upcast tube, bent over at the top above the surface of the dissolving liquid. When the cylinder is charged with solvent and the salt to be dissolved, air is drawn through the apparatus by an aspirator connected with the short bent tube on the right, and the inflowing current carries up with it from the Y-tube small columns of the saturating solution drawn through the lower limb, which are discharged at the top and are automatically replaced by fresh portions of the solvent descending the cylinder.

The apparatus is very rapid in action, 30 grammes of copper sulphate having been dissolved in 200 c.c. of water at 19° C. in forty minutes; and with a larger cylinder 1 kilo of ammonium carbonate was dissolved in 4 litres of water and 1 litre of ammonia in about half an hour. C. S.

INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND.

THE following is a list of the names of the candidates who passed the examination of the Institute of Chemistry held in January, 1900:

INTERMEDIATE EXAMINATION.—Aston, F. W., Mason University College, Birmingham. Austin, J. H., Mason University College, Birmingham. Bailey, H. J., University College, Sheffield. Bayly, H. G., King's College, London. Clarke, G., jun., University College, Nottingham. Danks, M. W., Mason University College, Birmingham. Blake Smith, R. E., B.Sc. (Lond.), University College, London. Taylor, Thomas, Glasgow and West of Scotland Technical College. Webster, John, Mason University College, Birmingham. Woodman, W. E., King's College, London.

A.I.C. EXAMINATION (old regulations).—Brooke, J. R., Pharmaceutical Society's Laboratories and King's College, London. Priest, M., Finsbury Technical College. Tickle, T., Pharmaceutical Society's Laboratories, King's College and University College, London.

FINAL A.I.C. EXAMINATION.—*In Branch A (Mineral Chemistry)*: Fyffe, W. A., University College, Dundee. Wright, L. V., B.A., Sidney College, Cambridge. *In Branch B (Metallurgical Chemistry)*: Winch, H. J., A.C.G.I., City and Guilds of London Central Institution and Finsbury Technical College. *In Branch C (Physical Chemistry)*: Price, T. S., B.Sc. (Lond.), Ph.D. (Leipzig), Mason University College, Birmingham, and the Universities of Leipzig and Stockholm. *In Branch D (Organic Chemistry)*: Edmed, F. G., Assoc.R.C.Sc. (Lond.), B.Sc. (Lond.), Royal College of Science, London. Eynon, L., Finsbury Technical College. Hall, H., University College, Nottingham. Shedden, F., B.Sc. (Lond.), Mason University College, Birmingham. *In Branch E (the Analysis of Food and Drugs, including an Examination in Therapeutics, Pharmacology, and Microscopy)*: Stansell, L. W., Maidstone. Thorp, W., B.Sc. (Lond.), Limerick. Both for the Fellowship.

The examiners in Chemistry were Dr. Bernard Dyer, F.I.C., and Professor Percy F. Frankland, F.R.S., F.I.C., and the examiner in Therapeutics, Pharmacology, and Microscopy was Dr. Thomas Stevenson, F.R.C.P.

SALE OF FOOD AND DRUGS ACT.

(Reprinted from the "Times" of February 1, 1900.)

THE Right. Hon. W. H. Long, M.P., President of the Board of Agriculture, has appointed a departmental committee to inquire and report as to what regulations, if any, may with advantage be made by the Board of Agriculture under section 4 of the Sale of Food and Drugs Act, 1899, for determining what deficiency in any of the normal constituents of genuine milk or cream, or what addition of extraneous matter or proportion of water, in any sample of milk (including condensed milk) or cream shall, for the purposes of the Sale of Foods and Drugs Acts, 1875 to 1899, raise a presumption, until the contrary is proved, that the milk or cream is not genuine.

The committee will consist of the following gentlemen, viz., Lord Wenlock, G.C.S.I., G.C.I.E. (chairman), Mr. George Barham, Mr. George Cowan, Major Patrick George Craigie (an assistant secretary of the Board of Agriculture), Mr. S. W. Farmer, Mr. Shirley F. Murphy, M.D., Prof. Thorpe, F.R.S. (Principal Chemist of the Government Laboratories), and Mr. J. Augustus Voelcker, Ph.D. Mr. Robert Henry Rew, of the Board of Agriculture, will act as secretary to the committee.

THE ANALYST.

MARCH, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, February 7, in the Chemical Society's Rooms, Burlington House. Mr. Alfred H. Allen, in the absence of the President, occupied the chair.

The minutes of the annual general meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. Norman Parr Booth, John Macallan, and C. T. Tyrer were read for the second time; and certificates in favour of Messrs. James Eugene Kirkpatrick, Analytical Chemist, Taunton; A. J. Murphy, Analytical Chemist, 11, Lyddon Terrace, Leeds; and John Alexander Ramsay, Chief Chemist and Manager, Sugar Experiment Station, Mackay, Queensland, were read for the first time.

Mr. B. W. J. Warren was elected a member of the Society.

The following papers were read: "Note on the Separation of Oleic Acid from other Fatty Acids," by J. Lewkowitsch, Ph.D.; "Analysis of a Sample of Treacle and of a Sample of so-called 'Golden Syrup,'" by C. G. Matthews and A. Hyde Parker; and a "Note on Sour Milk," by H. Droop Richmond and J. B. P. Harrison.

THE PRESIDENT'S ANNUAL ADDRESS.

(Delivered at the Annual Meeting, January 24, 1900.)

IN addressing the Society at the close of a year of office, it is the duty of your President to take stock of the present condition of the affairs of the Society, to review the proceedings of the year, not without remembrance of older histories, and finally to forecast with "intelligent anticipation" the future course of events. The past we may regard with mixed feelings when we consider hopes not fulfilled or realized, but we may still look to a future without a dark cloud in prospect.

Looking back upon the Presidents' addresses in past years, say for ten years, I find certain topics uppermost in the minds of former occupants of this chair—the position of the Society; the prospects of amendment of the laws relating to our official duties; and the relations of Public Analysts to what was known as Somerset House—and these appear still to be the points of chief interest at the present moment.

During the past year we have had to lament the loss of one of our Senior Honorary Fellows, Sir Edward Frankland, whose death last August came so unex-

pectedly, and is felt by many as a personal loss of no ordinary kind. Some here present doubtless owe to him no small part of their education as chemists, others have been associated with him in the affairs of the Royal Society, the Chemical Society, and especially in the Institute of Chemistry, with the affairs of which he was so deeply concerned, and of which he was the first President, and in the welfare of which he remained faithfully and constantly interested. Apart from his eminence in pure science, he held a position of enormous responsibility as a professional chemist, and the high standards of purity by which he judged the character of the water-supply of London have been, without question, largely instrumental in bringing that supply to its present excellent condition, and incidentally set a similarly high standard for other public supplies, not only in this country, but in Europe and the United States, and practically the whole civilized world. The Sixth Report of the Rivers Pollution Commission, that monument of industry and research, in which his share was so large, co-ordinated and established on a sound basis the true principles for the scientific judgment of waters—their comparison with natural supplies of the districts where they are obtained.

An old member of our Society, Dr. Hodges of Belfast, has passed away at the ripe age of eighty-four, and will be much missed in the North of Ireland, where for many years he had done such good work, of which a notice recently appeared in THE ANALYST.

Two other senior members and veteran chemists have been lost to us—Mr. G. H. Ogston, long in professional practice in London, and Mr. R. Oxland, of Bristol, one of the earlier Public Analysts, and who was appointed in 1878 at Plymouth and Davenport.

As our Society was founded at the end of 1874, and held its first general meeting on February 25, 1875, it is now a quarter of a century old, half-way to its jubilee—at the silver-wedding age—and I am happy to say the Society was never stronger numerically or financially, and, I think I may fairly add, never more efficient or vigorous. The new rules came into operation at the beginning of 1899, and although a few associates gave up their connection with us, out of the total number of thirty-two no less than fifteen were elected at the first possible meeting, and eight others have since taken up their freedom, thus increasing the strength of the Society and bringing the younger members into closer association with its business. Forty-one members in all have been elected, making our actual members 9 honorary and 248 ordinary members—a complete total of 257. Two members have withdrawn during the year, but I think, owing to the judicious changes in our rules during the office of my predecessor (Dr. B. Dyer), we may look forward to yet further development.

The Honorary Treasurer has, I am happy to say, been able to give us a cheerful report of his exchequer, notwithstanding the fact of an exceptional amount of expenditure upon the journal and for printing expenses in connection with the Food and Drugs legislation of the past year. I am sure we are most grateful to him for the trouble he has taken on our behalf, not only by those gentle reminders which I hear he has sometimes to send to the forgetful few, but for the zeal he shows in the scrutiny of the various expenditures which are in his departmental control. One

way in which we may venture to show our gratitude is by sending our annual guinea without waiting for the gentle reminder.

I think we all feel that THE ANALYST is year by year increasing in interest and usefulness, and this is dependent upon those gentlemen who contribute their original and valuable work to its pages, and also to our friend Dr. Sykes, the Editor, who, with his coadjutors gather and condense so admirably the analytical matter constituting the rest of the journal. Possibly before long some enlargement of THE ANALYST may be necessary if the number of original contributions increases; but this will not necessarily mean loss to the Society, as growth of this character will be covered by an increase of membership and increased sales.

THE ANALYST is, of course, one of our heaviest items of expenditure, but at the same time one of the most necessary, and keeps the Society alive: it is the bond of union between those present at the meetings and absent members, which no Home Ruler would wish to repeal. The Society, however, has been urged again recently to modify the character of THE ANALYST, and save some part of the expense of its maintenance by accepting advertisements which are at present excluded, relating to articles of food and drink, as well as medical preparations of various kinds. We have not acceded to the suggestions, and I believe we have acted in the best interests of the Society and of professional chemistry. Unless control were exercised, some of the most objectionable forms of advertisement, with their testimonials of a similar class, would appear in the pages of our Journal, while, if a censorship were established, by which one manufacturer's advertisements might be excluded and another admitted, the fact would be taken as a form of guarantee of the wares, or an implied acquiescence in the terms of the advertisement. As Public Analysts, we must feel we are in a delicate position in this regard, and we have acted, therefore, on the simple intelligible principle of inserting no advertisements relating to articles which may be within the purview of the Food and Drugs Acts, and which we may be called upon to examine officially. This policy will, I believe, commend itself to the members of the Society generally, and will, I trust, be adhered to by our uccessors who may be responsible in the future for the conduct of the Society's affairs.

The list of papers read before the Society numbers twenty-eight, and some of the contributions are of permanent value and importance, and much interesting discussion on some of the papers has taken place at the evening meetings. Now that the amended and extended definition of food has been brought into the Act, a very large number of additional articles, and especially sauces and condiments, will come before the notice of analysts, and I hope to see during the next year further contributions to our knowledge from a study of the composition of such articles, now that more attention has been given to them. Those younger members anxious to find fresh ground for research need not want for material for some time to come.

Papers read in 1899:

"The Occurrence of Barium Compounds in an Artesian Well Water." By John White.

"A New Test for Formaldehyde." By Norman Leonard, B.Sc., and Harry M. Smith.

"On Caper Tea." By Charles Estcourt.
"The Adulteration of Sweet Spirit of Nitre with Potassium Nitrate." By W. F. Lowe, A.R.S.M.
"Some Analyses of Ginger." By E. G. Clayton.
"Note on Boric Acid in Milk Samples." By E. G. Clayton.
"Caper Tea." By John White.
"Note on a Possible Source of Error in Modifications of the Leffmann and Beam Method of Fat Estimation in Milk." By H. Droop Richmond and F. R. O'Shaughnessy.
"On a Recent Ginger Case." By E. J. Bevan, Bernard Dyer, D.Sc., and Otto Hehner.
"The Composition of Milk and Milk Products." By H. Droop Richmond.
"An Attempt to Compute Mathematically the most Probable Limits for Milk." By H. Droop Richmond.
"Note on the Estimation of Ether and Alcohol when mixed with Petroleum Ether and other Solvents." By H. Droop Richmond.
"The Estimation of Fat in Milk, using Petroleum Ether as a Solvent." By H. Droop Richmond and C. H. Rosier.
"Notes on Milk Analysis, including the Molybdate Test for Cane-sugar." By L. de Koningh.
"A New Form of Distilling Flask for Use in Water Analysis." By Mr. W. P. Skertchley.
"The Assay of Belladonna, B.P." By F. C. J. Bird.
"On the Use of Boric Acid and Formaldehyde as Milk Preservatives." By S. Rideal, D.Sc., and A. G. R. Foulerton, F.R.C.S.
"The Value of the Estimation of Pentosans in Food Materials." By Otto Hehner and W. P. Skertchly.
"On some Comparative Analyses of, and Digestive Experiments with, White and Wholemeal Breads." By Otto Rosenheim, Ph.D., and P. Schidrowitz, Ph.D.
"Note on Coffee Extracts." By C. G. Moor, M.A., and Martin Priest.
"On the Determination of the Iodine Value." By J. Lewkowitsch, Ph.D.
"On the Influence of Ammonium Salts on the Precipitation of Nickel by Ammonia." By Arthur Marshall.
"The Meaning of the Acetyl Value in Fat Analysis." By J. Lewkowitsch, Ph.D.
"On Some Analyses of Modern Dry Champagne." By Otto Rosenheim, Ph.D., and P. Schidrowitz, Ph.D.
"Note on Asafœtida." By J. M. Martin, B.A., M.B., and C. G. Moor, M.A.
"On the Determination of the Iodine Value." By Dr. J. J. A. Wijs.
"Treacle or Golden Syrup." By E. W. T. Jones.
"On a Method for Distinguishing between Hops and Quassia." By Alfred C. Chapman.

The prospects of amendment of the Food and Drugs Act of 1875—the Act which brought us and our Society into being—have occupied the Society and its officers for several years; but, with all its admitted defects, the old Act has worked

to the advantage of the public in no small degree. Mr. Hehner, in his address as President in 1892, pointed out that the percentage of adulteration, which from 1877-81 was 16·2 per cent. of adulterated samples, had fallen to 11·2 per cent. in 1890. The total number then analysed in the year was 27,465, of which 3,069 were adulterated; and it is interesting to note that the latest accessible return (1898) gives 49,555 samples examined, with 4,319 returned as adulterated—a proportion of 8·7 per cent. The Act has done much to check adulteration, although in ten County Councils and sixteen boroughs its provisions have been greatly or altogether neglected.

In the dark ages of 1890 Mr. Hehner observed that Oxfordshire was at the bottom of the list, but I am glad to say we now occupy a less conspicuous position.

In 1893 Mr. Hehner reviewed the Bill of Dr. Cameron which had met with the doom of the Innocents, and was not lamented; but that year was important for a discussion of proposals in this Society for amending the Acts, and the suggested Chemical Department of the Local Government Board. Our President in 1896 urged the need of the establishment of standards and limits, to be fixed by a competent and authoritative body on which Public Analysts should be represented; the Adulteration of Food Committee sat and reported, and, as you know, embodied in their report many of the suggestions and proposals of our Society.

The session of 1897-98 saw the introduction of another attempt justly described by the President, Dr. Dyer, as disappointing, since it almost ignored all the improvements, so much needed, which had been recommended by the Committee of the House after an exhaustive and careful inquiry. Our Council, as you will remember, took up a line of strong opposition, and the Bill was happily dropped.

At length, in 1899, the new Food and Drugs Bill was brought in, and, being a serious attempt to carry out the recommendations of the special committee, was on the whole favourably received; and after much interesting discussion and considerable changes, passed through Parliament, and came into operation in January of this year, 1900. The Society has been already informed of the modifications suggested by your Council, and the courteous way in which they were considered and received, and I am pleased to say in many cases the suggestions were accepted by Mr. Long and are incorporated in the Act.

Many of the new proposals emanated from the committee of 1896, and were commented upon by your President two years since. Experience alone can teach us the defects of this Act, which will indeed be a marvel of perfection if everybody is satisfied with it. The buyer and the seller, the inspector and the analyst, the prosecuting and defending solicitors, the local authorities, the Board of Agriculture, the Government chemists, besides the magistrates and Her Majesty's judges, will be concerned in various ways in carrying out, interpreting, or finding loopholes in the provisions of the new Act, and its effects will not perhaps be quite in accordance with what was intended; but I look upon many of the new provisions as excellent, and have great hopes of their future usefulness.

It is probable that the number of samples purchased under the Act will increase, especially in certain districts, where little use has been made of its provisions in the past, now the machinery can be set in motion from the Central Authority, and the provisions referring to the use of warranty as a defence will, it is to be hoped,

protect the innocent retailer, and enable the real offender to be punished for adulteration, in fact, put the saddle on the right back.

An important new departure arises from the provision that a certificate of analysis by a Public Analyst, made for the defendant, will be evidence of the facts stated therein, without his personal attendance at the hearing. This seems a fair arrangement, and will be a convenience to those gentlemen who may be asked to make an analysis for the seller. Some fears have been expressed that this provision may lead to undignified disputes in court, and that contradictory certificates will be produced, to the detriment of our profession and the hindrance of justice, but I do not share in these misgivings. Every Public Analyst who may be asked to examine an article for the defendant will do the work with the full responsibility which rests upon him for all his official analyses, and I have no doubt will report impartially on the case. And if he should conscientiously differ in opinion from the analyst for the other side, the case would probably be referred to the Government Laboratory to decide between the opposed opinions. It must be remembered that the correctness of a Public Analyst's certificate is seldom seriously disputed; the number of cases referred to the Government Laboratories is a very small proportion of those reported as adulterated (about 1·5 per cent.), and in three cases out of four the analyst's certificate is confirmed by the referees.* It will doubtless happen that a defendant will have his reserve sample examined, not possibly knowing its real character, only to find the certificate of the buyer confirmed in the large proportion of cases.

Another consequence arising out of the new Act is the appointment of a Departmental Committee to inquire into the questions of preservatives and colouring matters in food. That Committee is now sitting and taking evidence, and, as is only natural where diverse interests are concerned, evidence of very conflicting character has been tendered. But there appears to be a growing conviction that the unrestricted use of preservatives, which hitherto it has been difficult to deal with, should not go on, and some limits should be imposed, and for some articles an entire prohibition of preservatives is necessary. Your Society appointed two representatives, the President and Dr. Stevenson, and many members of the Society have individually given, or will give, their experiences and opinions to the Committee; others, in response to an invitation sent out, have furnished your representatives with much valuable testimony as to the nature and extent to which preservatives are employed in different parts of the country. I anticipate, when the Committee reports, that many disputed points as to the desirability or otherwise of permitting certain additions to food will be finally settled and disposed of.

It may be some time before the Committee is able to collect all the information they would desire, and I should like to invite any of our members who have not yet returned the schedules of preservatives and colouring matters to send them to the secretaries, with any information they may be able to gather on the subject. Probably some suggestions to inspectors in various districts may lead to the purchase of articles on which our information is scanty, as they are seldom bought under the Act.

* 49,555 samples in 1898; 4,319 adulterated, 74 references, with only 17 disagreements.

Our relations with Foreign Powers, I am happy to say, continue friendly, although your Council has had some diplomatic correspondence with the Government chemist, which appeared in the journal of the Society. I do not desire to revive old controversies, and I am glad to notice that the proportion of cases in which the opinion of the referees differed from that of the Public Analyst in respect of disputed samples is diminishing. Doubtless there will be some differences of opinion in the future, as in the past, since the natural variations in composition of animal and vegetable products makes it impossible to fix an exact limit or analytical standard; but since some standard must be used in forming a judgment after every analysis, it is surely better to settle by friendly discussion the lines on which we will work and the limits of variation to be allowed. In this way the unsatisfactory conflict of evidence between a responsible public officer and a Government official could frequently be avoided.

In the report of the Government Laboratory on the samples referred under the Food and Drugs Act, I notice that seventy-four samples came before them for judgment, of which forty-seven were milks. They confirmed the Public Analyst's opinion as to forty milks, and dissented from him in seven cases, which looks as though we have somehow arrived at a common standard of reference for the composition of milks. Also, in three cases out of four, the analyst's verdict was confirmed as to undue dilution of spirits, and here, again, the standard is very definite. But in those cases of ground ginger and caper tea referred to in our correspondence with the Government chemists it is evident that the divergence of opinion rests solely on the diverse interpretation of practically concordant analyses; how far ginger may be impoverished by washing, and how much extraneous matter should be permitted in tea, are the simple questions at issue, and these should be settled once and for all.

The President (Dr. Stevenson) addressing the Society in 1897 quoted the statement of the Adulteration Committee, that "they regarded it as of great importance, in the interests of the public, that Public Analysts should, as far as possible, be made acquainted with the methods adopted by the Government Laboratory in the analysis of food, and with the considerations kept in view by them in determining whether an article has been adulterated"; and added the comment that "this pronouncement we may expect to have a generous and not tardy response, and that the official book, which ought to be, and possibly is, in preparation by Somerset House, placing all the analytical methods used in food and drug analysis, and the deductions that ought to be drawn from the results of analysis, at our disposal, will be welcomed by Public Analysts as a priceless boon."

Dr. Thorpe, at the Society's Dinner in 1896, told us "he had no stronger desire than that both he and we, public servants as we are, should work together cordially and harmoniously in the discharge of our public duties," and he looked forward to an opportunity of personal adjustment of such questions as had been referred to.

Well, gentlemen, I am extremely pleased to say that the Chief Chemist has recently made a suggestion for a conference between this Society and some of the staff, with the special view of coming to an understanding upon the methods to be employed in judging samples of margarine under the new Act. This proposal, naturally, has been cordially accepted, and I have every confidence that we shall

arrive at an understanding both as to a common method of working and the analytical limits to be adopted whereby we can obtain concordant results when the samples have to be examined by both sides.

I venture also to hope that this is only the first conference of its kind, which will be followed by others relating to points where any differences of opinion may arise in regard to other articles.

NOTE ON THE SEPARATION OF OLEIC ACID FROM OTHER FATTY ACIDS.

By J. Lewkowitsch, Ph.D.

(*Read at the Meeting, February* 7, 1900.)

In the course of a technical research on oleic acid, I had occasion to examine two methods which had been proposed recently by Twitchell and by Farnsteiner—the one for the separation of oleic acid (and other liquid acids) from solid fatty acids, the other for the separation of oleic acid from less saturated fatty acids.

I find the two methods practically useless for quantitative purposes, and, unpleasant though it be to publish results of this kind, I think some little service may be rendered to my colleagues by placing my results on record.

Twitchell's method is based on the insolubility in petroleum ether of the oleo-sulpho compound, obtained on treating a mixture of saturated and oleic acids with 85 per cent. sulphuric acid. He obtained apparently very good results in the case of a commercial oleic acid of a cold test of 12° C., his method yielding a little over 7 per cent. solid acids.

I examined a commercial oleic acid made from tallow, having the solidifying-point of 8·5° C. and the iodine value 82·27, so that it may be accepted that the acid contained about 90 per cent. of true oleic acid, and practically very little of less saturated acids, if any.

I obtained in two experiments, when the petroleum ether was allowed to stand with the compound for a short time only, from 21·6 to 25 per cent. solid acids, and in two other experiments, where the mass was allowed to stand with the petroleum ether overnight, from 17·8 to 18·7 per cent. solid acids.

Another sample of oleic acid from the same source, having the iodine value 84·16 and hence containing about 7·25 per cent. solid fatty acids, gave by Twitchell's method from 35·36 to 44·30 per cent. solid acids. The best results were obtained by cooling the oleic acid in ice-water and allowing to stand with the acid for twelve hours before adding the petroleum ether. But even then, in four experiments, from 15·35 to 16·58 per cent. of soluble (supposed solid) acids were found, so that further attempts had to be abandoned.

Farnsteiner's method is based on the insolubility of barium oleate in cold benzene containing a little alcohol, in which menstruum the barium salts of the saturated acids are also insoluble. If this method yielded satisfactory results, an important step in the resolution of mixed fatty acids containing acids of the series $C_nH_{2n}O_2$, $C_nH_{2n-2}O_2$,

$C_nH_{2n-4}O_2$, and less saturated would be made, as all the acids of greater unsaturation than oleic acid could be removed by means of crystallizing the barium salts from benzene containing the prescribed amount of alcohol. From the mixture of saturated acids and oleic acid then remaining, the oleic acid could be separated in a practically satisfactory manner by well-known methods.

I therefore examined samples of linseed, cottonseed, and olive oils. The result is set out in the table. The discordant results suggested the examination of oleic acid. The oleic acid of iodine value 84·16 was employed for the experiments. A glance at the table shows the hopelessness of the method.

TABLE I.

Results of Farnsteiner's Method.

	Amount of Fatty Acids.				
	1st Filtrate.	2nd Filtrate.	3rd Filtrate.	Insoluble.	Total found.
Linseed oil	90·30	4·71	1·57	2·54	99·12
Linseed oil	86·38	4·55	0·98	2·43	94·34
Linseed fatty acids	61·62	17·20	7·80	1·50	88·12
Linseed fatty acids	65·32	14·02	4·40	2·80	86·54
Olive oil	28·20	26·65	10·67	24·16	89·68
Olive oil	29·17	18·65	29·30	12·12	89·77
Olive oil	33·58	22·55	18·36	11·53	86·02
Olive oil	31·93	21·64	24·31	12·34	90·22
Cottonseed oil	64·36	9·58	3·43	18·86	96·23
Cottonseed oil	61·44	10·57	3·00	19·95	94·96
Cottonseed oil	44·25	9·81	8·80	24·52	87·38
Cottonseed oil	44·67	12·26	7·80	22·26	86·99
Oleic acid	85·94	8·05	3·00	2·94	99·93
Oleic acid	85·96	5·28	2·68	3·49	97·41
Oleic acid	42·84	37·74	20·18	—	100·76
Oleic acid	23·28	43·74	29·43	4·20	100·65
Oleic acid	23·70	67·37	5·96	0·44	97·47
Oleic acid	10·68	66·26	20·12	0·40	97·46
Oleic acid	53·73	12·51	29·24	4·70	100·58
Oleic acid	47·90	15·00	34·45	0·63	99·95

An explanation of my failure is found in the following table, which proves that, contrary to Farnsteiner's statement, barium oleate is not insoluble in benzene, and much less so in the proposed mixture of benzene and alcohol.

TABLE II.

Barium Oleate, boiled 1½ hours under reflux condenser with 50 c.c. of Benzene, containing—

95 per Cent. Alcohol.		Yielded Soluble Salt.	
Cubic cents.	0·0	Per cent.	5.3
,,	0·0		14·4
,,	0·5		31·34
,,	1·0		37·17
,,	2·0		57·34
,,	2·0		56·59
,,	2·5		59·94

The experiments set out in the above table were carried out by Mr. C. D. Robertshaw, to whom my best thanks are due.

DISCUSSION.

Mr. HEHNER said that, on heating oleic acid with potassium hydroxide, one molecule of hydrogen was given off, whereas in the case of stearic acid and palmitic acid there was no evolution of hydrogen. It was to be presumed, also, that in the case of linolic acid, which contained one molecule of hydrogen less than oleic acid, no hydrogen would be given off on heating with potassium hydroxide. It would therefore seem that the hydrogen evolved on heating the mixture of fatty acids with potassium hydroxide ought to bear some relation to the quantity of oleic acid present, and might afford a means of determining it.

Mr. C. A. MITCHELL inquired whether the author had made any experiments on the lines of another paper of Farnsteiner, in which lead elaïdate was said to behave in petroleum spirit like the lead salts of the saturated fatty acids, though the results then obtained were not sufficiently constant for quantitative purposes. F. G. Edmed, in a recent paper before the Chemical Society, stated it to be possible, under certain circumstances, to convert oleic acid into elaïdic acid quantitatively, so that Farnsteiner's results in this direction, provided that they were reliable, might possibly now be of assistance in solving the problem.

Dr. LEWKOWITSCH said that Mr. Hehner's suggestion was certainly a valuable one, although the evolution of hydrogen could not be expected to be strictly quantitative so as to determine thereby pure oleic acid; and it would have to be shown that no evolution of hydrogen took place in the case of linolic acid. In reply to Mr. Mitchell, his own attempts to prepare elaïdic acid on a considerable scale led him to think it hardly possible that Edmed could have really obtained, as he stated, 98 per cent. of pure elaïdic acid. Also Farnsteiner had tried to convert quantitatively oleic acid into elaïdic, but had failed.

THE RELATION BETWEEN SPECIFIC GRAVITY, FAT, AND SOLIDS-NOT-FAT IN MILK.

By Norman Leonard, B.Sc., F.I.C.

Many of the formulæ which have at various times been devised to express the relation between the specific gravity, fat, and solids-not-fat in milk are open to criticism on one or more of the following points. In the earlier investigations the number of samples analysed was too small to allow of accurate conclusions being drawn, and the fat was assumed to exercise an influence on the specific gravity corresponding with its density in the isolated state. In many cases the analyses appear to have been made within a comparatively short period, a point which is of importance in connection with the fact, pointed out by Richmond (Analyst, xix., 73-87; xx., 1-3), and confirmed by myself (*vide infra*), that there exists a periodical variation in the constitution of milk. It would seem, also, that the formulæ hitherto proposed have been based on analyses executed by the most accurate, but not always the most generally used, methods, and under conditions more or less removed from those under which the practical analyst, for whose use the formulæ are intended, is compelled to work. The following remarks have reference to 137 samples of milk—genuine and adulterated—received throughout the year 1898 for analysis under the Sale of Food and Drugs Act; and although the analyses have no claim to absolute scientific accuracy, yet the deductions drawn therefrom may have a comparative and a confirmatory value, and the results will be of interest as being the outcome of ordinary routine work. As regards the analytical methods employed, the specific gravity was determined by a hydrometer, due corrections being applied for temperature and for inaccuracies in the graduation of the instrument; the total solids by evaporating 5 grammes to dryness in a platinum dish and drying the residue at 100° C. for three to four hours; the fat by the Werner-Schmid process; and the solids-not-fat by difference. Of the 137 samples examined 4 were "separated" milks, 74 contained from 1 to 3 per cent. of butter-fat, and 9 contained over 4 per cent. of fat; probably the majority of the samples were watered, since 105 contained less than 8·5 per cent. of solids-not-fat. The average composition was: specific gravity, 1029·3; total solids, 11·05; fat, 2·94; solids-not-fat, 8·11 per cent.

Assuming the excess gravity (G), fat (F), and solids-not-fat (S) to be connected by the equation $G = Ss - Ff$, where s and f represent the number of units by which the specific gravity (water = 1000) is raised or lowered by each 1 per cent. of solids-not-fat and fat respectively, the most probable values of s and f are given, according to the method of least squares, by the formulæ

$$s = \frac{\Sigma(SG).\Sigma(F^2) - \Sigma(FG).\Sigma(SF)}{\Sigma(S^2).\Sigma(F^2) - [\Sigma(SF)]^2},$$

$$f = \frac{\Sigma(SG).\Sigma(SF) - \Sigma(FG).\Sigma(S^2)}{\Sigma(S^2).\Sigma(F^2) - [\Sigma(SF)]^2}.$$

Making the calculations indicated, the formula $G = 3{\cdot}905S - 0{\cdot}815F$ is obtained, whence, since T (total solids) = S + F, $F = 0{\cdot}827T - 0{\cdot}212G$. On comparing the fats calculated by this formula with the experimental values, it is found that the errors

lie between $-0{\cdot}33$ and $+0{\cdot}35$ as extremes; in 70 per cent. of the analyses the error is not greater than 0·1, and in 90 per cent. it is not greater than 0·2; the probable error is $\pm 0{\cdot}078$. As has been shown by Richmond (ANALYST, xviii., 169-171), the magnitude of the error appears to be independent of the amount of fat, but there is distinct evidence that the fat calculated exceeds that found as the solids-not-fat rise. The magnitude of the error also varies with the season, as is shown in the table below, in which the 137 samples, arranged in order of date, are divided into six batches of 20 and one of 17, and the average error calculated for each batch. This point will be again referred to later.

Numbers.	Average Error.	s.	f.
1 – 20	– 0·13	4·035	0·954
21 – 40	– 0·04	3·888	0·716
41 – 60	+ 0·03	3·933	0·975
61 – 80	+ 0·05	3·838	0·710
81 – 100	+ 0·07	3·786	0·650
101 – 120	– 0·01	3·941	0·905
121 – 137	– 0·04	3·884	0·720

It may be here pointed out that although 3·905 and 0·815 are respectively the most probable values for s and f in the equation $G = Ss - Ff$ connecting specific gravity, fat, and solids-not-fat, the constants in the equation $F = 0{\cdot}827T - 0{\cdot}212G$, deduced therefrom by means of the relation $T = S + F$, are not the most probable for an equation connecting F, T, and G. The values of a and b in the equation $F = aT - bG$, independently calculated by the method of least squares, are 0·809 and 0·205 respectively; but the results obtained by the use of these figures are practically identical with those given by the formula $F = 0{\cdot}827T - 0{\cdot}212G$, and the probable error is not appreciably less.

In order to ascertain whether the changes in the error at different times of the year are due to variations in the value of either s or f, or of both these factors, their values were independently calculated for each of the batches in the table given above. It will be seen that both s and f vary in a somewhat irregular manner, but that at the time when the error attains its greatest positive value both s and f are at a minimum, whilst the largest negative error coincides with the maximum values of s and (nearly) of f.

The secular variation of the error suggested the use of an equation of the type $F = aT - bG + K$, in which K might be varied with the time of year. In this case the constants a, b, and K must be so chosen as to fulfil the condition

$$\Sigma(aT - bG + K - F)^2 = \text{a minimum.}$$

The values of K calculated for the seven batches of samples separately are very small—less than 0·002—but taking the whole number of samples, the equation $F = 0{\cdot}796T - 0{\cdot}210G + 0{\cdot}30$ is obtained. This gives results with a probable error of $\pm 0{\cdot}076$, and is therefore only slightly more accurate than either of the two formulæ previously suggested. On comparing the fats calculated by this formula with the experimental values and plotting the average monthly errors against the months of the year, a rough curve is obtained having a minimum point in February and a

maximum in August. The following average errors were read from the smoothed curve:

Month.	Error.	Month.	Error.
January ...	−0·12	July ...	+0·11
February ...	−0·13	August ...	+0·12
March ...	−0·09	September	+0·11
April ...	−0·03	October ...	+0·06
May ...	+0·02	November...	−0·01
June ...	+0·07	December...	−0·07

The corresponding corrections, which are of opposite sign to the errors, may be applied to the results obtained with the formula $F = 0{\cdot}796T - 0{\cdot}21G + 0{\cdot}30$, or, what is the same thing, the correction may be applied to the constant K, which thus assumes a different value for each month. With the formula thus corrected results are obtained with a probable error of $\pm 0{\cdot}065$. In 75 per cent. of the analyses the error is not greater than 0·1, and in 94 per cent. it does not exceed 0·2.

The equation $F = 0{\cdot}796T - 0{\cdot}21G + 0{\cdot}30$ may be written

$$F = \tfrac{4}{5}(T - \tfrac{G}{4}) + (0{\cdot}3 - 0{\cdot}004T - 0{\cdot}01G).$$

The value of the term within brackets practically never exceeds $\pm 0{\cdot}1$, and in the vast majority of milks dealt with by Public Analysts it is considerably less; hence the simple formula $F = \frac{4}{5}(T - \frac{G}{4})$ corresponds fairly accurately with the results.

The fats calculated in accordance with the formula $T = \frac{G}{4} + \frac{5}{4}F + 0{\cdot}14$, proposed by Richmond in 1895 (ANALYST, xx., 57), are higher than those given by the formula $F = 0{\cdot}796T - 0{\cdot}21G + 0{\cdot}30$ in the case of milks containing over 10 per cent. of total solids, and lower when the solids are less than 10 per cent. The difference does not, however, exceed 0·1, except in the case of rich milks.

My thanks are due to Dr. Thomas Stevenson for permission to make use of results obtained in his laboratory.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Determination of Glucose in Treacle. A. K. Miller and J. P. Potts. (*Journ. Soc. Chem. Ind.*, 1899, 1091.)—The authors are of opinion that as yet no satisfactory method has been devised for the quantitative analysis of sugar syrups adulterated with glucose, and that, failing this, analysts must be contented with a qualitative test. This, the authors consider, is afforded by the polarimeter; in many cases a single observation by this instrument will show the presence of glucose. It is in general better to extend the examination and proceed as follows: Determine reading of a 10 per cent. solution of the syrup; invert the cane sugar in a portion of the solution, again determine rotation, and calculate the rotation due to cane sugar. If this be deducted from the original rotation, the difference will represent the rotation due to

dextrose and lævulose if the sugar is a genuine sugar syrup, and the result will be a lævo-rotation. As dextrose and lævulose are not invariably present in equal amounts, no suspicion is to be attached to a sample showing a slight dextro-rotation at this point; but if glucose is present, a marked dextro-rotation will be found, and its degree will afford some guide as to the amount of glucose added. Should any doubt still remain, the sugar may be fermented, and the rotation of the solution again determined. As glucose syrups always contain large amounts of dextrin, the rotatory power of the fermented solution affords a good confirmatory test. A table of the analyses of various syrups, pure and adulterated, bearing out the authors' contentions, is appended. W. J. S.

On the Influence of Feeding on some of the Constants of Butter. A. Ruffin. (*Ann. de Chim. Anal.*, 1899, iv., 383-385.)—In order to determine to what extent the nature of the food given to the cow influences the constants of the butter, the author has analysed a number of samples, and summarizes his results in the following table:

Food of Cows.		Refraction No.	Saponification Value.	Reichert-Wollny No.
Fodder, lucerne, etc.	Max.	33	232	34·9
	Min.	30	224	27·6
Cotton-seed oilcake	Max.	30	228	29
	Min.	28·5	222	26·4
Cotton-seed oilcake and fodder	Max.	30	229	30
	Min.	29·5	221	28·4
Earthnut oilcake	Max.	31	228	29
	Min.	30	225	26·9
Earthnut oilcake and fodder	Max.	30	229	32
	Min.	28	221·9	28
Cocoanut oilcake	Max.	33	240	31
	Min.	32	231	28·5

C. A. M.

A New Reagent for Alkaloids, especially Opium Bases. Mecke. (*Zeits. öffentl. Chem.*, 1899, v., 351; through *Chem. Zeit. Rep.*, 1899, 273.)—A 0·5 per cent. solution of selenious acid in strong sulphuric acid gives characteristic colour reactions with colchicine, digitalin, veratrine, and more particularly with the alkaloids of opium. The reagent strikes a conspicuous green tint even with 0·005 milligramme of morphine and codeine, and the reaction is therefore more delicate than its predecessors, appearing immediately and in the cold. When the colours produced by sulphuric acid alone are red, they are very liable to be masked by the brown shade formed by the action of the acid upon extractive matters if the alkaloids are impure; the green yielded by selenious acid in presence of codeine and morphine, on the other hand, is distinctly visible even if the solution turns brown. F. H. L.

TOXICOLOGICAL ANALYSIS.

Determination of Morphine in Toxicological Cases. Russwurm. (*Pharm. C. H.*, 1899, xl., 544; through *Chem. Zeit. Rep.*, 1899, 284.)—The author modifies the usual process slightly so as to recover the alkaloid in a crystalline condition. The original ammoniacal solution is extracted with warm amylic alcohol, the latter is shaken with hydrochloric acid, the aqueous liquid is supersaturated with ammonia, and the solution is extracted with chloroform. The chloroform is evaporated till only a few c.c. are left, mixed with 50 grammes of petroleum spirit, and set aside for twenty-four hours. The liquor is poured off, the morphine crystals are dried first in the air, then at 80° or 90° C., and finally weighed. F. H. L.

Estimation of Chloral Hydrate in Toxicological Work. Russwurm. (*Pharm. C. H.*, 1899, xl., 543; through *Chem. Zeit. Rep.*, 1899, 283.)—Chloral hydrate only distils with difficulty in a current of steam. The substance should be made alkaline and then distilled; a portion of the distillate is boiled with alcoholic potash under an inverted condenser to split off the chlorine, which is then determined as usual. F. H. L.

ORGANIC ANALYSIS.

The Chemical Identification of Vegetable Fibre. E. Jandrier. (*Ann. de Chim. anal.*, 1899, iv., 337, 338.)—This is based on the property possessed by cellulose of being converted by the action of sulphuric acid into carbohydrates of an aldehydic character, which give colour reactions with various phenols.

Thus, for example, to detect cotton-fibre in a woollen fabric, the sample is well washed and warmed for thirty minutes on the water-bath with sulphuric acid of 20° Bé. The liquid is then diluted and tested for carbohydrates in the following manner: About 0·01 gramme of a phenol, such as resorcinol, is placed in a test-tube, into which is also introduced 1 to 2 c.c. of the incomplete solution of the sample. A little sulphuric acid, which must be completely free from nitrous compounds, is then poured down the sides of the tube, which, if necessary, is slightly warmed in the water-bath.

If the liquid obtained by treating with sulphuric acid a quantity of the fabric containing 1 gramme of cotton be diluted to a litre, the colour of the product becomes orange-yellow with resorcinol; violet with α-naphthol, morphine, and codeine; green with gallic acid; brown with hydroquinone and pyrogallol; and rose with thymol, menthol, etc. (*Cf.* ANALYST, xxi., 295.)

These reactions are said to be so extremely sensitive that traces of cotton can be detected even in dyed fabrics, and it is rarely necessary to decolorize the solution with animal charcoal.

By comparing the colours thus obtained with those given by solutions derived from a known weight of cotton under identical conditions as to temperature, etc., the reaction may be made quantitative.

C. A. M.

The Estimation of Sugar in Diabetic Urine. G. Patein and E. Dufau. (*Journ. Pharm. Chim.*, 1899, x., 433-438.)—As certain albuminous substances in urine are incompletely precipitated by the basic or normal acetate of lead, the authors prefer a solution of mercuric nitrate for the purpose. This is prepared by mixing 200 c.c. of acid mercuric nitrate (*nitrate acide de mercure*) with 500 to 600 c.c. of water, adding a few drops of a solution of sodium hydroxide, until, on shaking, a slight yellow precipitate is formed, and making up to a litre.

In making an analysis, this reagent is added to 50 c.c. of the urine so long as a precipitate is formed. Sodium hydroxide solution is then added drop by drop with continual agitation until the liquid is very slightly alkaline, after which it is made up to 100 or 150 c.c. and filtered. The filtrate will contain only traces of mercury, and can be used directly for the volumetric determination of the sugar.

For a polarimetrical estimation, the last traces of mercury may be eliminated by adding a small quantity of sodium hypophosphite, and gently heating the liquid, when the mercury will be precipitated in the metallic form, and the filtrate can be examined in a polarimeter in the ordinary way.

In order to determine the extreme maximum limit at which it might be necessary to use the mercuric nitrate reagent, the authors added to a diabetic urine 10 grammes of peptones and 20 grammes of sodium chloride per litre, and 50 c.c. of this urine only required 60 c.c. of the reagent.

The following table is given in illustration of the author's experiments :

	Sugar, Grammes per litre.			
	1.	2.	3.	4.
Estimated by polarimeter :				
Urine, simply filtered	47·15	55·35		
,, lead subacetate precipitation ...	45·50	55·15	11·95	7·20
,, normal lead acetate precipitation	48·17	55·96	12·40	7·45
,, mercuric nitrate precipitation ...	48·20	55·50	12·71	7·79
,, with addition of peptones and salt, mercuric nitrate precipitation	47·90	55·60	12·30	7·38
Estimated with Fehling's solution in the urine after precipitation with mercuric nitrate	47·50	55·30	12·10	7·20

From these results the authors conclude : (1) That dextrose may be precipitated by basic lead acetate, which may be replaced with advantage by the normal acetate. (2) That certain lævorotatory substances in urine are not precipitated by either of the acetates, and that in such cases concordant results may be obtained by the optical or volumetric methods by the use of acid mercuric nitrate in the manner described above.

They have also made satisfactory estimations by using mercuric sulphate as a precipitating agent in the proportion of from 2 to 5 grammes to 100 c.c. of urine.

C. A. M.

The Solubility of Essential Oils in Sodium Salicylate.* M. Duyk. (*Bull. de l'Acad. belge royale ;* through *Journ. Pharm. Chim.*, 1899, x., 448-452.)—*Oil of Lemon.* —Two treatments with sodium salicylate solution (specific gravity, 1·24) are usually

* *Cf.* ANALYST, this vol., p. 12.

sufficient for the complete extraction of the soluble constituents. A specimen of lemon oil, with specific gravity 0·856 and rotatory power +62·7°, yielded 4·40 per cent. of soluble substances.

The soluble portion was a colourless oil with an odour of citral. Its specific gravity was 0·912, and its optical rotation +2·14°. It was soluble in 20 volumes of alcohol at 60° C., and combined with sodium bisulphite.

The insoluble portion was a colourless oil with a slight odour. Its specific gravity (0·851) and boiling-point (176° C.) agreed with those constants of limonene, but its optical rotation was different.

Eucalyptus Oil.—This contains variable quantities of eucalyptol, according to its origin. As this substance is the most important constituent, the author considers that preference ought always to be given to the oil which yields the largest proportion of soluble constituents to a concentrated salicylate solution.

Oil of Fennel.—This is almost entirely insoluble.

Geranium Oil.—The nature and amount of esters vary in the different species, the oil of geranium palmarosa being relatively very poor in them as compared with the French, Turkish, and African oils. The separation of these esters by means of sodium salicylate solution is never complete, owing to the solvent action of the large quantities of free alcohol present.

Indian or Palmarosa Geranium Oil (*Andropogon Schoenanthus*).—Specific gravity, 0·890; optically inactive; free geraniol, 94·6 per cent. This was completely soluble in 4 volumes of the solution with 1 of water. The product of the acetylation of the oil was completely insoluble.

African Geranium Oil (*Pelargonium*).—Density, 0·892; rotation = −9·2°; geranylic esters, 29·9 per cent. This was almost completely soluble in concentrated salicylate solution. On treatment with 4 volumes of salicylate solution and 1 volume of water, it yielded 7 per cent. of insoluble constituents, probably terpenes.

French Geranium Oil (*Pelargonium*).—Density, 0·900; geranylic esters, 19·60 per cent. Almost completely soluble in the concentrated salicylate solution. On treatment with a dilute solution (4 : 1), it yielded equal parts of soluble and insoluble constituents.

Oil of Cloves.—This contains a large proportion of a phenol (eugenol) and a small quantity of a sesquiterpene (caryophyllene). When shaken with dilute salicylate solution (4 : 1) the whole of the phenol is dissolved, while the sesquiterpene is left. According to the author, good clove oil should contain at least 90 per cent. of soluble constituents.

Essence of Cherry Laurel.—This is completely soluble in dilute salicylate solution.

Oil of Lemon Grass.—This oil is rich in citral, and has also been found to contain geraniol and methylheptenone. When treated with a mixture of 4 parts of the concentrated salicylate solution and 1·5 part of water, it dissolves to a large extent (up to 91 per cent.).

In the author's experiments the insoluble portion had a dark colour, a strong and disagreeable odour, and was strongly lævorotatory. The soluble portion had a strong odour of citral, and had the same density (0·898). Its optical rotation was −0·56°, citral being inactive. C. A. M.

Reactions of Bromine with Phenol and the Cresols, a Process for Calculating the Composition of Mixtures thereof. H. Ditz and F. Cedivoda. (*Zeits. angew. Chem.*, 1899, 873 and 897.)—If either *o*- or *p*-cresol, in alkaline solution, is mixed with a known excess of bromine dissolved in sodium hydroxide, and the liquid is acidified with 1 : 1 hydrochloric acid and agitated for one minute, on adding potassium iodide and titrating with thiosulphate, 2 atoms of bromine will be found to have been taken up by each molecule of the aromatic compound. If either phenol or *m*-cresol is treated similarly, 3 atoms of halogen are absorbed. On the other hand, if either *o*- or *p*-cresol in presence of the bromine and sodium hydroxide is allowed to stand for ten minutes after acidification with strong sulphuric acid, then shaken for five minutes, and the insoluble matter removed by filtration, on adding potassium iodide to the filtrate and titrating with thiosulphate, 3 atoms of bromine will be found to have combined with each molecule of the phenolic body. If either phenol or *m*-cresol is treated in the latter manner, 4 atoms of bromine are absorbed.

Depending on these reactions, it is possible, by suitable calculation, to separate a mixture of any three of the above-mentioned phenols into one which combines with the lower (higher) proportion of halogen, and into two which combine with the higher (lower) proportion of halogen; the results being quite satisfactory. And it is also feasible, though with less accuracy, to separate a mixture containing phenol and each of the isomeric cresols into phenol, *m*-cresol, and *o*- plus *p*-cresol. For the former purpose only one process of absorption is requisite; to attain the latter, both must be carried out. When all four phenolic bodies are present simultaneously, the method of calculation is as follows: a is the total weight of mixed phenols, x the true phenol, y the *o*- plus *p*-cresol, z the *m*-cresol, b the bromine taken up when hydrochloric acid is used, and c the halogen absorbed after treatment with strong sulphuric acid and filtration.

$$x + y + z = a \ldots . \qquad \ldots . \qquad (1).$$

$$\frac{3Br}{94{\cdot}06} \times x + \frac{2Br}{108{\cdot}08} \times y + \frac{3Br}{108{\cdot}08} \times z = b \ldots . \quad (2).$$

$$\frac{4Br}{94{\cdot}06} \times x + \frac{3Br}{108{\cdot}08} \times y + \frac{4Br}{108{\cdot}08} \times z = c \ldots . \quad (3).$$

In order to obtain the original phenols in a condition suitable for bromination, all hydrocarbons, fatty acids, and water must be removed. The authors bring them into ethereal solution, dry the extract with calcium chloride or sodium sulphate, and distil off the solvent. The last traces of ether are driven off by heating the mixture two or three times in a fractionating flask to almost 180° C., and then driving over the phenolic bodies themselves. Care must be taken that the excess of bromine is sufficient in all cases; and in the presence of *p*-cresol, when brominating with hydrochloric acid, the time of standing must not be prolonged.

F. H. L.

Volumetric Estimation of Orthocresol with Bromine. R. Clauser. (*Oesterr. Chem. Zeit.*, 1899, ii., 585.)—The publication of Ditz and Cedivoda's recent process for the separation of mixtures of phenolic bodies (see preceding

abstract) constrains the present author to place on record certain similar results he has himself obtained in the investigation of *o*-cresol.

As Benedikt has already shown, in contact with a large excess of bromine, phenol yields bromoxytribromophenol, which is fairly resistant to the action of water, alkalies, and acids, but gives ordinary tribromophenol on treatment with potassium iodide, according to the reaction :

$$C_6H_2Br_3OBr + 2KI + H_2SO_4 = C_6H_2Br_3OH + HBr + K_2SO_4 + I_2.$$

Clauser has therefore examined the behaviour of the analogous bromoxy-compound of *o*-cresol to see whether, and under what conditions, it is attacked by potassium iodide to regenerate the dibromo-*o*-cresol. He finds that the cresol solution which is treated with the bromine should have a concentration of 1 : 30,000 or 1 : 40,000 ; that too large an excess of bromine should be avoided, the best proportion being 6 atoms of bromine to 1 molecule of the cresol ; that directly the liquid becomes yellow—which occurs in about five minutes, and is due, not to free halogen, but to the formation of the bromoxy-compound—the potassium iodide should be added ; and that the liquid should stand at least half an hour before titration, which should be done in the cold. By attending to these points, *o*-cresol can be determined by the Koppeschaar process with a maximum error of +0·5 per cent. ; exactly 4 atoms of bromine being employed in the reaction per 1 molecule of cresol. Under the conditions of the analysis there is no danger of the iodine liberated from the iodide reacting with the aromatic molecule. F. H. L.

Valuation of Indigo. **R. Clauser.** (*Oesterr. Chem. Zeit.*, 1899, ii., 521.)—This is essentially an improvement upon Schneider's naphthalene process (ANALYST, 1895, xx., 211). According to its quality, 0·3 to 0·5 gramme of the indigo is mixed with 2 or 3 grammes of sand, placed in a paper thimble, such as is used with a Soxhlet, and covered with a layer of glass-wool or asbestos. The extracting vessel consists of a wide test-tube, through the cork of which passes a long vertical glass tube, somewhat narrowed at its lower extremity. Just above the contraction two lateral holes are made opposite one another, and a wire is pushed through the upper part of the thimble and through these holes, so that the indigo mixture is supported about halfway up the test-tube, and underneath the end of the glass tube which serves as condenser. Thirty or forty grammes of pure naphthalene are brought into the vessel, a metal jacket is put round it, and it is heated on a perforated asbestos plate for not more than three hours, till the drops of solvent fall from the thimble colourless. The apparatus is disconnected, the naphthalene melted, and a piece of copper wire with a coil at its end (to serve as a handle) is dropped in ; the mass is next solidified thoroughly, and loosened from the tube by a momentary insertion in boiling water. To separate the indigo-red and naphthalene from the indigotin, ether is used. The apparatus consists (A) of a round-bottomed flask with a side leading tube bent upwards ; (B) of a filter tube made of combustion tubing, with a bulb packed with asbestos above its narrow portion which descends through the cork of A ; (C) of a wide glass cylinder (rather wider than the test-tube previously employed) tapering to

a narrow tube which enters the top of B, and with a side-tube passing from its top downwards (externally) to meet the ascending tube from A. Above C is an inverted condenser. The mass of napthalene and indigotin is dropped into C, the test-tube is rinsed with 50 c.c. of ether, which, with another 150 c.c., is poured into A, and the apparatus is heated on the water-bath for about fifteen minutes till all the naphthalene and indigo-red are dissolved, and the indigotin itself remains on the asbestos filter. B is then dried at 100° C. and weighed; the bulb is next heated in a rapid current of air until the indigo has sublimed, and weighed again. The loss in weight represents the indigotin. The whole operation takes only five or six hours.

F. H. L.

The Solubility of Proteoses and Peptones in Alcohol. J. Effront. (*Bull. Soc. Chim.*, 1899, xxi., 676-680.)—Several methods of estimating the various products of the peptic digestion of albuminous substances have been based on their different solubility in alcohol of different degrees of strength, but the results obtained by one method do not agree with those given by another.

The author has made a number of experiments on this point, from which it appears that the degree of solubility of a series of peptonized products is largely dependent on the reaction of the solvent.

This point is illustrated in the following results obtained with the same crude peptone when treated with 95 per cent. alcohol acidified with different quantities of hydrochloric acid:

	Alcohol, 95%.	Peptone.	Acid.	Insoluble Part.		Ash in Insoluble Part.
		Grammes.	Centigrammes.	Grammes.	Per cent.	Per cent.
1 ...	100 c.c.	2	0	1·099	54·9	5·2
2 ...	100 c.c.	2	14	0·523	26·1	8·79
3 ...	100 c.c.	2	35	0·190	9·5	9·1

On increasing the quantity of acid a point is reached at which no precipitate whatever is obtained. On the other hand, it is possible to get results in close agreement if the alcohol employed be perfectly neutral. C. A. M.

The Estimation of Albumoses and Peptones. J. Effront. (*Bull. Soc. Chim.*, 1899, xxi., 680-683.)—The following method of analysis is based on the author's observations on the solubility of these substances in alcohol (see preceding abstract):

Fifty c.c. of a 5 per cent. solution of the crude peptone are neutralized with decinormal soda and allowed to stand for two hours. The precipitate of syntonin formed is collected on a weighed filter, washed with water and absolute alcohol, dried at 100° C., and weighed. The ash present is also determined and deducted.

A fresh portion of 50 c.c. of the original solution is neutralized in the same way, the liquid diluted to 55 c.c., and the syntonin filtered off after some time, but not washed. To 44 c.c. of the filtrate, corresponding to 40 c.c. of the original solution, are added 8 c.c. of normal hydrochloric acid, and then by degrees 250 c.c. of 95 per

cent. alcohol. After the addition of 8 c.c. of normal sodium hydroxide to the clear solution, the mixture is well shaken, and allowed to stand for two hours, and the resulting precipitate collected on a weighed filter, washed with 75 per cent. alcohol, dried at 100° C., and weighed as albumose.

The filtrate and washings are evaporated on the water-bath, and the residue, consisting of peptones and mineral matter, dried and weighed.

When the substance under examination contains a large proportion of mineral matter, it is advisable to determine the percentage of nitrogen in the different precipitates. In such cases it is also often possible to remove much of the mineral matter by allowing the acidified alcoholic solution to stand for some time before adding the alkali and filtering off the deposited salt.

In illustration of this method the author gives the following results of the analysis of a crude mixture of fibrin derivatives (practically free from ash) at various stages of continued peptonization :

	Original Mixture.	After Three Hours.	After Six Hours.	After Twelve Hours.	After Forty-eight Hours.
	Grammes.	Grammes.	Grammes.	Grammes.	Grammes.
Syntonin	1·14	0·30	0·25	0·2	0·0
Albumoses	1·82	1·869	1·780	1·452	1·41
Peptones	1·32	2·255	2·350	2·750	3·02

C. A. M.

The Estimation and Separation of Ferrocyanides and Carbonyl-ferrocyanides. J. A. Muller. (*Bull. Soc. Chim.*, 1899, xxi., 475-477.)—*A. Estimation of Ferrocyanides.*—The solution containing 4 to 5 grammes per litre is rendered slightly acid with nitric or acetic acid, and lead nitrate or lead acetate added so long as a precipitate results. After twelve hours the liquid is filtered and the precipitate washed with boiling water, dried, detached from the filter, and treated with a mixture of 5 parts of concentrated sulphuric acid and 3 parts of water. The crucible is covered and heated on a sand-bath to expel the excess of sulphuric acid, and then for some time in a muffle at a dull red heat. The residue of lead sulphate and ferric oxide is weighed, and the weight added to that obtained by treating the filter-paper in the same manner.

The combined results, multiplied by 0·5378, give the corresponding amount of potassium ferrocyanide.

In this way the author obtained 99·72 per cent. in nitric acid solution and 100·20 per cent. in an acetic acid solution of ferrocyanide.

B. Estimation of Carbonyl-Ferrocyanides.—An excess of pure cupric acetate is added to the dilute solution of the carbonyl-ferrocyanide, previously acidified with acetic acid. After a day the liquid is filtered and the precipitate thoroughly washed. It is then transferred to a platinum crucible and treated with dilute sulphuric acid (5 : 3). The crucible is heated at first gently on a sand-bath, and then more strongly, until the carbon is completely oxidized. The residue is dissolved in

fuming hydrochloric acid and the copper estimated as cupric sulphide by Rose's method.

The weight of cuprous sulphide, multiplied by 2·787, gives the corresponding amount of potassium carbonyl-ferrocyanide. In test experiments by this method the author obtained 99·12 per cent. of the theoretical amount.

Separation of Ferrocyanides and Carbonyl-Ferrocyanides.—It is not possible to estimate a ferrocyanide by simply precipitating it in the manner described above, when a carbonyl-ferrocyanide is also present in the solution, since some of the latter compound is simultaneously precipitated.

In such cases the author has found the following method satisfactory: The solution of the two ferrocyanides (4 to 5 grammes per litre) is slightly acidified with acetic acid (8 to 10 grammes per litre), and a solution of lead acetate added little by little, with constant shaking, until in slight excess. The vessel is left in a dark place for two or three days until the supernatant liquid is clear. This liquid is then decanted, filtered several times until bright, and an excess of cupric acetate added to precipitate the carbonyl-ferrocyanide.

The lead precipitate is dissolved in a slight excess of a solution of pure sodium hydroxide, and the solution poured into water containing sufficient acetic acid to leave the final liquid acid. The precipitate is left for about a day to settle, and twice redissolved and reprecipitated.

The final precipitate is then treated as described above in *A*; the filtrates are precipitated with cupric acetate, and the precipitates treated as in *B*.

In a test mixture of potassium ferrocyanide and carbonyl-ferrocyanide the author found by this method 99·37 per cent. of the former salt and 100·37 per cent. of the latter. C. A. M.

INORGANIC ANALYSIS.

Estimation of Arsenic in Paris Green. T. Smith. (*Journ. Amer. Chem. Soc.*, vol. xxi. [9], pp. 769-772.)—Two grammes of the substance are boiled for a few minutes with 100 c.c. of water and 2 grammes of sodium hydroxide, the solution being made up to 250 c.c. on cooling, and filtered. Fifty c.c. are then concentrated to one half, cooled to about 80° C., and treated with an equal volume of strong hydrochloric acid and 3 grammes of potassium iodide. After standing for about ten minutes, the precipitate is dissolved by an addition of water, and dilute sodium thiosulphate is added until the deep red colour of the solution just disappears. It is then neutralized with dry sodium carbonate, treated with an excess of sodium bicarbonate, and titrated with $\frac{N}{10}$ iodine, using starch solution as indicator.

To facilitate calculation, it is preferable to use an iodine solution 1 c.c. of which equals 0·005 gramme of arsenic trioxide, instead of decinormal iodine, the number of c.c. consumed, multiplied by 1·25, then giving the percentage of arsenic trioxide in the Paris green. Though the deep red colour developed during the titration helps to mask the end-point, the blue can be easily seen after a few trials, and duplicate tests agree to within 0·05 per cent. C. S.

Determination of Thallium as Chromate. P. E. Browning and G. P. Hutchins. (*Zeits. anorg. Chem.*, 1899, xxii., 380.)—This is an investigation of the process proposed by Crookes for precipitating thallium as thallous chromate by means of potassium bichromate in alkaline solution. The liquid should be heated to 70° or 80° C., made distinctly alkaline with potassium (rather than ammonium) carbonate, and then the bichromate added. After shaking well to make the precipitate cohere, the liquid is allowed to cool, filtered through asbestos in a Gooch crucible, and the chromate dried to constant weight over a small flame. Precipitation in the cold causes some of the chromate to pass through the filter, and although this can be partly avoided by adding ammonium nitrate, the hot treatment is preferable. The results are satisfactory.

By employing a known excess of a standardized bichromate solution, and estimating the portion of the reagent remaining in the filtrate from the thallous chromate, the process can be made volumetric. The filtrate is acidified with sulphuric acid and mixed with a measured excess of arsenious acid; when the colour has become bluish-green, the whole is rendered alkaline with potassium bicarbonate, and the unaltered arsenious acid titrated with iodine. The original bichromate is standardized similarly. Allowing for the high molecular weight of thallous oxide in comparison with chromic acid, this method is also fairly satisfactory. F. H. L.

Electrolytic Determination of Zinc in Presence of Manganese. E. J. Riederer. (*Journ. Amer. Chem. Soc.*, vol. xxi. [9], pp. 789-792.)—The author employed the following reagents: Lactic acid solution containing 0·937 gramme per 1 c.c.; ammonium lactate solution, 0·5 gramme per 1 c.c.; and crystalline ammonium sulphate. The total volume of solution was 230 c.c.; the silvered platinum cathode surface, 150 sq. cm.; distance between anode and cathode, 1·5 cm.; temperature, 26° C.; strength of current, 4 volts, equal to 1·5 volts and 0·20 to 0·26 ampère for each 100 sq. cm. of cathode area; time, four to five and a half hours. Continued stirring gives a more rapid and uniform deposit of zinc. No manganese was deposited on the cathode, though in several cases small amounts of the hydroxide were found on the anode.

The zinc deposit is washed with water, alcohol, and finally with pure ether, and weighed after drying in a hot-water oven and desiccator—this part of the operation taking only *five minutes*. The liquid assumed a dark colour during electrolysis when manganese was present, but this disappeared shortly after the stoppage of the current.

The results obtained with zinc sulphate and manganese sulphate varied by not more that 0·10 per cent. of the theoretical value of the zinc. C. S.

New Volumetric Method for Magnesium. R. K. Meade. (*Journ. Amer. Chem. Soc.*, vol. xxi. [9], pp. 746-752.)—The solution, free from any large excess of ammonium chloride or ammonium oxalate, is strongly agitated in a flask with

one-third its volume of strong ammonia and 50 c.c. of sodium arsenate for about ten minutes. The precipitate is washed with dilute ammonia (1 : 3) until the washings just cease to react for arsenic, and then dissolved in dilute hydrochloric acid (1 : 1), the filter being washed with the same until a total volume of 75 or 100 c.c. is obtained. When cool, the solution is treated with 3 to 5 grammes of potassium iodide (free from iodate), and titrated with standard sodium thiosulphate until the iodine fades to pale straw colour, whereupon starch is added and the titration continued until the colour of the iodide of starch is discharged. If preferred, an excess of thiosulphate may be added, and titrated back with starch and standard iodine until the blue colour is developed. The brown precipitate formed when potassium iodide is added to the acid solution redissolves in presence of thiosulphate. C. S.

Estimation of Sulphuric Acid in Presence of Iron. F. W. Küster and A. Thiel. (*Zeits. anorg. Chem.*, 1900, xxii., 424.)—This is the third contribution, partly polemical, published by the present authors, dealing with the question of avoiding contamination of barium sulphate with iron when sulphuric acid is precipitated by means of barium chloride from a solution containing that metal. The authors sum up their results and the general position as follows: If sulphuric acid is precipitated from a hot liquid which contains ferric ions, the barium sulphate is mixed with the compound $BaFe_2(SO_4)_4$. The formation of this double salt may be avoided either by removing the ferric ions or by producing conditions in which the said double salt is not formed. The ferric ions can be removed either by precipitation with ammonia—filtration being unnecessary—or they can be converted into some complex form—*e.g.*, by the addition of ammonium oxalate—in which they are no longer harmful. The conditions that prevent the formation of the double salt are either precipitation in the cold or a reversed precipitation—that is to say, in hot liquids the addition of the mixture of ferric salt and sulphuric acid to the solution of barium chloride. Conversion of the ferric ions into ferrous ions by treatment with zinc, etc., is not a perfect cure for the trouble, since, although the main source of error is thus avoided, the barium sulphate may still be contaminated with zinc sulphate or ferrous sulphate. (*Cf.* ANALYST, xxiv., 137 and 164). F. H. L.

Iodometric Analysis of Mixtures of Chlorates and Hypochlorites. H. Ditz and H. Knöpfelmacher. (*Zeits. angew. Chem.*, 1899, 1195 and 1217.)—In carrying out the process indicated by the above title, it is customary to decompose the chlorates by heating them with hydrochloric acid and potassium iodide in a closed vessel. The authors find that the reaction, which should be represented by the equation,

$$KClO_3 + 6HCl + 6KI = 6I + 7KCl + 3H_2O,$$

does not proceed quantitatively at ordinary temperatures, nor can it be made to do so by varying the strength of the acid or the time of treatment. If, however, the potassium iodide is replaced by bromide, and if every precaution is taken to avoid loss of bromine vapours, the process becomes quite accurate. A 1-litre bottle is

provided with a hollow glass stopper, which carries centrally a pear-shaped separating funnel (with its own stopper and stopcock), and laterally a small washing flask, the exit tube of which also has a stopper. The main bottle is also fitted with a plain stopper for use when the rest of the apparatus is not being employed; and thus everything is composed of glass. The washing flask is charged with potassium iodide solution. In the bottle are placed the chlorate (0·06 to 0·08 gramme of $KClO_3$) and 20 c.c. of a 5 per cent. solution of potassium bromide; 50 c.c. of strong HCl are run in through the funnel, and the exit stopper of the washing flask is quickly inserted. After an hour, 200 or 300 c.c. of water are added, 20 c.c. of 5 per cent. potassium iodide are introduced, the mixture is well shaken, the iodide in the side flask is blown back into the rest of the liquid, and the whole is titrated with decinormal thiosulphate.

The process is equally available for pure chlorates or for chlorates mixed with hypochlorites, the amount of the latter being ascertained separately. If, however, the proportion of chlorates is very small in comparison with the hypochlorites, as, for example, in bleaching powder, the latter should be destroyed first. The authors doubt whether any of the methods hitherto suggested for this purpose are free from objection; perhaps treatment with carbon dioxide, hydrogen peroxide, or barium peroxide is the best. This matter is being further investigated, and will be dealt with later. F. H. L.

Estimation of Nitrogen in Nitrates. M. Schmoeger. (*Chem. Zeit.*, 1899, xxiii., 829.)—The author has investigated the accuracy of four processes for the estimation of nitrogen by employing them on specimens of potassium and sodium nitrate of known purity. The methods examined were: I., the Kühn or Raab process (reduction with zinc and iron in alkaline solution); II., the Ulsch process; III., the Devarda process (reduction in alkaline solution with an alloy of aluminium, copper, and zinc); and, IV., the Kjeldahl-Förster process. His results, as shown by the table, prove Devarda's plan to be the best, Kühn's to be the worst. Blank analyses are required in all cases, and in II. the purity of the iron must be ascertained (*cf.* ANALYST, 1899, xxiv., 80).

	$NaNO_3$	KNO_3
I.	16·24	13·63
II.	16·37	13·80
III.	16·41	13·83
IV.	16·41	13·80
Theory	16·50	13·88

F. H. L.

A New Reagent for Detecting and Estimating Nitrites in Water. H. Erdmann. (*Zeits. angew. Chem.*, 1900, 33.)—This substance consists of amidonaphtholdisulphonic acid [$NH_2 : OH : HSO_3 : HSO_3 = 1 : 8 : 4 : 6$], which is prepared by nitrating, reducing, and heating with sodium hydroxide the naphthalene (1 : 3 : 5) trisulphonic acid lately described by the author (*Berichte*, 1899, xxxii., 3186). Fifty c.c. of the water are mixed with 5 c.c. of a 0·2 solution of sodium aniline-*p*-sulphonate containing hydrochloric acid, and after ten minutes (diazotation is not completed instan-

taneously in such very weak liquids) 0·5 gramme of solid amidonaphtholdisulphonic acid is added in the form of its acid alkali-metal salt. In presence of nitrous acid a brilliant Bordeaux-red colour appears, which attains its maximum intensity in one hour. The test may be rendered quantitative by colorimetric comparison with $\frac{N}{1,000,000}$, $\frac{N}{100,000}$, and $\frac{N}{10,000}$ solutions of sodium nitrite; or by means of a coloured paper scale previously prepared. These weak nitrite solutions should be diluted from the normal liquid when they are required.

As regards the determination of nitrites when nitrates are present, Gries's test with *a*-naphthylamine, which is officially recognised in Alsace and Lorraine, is not suitable for the examination of water: the orange colouring matter is very insoluble, and is often thrown down in hard or saline water as a flocculent precipitate, which renders colorimetry impossible. Riegler's process (ANALYST, 1897, xxii., 305) is not recommended by Erdmann: naphthionic acid and numerous easily diazotizable substances give fluorescent liquids, and the fluorescence is inconvenient. The above naphthol compound does not fluoresce under the special conditions of the test; moreover, oxidizing agents such as ferric chloride colour it yellow, a tint that cannot be mistaken for the red caused by nitrous acid. Phenylenediamine and analogous bodies yield brown colours both with nitrous acid and with oxidizing agents; and for similar reasons the starch-zinc iodide test, still popular in many bacteriological laboratories, must be rejected.

Free samples of Erdmann's new reagent ready for use can be obtained from J. F. Schwarzlose Söhne, Markgrafenstrasse, 29, Berlin, S.W., and the author appeals to analysts to test its value. F. H. L.

Notes on the Determination of Sulphur in Pig Iron. M. J. Moore. (*Journ. Amer. Chem. Soc.*, vol. xxi. [11], pp. 972-975.)—The author finds that the physical treatment of the sample is largely responsible for the inaccuracies experienced in the volumetric determination of the sulphur, "shot samples" taken from the cupola (because of the difficulty of drilling the cast metal) giving an apparently lower sulphur content than those caught in a sand mould from the mixer. On comparing samples taken by the two methods from the same charge in the mixer, the results of the volumetric tests averaged 0·018 higher for the sand-mould samples, thus showing the unsuitability of "shot" sampling for this mode of analysis. In the gravimetric method, on the other hand, the results were practically identical in both cases. With Bessemer iron low in sulphur the difference (average 0·005 in "sand" samples) between the gravimetric and volumetric results is not so apparent until No. 2 grade is reached. C. S.

Preservation of Hübl's Reagent. R. Bolling. (*Amer. Chem. Journ.*, vol. xxii. [3], pp. 213, 214.)—A standard solution of the reagent was divided and stored under different conditions, viz.:

A1.—In clear glass bottles one-third to a quarter full, loosely stoppered, frequently opened, and exposed to daylight.

A2.—In similar bottles, quite full, closely stoppered, and exposed to daylight.

A3.—In amber-coloured bottles, filled, closely stoppered, and kept in darkness.

A similar solution, but prepared with absolute alcohol, was also stored in filled, closely-stoppered bottles, exposed to daylight (B2) and in darkness (B3).

On testing 5 c.c. with sodium thiosulphate, the initial quantity of free iodine (0·1250 gramme) was found to progressively decrease with storage, the amounts remaining at the end of eight weeks being: A1, 0·0641; A2, 0·0629; A3, 0·0702; B2, 0·0811; B3, 0·0835 gramme, the conditions having but little influence on the result. C. S.

Perezol: a New Indicator. M. Duyk. (*Ann. de Chim. Anal.*, 1899, iv., 372-374.)—Perezol, or pipitzahoic acid, is a compound obtained from the rhizome of the Mexican plant *perezia adnata*. It is an extremely sensitive indicator, for even the weakest alkalies yield with it salts of a violet to black hue. When distilled water containing a drop of the indicator (0·5 per cent. alcoholic solution) is boiled in a glass vessel, the liquid becomes rose-coloured owing to the traces of alkali dissolved. In addition to the fixed and volatile alkalies, the colour of perezol is also changed by alkaloids.

The alkaline, rose-coloured liquid becomes colourless, without any transition stage on treatment with mineral acids, carbonic acid, and organic mono- and poly-basic acids. Boric acid, however, is an exception, and an addition of glycerin is required for the titration. Mineral salts of the strong acids do not affect perezol, but carbonates, bicarbonates, borates, and acetates produce a rose or mauve tint. Ammoniacal salts are also without influence. C. A. M.

APPARATUS.

A Simple Method of Protecting Platinum Wires fused into Glass Tubes. A. Rosenheim. (*Berichte*, 1899, xxxii., 2570, 2571.)—The device adopted by the author to prevent platinum wire fused into glass from being broken is shown in the accompanying figures.

The platinum wire *D*, fused into the vessel *A*, is surrounded on the exterior by a glass tube, *R*, fused on to *A*. This tube is partially filled with mercury, *Q*, in which is immersed the connecting wire, *L*, of the battery. In Fig. 2 and Fig. 3 the tube *R* is adapted for the protection of a wire fused into the side or bottom of a vessel. The tube (Fig. 3) can be easily filled with mercury with the aid of an air-pump. In order to prevent the mercury from being spilled, the opening of the tube may be narrowed, as shown in Fig. 2. C. A. M.

APPEAL ON ACTION SUPPOSED TO HAVE BEEN TAKEN UNDER WRONG SECTION OF THE FOOD AND DRUGS ACT.

QUEEN'S BENCH DIVISION.

(Before Mr. JUSTICE CHANNELL and Mr. JUSTICE BUCKNILL.)

BEARDSLEY *v.* WALTON AND CO.

(*From the* TIMES *of February* 9, 1900.)

THIS was an appeal by case stated from Justices of Wiltshire. An information was laid by the appellant against the respondents charging them with selling to the prejudice of the purchaser a drug—to wit, camphorated oil—which was not of the nature, substance, and quality demanded by the purchaser, the said camphorated oil only containing 8 parts per cent. by weight of camphor, or less than half the quantity of camphor proper to camphorated oil as described in the British Pharmacopœia, contrary to section 6 of the Sale of Food and Drugs Act, 1875. The Justices dismissed the information on the ground that the camphorated oil was a compounded drug, and that consequently the summons could only be issued under section 7 of the Act. Section 6 of the Act provides as follows: "No person shall sell to the prejudice of the purchaser any article of food or any drug which is not of the nature, substance, and quality of the article demanded by such purchaser under a penalty not exceeding £20, provided that the offence shall not be deemed to be committed under this section in the following cases—that is to say . . . (3) Where the food or drug is compounded as in this Act mentioned." Section 7 is as follows: "No person shall sell any compound article of food or compounded drug which is not composed of ingredients in accordance with the demand of the purchaser under a penalty not exceeding £20."

Mr. F. R. RADCLIFFE, for the appellant, contended that camphorated oil was not a compounded drug, because the oil was only a vehicle to enable the camphor to be applied. He also contended that subsection 3 of section 6 did not prevent section 6 applying in the case of compounded drugs sold to the prejudice of the purchaser. He cited White *v.* Bywater (19 Q.B.D., 582) and Houghton *v.* Taplin (13 The *Times* Law Reports, 386).

Mr. BRUCE WILLIAMSON, for the respondent, contended that the effect of subsection 3 was to take offences in regard to compounded drugs out of section 6 and to bring them under section 7.

The Court on Wednesday allowed the appeal.

Mr. Justice CHANNELL said that the difficulty of the case arose from the use by the Justices of the word "consequently." If they had said that camphorated oil was a drug compounded as in this Act mentioned, then the consequence might have followed. The only possible explanation of the words "as in this Act mentioned" was that there was in the Bill a clause dealing with compounded drugs which was afterwards struck out. Their Lordships were not entitled to know that that was the case, but they were entitled to assume so from the language as it stood. The only section in the Act which it could be read as referring to was section 7, which did not in language correspond with it, but did deal with compounded drugs. If so, it must mean that nothing should be an offence under section 6 with reference to compounded drugs unless it was also an offence under section 7. Whatever meaning subsection 3 bore, this offence was equally within section 6.

Mr. Justice BUCKNILL concurred.

THE ANALYST.

APRIL, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, March 7, in the Chemical Society's Rooms, Burlington House. The President, Mr. W. W. Fisher, M.A., occupied the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. J. E. Kirkpatrick, A. J. Murphy and A. A. Ramsay were read for the second time; and certificates in favour of Messrs. Thomas Eustace Hill, M.B., B.Sc. (Edin.), F.I.C., Shire Hall, Durham, Medical Officer of Health for the County of Durham; Thomas Macara, 6, West Bank, Hillhead, Glasgow, assistant to Dr. John Clark; and William E. F. Powney, 67, Barrett's Grove, Stoke Newington, chief assistant to Mr. G. T. Holloway, were read for the first time.

Messrs. Norman Parr Booth, John Macallan and C. T. Tyrer were elected members of the Society.

The following papers were read: "The Determination of Carbon and Sulphur in Steel," by Bertram Blount; "Maize Oil," by Rowland Williams; and a "Note on the Assay of Creosote," by A. D. Hall, M.A.

THE ANALYSIS OF GOLDEN SYRUP.

By NORMAN LEONARD, B.Sc.

IN the December number of the *Journal of the Society of Chemical Industry* (1899, xviii., p. 1091) there appears, under the title of "Notes on the Analysis of Some Sugar Syrups," a criticism, by Messrs. A. K. Miller, Ph.D., and J. H. Potts, of a recent paper on the analysis of golden syrup by Mr. R. Bodmer, Mr. H. M. Smith, and myself (ANALYST, 1899, xxiv., p. 253). Whilst admitting the fairness, from their own standpoint, of the objections raised to our work by Dr. Miller and his colleague, I wish to emphasize the fact that our paper was communicated to the Society of Public Analysts, and was written from the point of view of the Public Analyst; it was not in any way intended as an introduction of new processes for the exact analysis of sugar syrups. At the time we wrote, the analysis of golden syrup was new to Public Analysts, *qua* Public Analysts, and since numerous inquiries addressed

to one of us indicated a lack of information on the subject, we thought it useful to outline a scheme of analysis, the details of which might be altered or extended to suit individual preferences, and to show how, by a balancing of probabilities, a fairly safe and generally intelligible opinion as to the nature of a sample might be arrived at. It is doubtful if any Public Analyst would care to certify the amount of glucose added to golden syrup more accurately than to the nearest 5 per cent., and even then, seeing the variable composition of glucose and golden syrups, the adoption of such expressions as "*about* 50 per cent. of glucose syrup" or "*at least* 70 per cent. of glucose syrup" is advisable. It will thus be seen that the meanings attached to the word "approximate" by Messrs. Miller and Potts on the one hand, and by ourselves on the other, are rather different, and that consequently many of the objections raised to our analyses lose somewhat of their force.

Messrs. Miller and Potts seem not to appreciate the position of the Public Analyst, who is bound by the form of certificate prescribed by the Sale of Food and Drugs Acts to give a quantitative expression of the composition of an article which he believes to be adulterated; he is not permitted to "be content with a qualitative test." This being so, recourse must be had to the method of averages, so much deprecated by Dr. Miller and Mr. Potts, which those whose business it is to examine products of variable composition are often obliged to employ. An exact determination of all the constituents of a sugar syrup would doubtless be of great interest to the chemist and to the manufacturer, but such an analysis would, as a rule, be quite unintelligible both to the magistrate and to the vendor charged with adulteration. The analytical results would therefore require to be expressed in terms of such comparatively familiar substances as cane-sugar syrup and glucose syrup, and this would again necessitate the use of averages, for it would be impossible to say accurately how the water, ash, and organic matter were distributed between the two syrups in a mixture.

Respecting the errors introduced into the estimation of the water by neglecting the influence of the ash on the specific gravity of the syrup solution, I may observe that the amount of water present is, to the Public Analyst, of very little importance. We were aware of this source of error, but it may be pointed out that large amounts of ash are, I believe, rarely found except in crude, genuine syrups which would be passed without comment by a Public Analyst, whilst in those samples which are largely adulterated with glucose syrup the ash is usually low, and the resulting error, which here becomes of more importance, is also small, and comparable with that inherent in the divisor process when applied to such complex mixtures as those in question.

Although not claiming so much accuracy for our analyses as Dr. Miller appears to have thought was the case, it may be of interest to make some remarks on the minus values obtained for invert sugar in No. 4 sample and some others. These values, which we had understood were not uncommonly obtained in the indirect analysis of complex and impure syrups, had not escaped our notice, and we had followed the matter up even farther than our critics seem to have done. For although it is quite true, taking $i = 0$ in the equation $K = i + 0{\cdot}53x$, that the *maximum* percentage of glucose (on the basis of the 53 factor) in No. 4 sample is 62·6, it is

possible to look at the matter from another point of view. Thus, in the equation $[\alpha]_D = \frac{66{\cdot}5s + 134x - 23{\cdot}1i}{100}$, if there is no invert sugar i must equal 0 and x (glucose) becomes 75·8; and this is the *minimum* percentage of glucose on the basis of the 134° factor. This sample is not improbably adulterated with a glucose syrup having a lower reducing power than the average assumed by us, and we have here an example of the discrepancies inseparable from the use of averages, which, however, as already stated, must necessarily be employed.

It should be remembered that the Public Analyst, whilst making use of average analyses as a basis for calculation and comparison, is, or should be, fully aware of the greater or less amount of reliance to be placed on them, and is accustomed to regard his results from various points of view, knowing that the most elaborate and accurate analysis may lead him astray unless due regard is paid to modes of interpretation and to other circumstances than analytical details. The statements of the proximate composition of the mixed syrups given at the close of our paper (ANALYST, xxiv., p. 257) are to be regarded in this light, and, although more accurate methods are greatly to be desired, Messrs. Miller and Potts appear unable to suggest a process better adapted to the wants of the Public Analyst than that described by Mr. Bodmer, Mr. Smith, and myself.

TREACLE, OR GOLDEN SYRUP.

By E. W. T. JONES.

AT the request of certain friends, I beg to lay before the Society of Public Analysts my method of treating the subject of the adulteration of golden syrup with starch glucose syrup, because, although there have been several excellent papers bearing on the subject, I believe my view of the question simplifies matters without detracting from the practical accuracy obtainable by more detailed methods. Of course, I do not advocate blindly applying my formula to every sample that may be presented. I am taking things as we find them at present, and a public analyst will naturally adapt himself with intelligence to any varying conditions which may arise.

Golden syrup, whether the natural by-product of the sugar industry or the artificial product from refined sugar, consists essentially of sucrose and invert sugar, the difference between the two classes of products consisting mainly in the relative proportions of sucrose and invert sugar. By converting the sucrose into invert sugar considerable uniformity, from a polarimetric point of view, is obtained in the case of genuine samples, which at the same time are made to exhibit a greater divergency from glucose syrup, which always has a high dextro-rotation, genuine samples of golden syrup being, after inversion, lævorotatory. The following two samples will illustrate this statement. The one is Crosfield's genuine cane syrup, and the other is Lyle's golden syrup, the former containing nearly 40 per cent. of sucrose and the latter about 30 per cent.:

	Specific Rotatory Power, at 17·5° C.			
	Original.		After Inversion.	
	$[\alpha]_J$	$[\alpha]_D$	$[\alpha]_J$	$[\alpha]_D$
No. 1. Crosfield's	+26·90	+24·21	−12·30	−11·07
No. 2. Lyle's	+16·13	+14·52	−15·37	−13·83

Glucose syrup is not sensibly altered by a careful inversion treatment. The sample in my possession, which is representative of what is used, has a specific rotatory power at 17·5° C. of $[\alpha]_J + 121$ or $[\alpha]_D + 109$. I therefore suggest the following simple formula for arriving at the percentage of glucose syrup in a sample of golden syrup, if the same *after inversion* has a *dextro*-rotation:

$$[\alpha]_J \frac{([\alpha]_J \textit{ after} \text{ inversion} + 12{\cdot}3)100}{133{\cdot}3} = \text{per cent. glucose syrup.}$$

$$[\alpha]_D \frac{([\alpha]_D \textit{ after} \text{ inversion} + 11)100}{120} = \text{per cent. glucose syrup.}$$

A sample of golden syrup was sent to me, said by the manufacturer to contain 18 per cent. glucose syrup. It had a specific rotatory power *after* inversion of:

$[\alpha]_J$ +12·3 $[\alpha]_D$ +11·07

By the above formulæ, it shows 18·4 per cent. of glucose syrup.

I have taken the figure of the No. 1 syrup because these darker-coloured syrups are those used generally to mix with glucose syrup.

The way I actually proceed with a sample is to make a 10 per cent. solution at 15·5° C., and take the specific gravity. This should not be sensibly less than 1032, which indicates 20 per cent. of water, for I have found by carefully estimating the water in vacuo, or by drying after incorporation with thirty times its weight of sand, that the divisor 4 for specific gravity over 1,000 in a 10 per cent. solution is practically correct for the solid matter. The divisor 3·86 is correct for about 10 per cent. solution of *pure sucrose*, but gives low results, to the extent of about 3 per cent. of water in the case of ordinary golden syrup, thus all Messrs. Bodmer, Leonard and Smith's estimations of water given in their paper (Analyst, vol. xxiv., p. 255) are about this much too low.

The 10 per cent. solution above mentioned (if I wish to estimate the sucrose) I raise to a temperature of 17·5° C., and examine in the polarimeter in 100-millimetre tube. Fifty c.c. of the same solution + 5 c.c. N acid are heated in a 100 c.c. flask in boiling water for twenty minutes, then cooled, and 5 c.c. N soda are added, and the bulk made up to 100 c.c. at 15·5° C. This solution is examined through the 100-millimetre tube at the proper temperature, 17·5° C., and the reading multiplied by two to make it correspond to the 10 per cent. solution.

I do not use the 200-millimetre tube, since the inverted solution is often too dark, and I purposely avoid the use of decolorizing agents. Mine is a Ventzke-Scheibler polarimeter, and, as a matter of fact, I generally for this purpose work with scale degrees.

The sample referred to as adulterated with 18 per cent. glucose syrup, gave for the 10 per cent. solution after inversion +3·2 scale divisions:

$$\frac{\text{Plus scale divisions observed in sample after inversion} + 3{\cdot}2}{0{\cdot}347} = \text{per cent. glucose syrup.}$$

Thus it comes to 18·4 per cent.

For the copper reduction, if it is required, I take 10 c.c. of the first solution and make up to 100 c.c.; 20 c.c. of this (=0·2 gramme of the sample) I add to 50 c.c. of Fehling solution diluted with 30 c.c. of water, which has acquired the temperature of, and still stands in, *boiling* water. The mixture is allowed to remain twelve minutes, and then filtered through an ashless filter, well washed, dried, ignited in a porcelain crucible (very slowly at first, only *just smouldering* the filter away. The CuO then does not cohere, and is fully oxidized). The CuO × 0·4307 (Log $\bar{1}$·63414) = invert sugar. Of the inverted solution I take 20 c.c. and make up to 100 c.c., and take 20 c.c. (=0·2 gramme of the sample), add to Fehling solution, and proceed as above. The quantity of CuO found in the preceding experiment is deducted from that obtained after inversion, and the difference × 0·4091 (Log $\bar{1}$·61186) = cane sugar in 0·2 gramme of the sample.

I have examined a great many samples very thoroughly, and find that the simple method I gave at the commencement of this paper has afforded very consistent results. It has been suggested that the alcohol test for dextrin is of no use, but if it is always applied in a definite way, viz., taking 2 c.c. of the 10 per cent. solution and adding 20 c.c. of strong (miscible) methylated spirit, the *white* cloudiness formed is quite distinguishable from the occasional turbidity of some samples not containing dextrin.

ANALYSIS OF A SAMPLE OF TREACLE AND OF SO-CALLED GOLDEN SYRUP.

By Charles George Matthews, F.I.C., and A. Hyde Parker.

(*Read at the Meeting, February* 7, 1900.)

Values used in Calculating the two Analyses.

The usual divisor for carbohydrates, 3·86.

Value of a 1 per cent. solution of the sugar observed in a 200-millimetre tube:

	Soleil-Ventzke-Scheibler Divisions.		Laurent Degrees.
Maltose	8·02		2·76
Dextrin	11·56		3·98
Dextrose	3·05	× 0·344 =	1·05
Gallisin	4·85		1·67
Cane sugar	3·84		1·32

Cupric-reducing values:

	CuO equivalent to 1 Gramme of Substance.
Maltose	1·37 grammes
Dextrose	2·46 ,,
Gallisin	1·01 ,,

SAMPLE OF TREACLE (FULL COLOUR, GOOD FLAVOUR, BUT SLIGHTLY SALINE).

A. *Calculation of the Gravity due to Ash.*—Five grammes of the sample yielded 0·373 gramme of non-sulphated ash, equal to 7·46 per cent. This was shaken up with 100 c.c. of water and the specific gravity of the mixture found to be 1,003·25; by division $\frac{3{\cdot}25}{0{\cdot}373} = 8{\cdot}7$ was obtained as solution factor.

Another 5 grammes yielded 0·4485 gramme of sulphated ash, equal to 8·97 per cent., and this, similarly treated, gave a mixture with a specific gravity of 1,004·35 and a solution factor of 9·7.

The mean of these two percentages of ash was 8·21, and the mean solution factor 9·2.

Determination of the Dry Solids.—The specific gravity of a 10 per cent. solution of the sample was 1,032·10, and the mean specific gravity due to ash in a solution of the same strength was 1,007·55, therefore the specific gravity due to carbohydrates was 1,024·55, which, divided by 3·86, gives 63·6 per cent. of carbohydrates, and this figure added to that of the ash gives 71·81 per cent. total solids.*

B. *Determination of the Cane Sugar.*—One gramme of pressed yeast was added to 50 c.c. of a 10 per cent. solution of the sample, the mixture kept at a temperature of 52° C. for five hours, boiled to destroy bi-rotation, made up to bulk, filtered, and examined in a 200-millimetre tube.

	Soleil-Ventzke-Scheibler Divisions.	Laurent Degrees.
Before inversion	... +16·16	+5·56
After ,, ...	... − 6·33	−2·18
Difference ...	... +22·49	+7·74

The Soleil-Ventzke-Scheibler divisions, 22·49 × 10 and divided by 5·02,† or the Laurent degrees, 7·74 divided by 0·1727, give 44·8 per cent. of cane sugar.

C. *Cupric-reducing Power.* — Five grammes of the sample were dissolved in 100 c.c. of water, and the amount of cupric reduction in 2 c.c. estimated gravimetrically by the filter-paper method and weighing as cupric oxide.‡ The weight found 0·0305 grammes × 100 gives 3·05 for a 10 per cent. solution. This figure multiplied by 10 and divided by 2·36§ = 12·92 per cent. reducing sugars.

* Heron (*Trans. Fed. Insts. Brewing*, 1896, p. 449) regards the sulphated ash as accurately representing the ash without any correction, and he takes the solution factor for the ash as being about double that for the carbohydrates (approximately eight), but seeing that the sulphated ash is perceptibly higher than the plain ash, and the solution factor also higher, the number eight would in our view be sufficiently accurate as applied to the sulphated ash.

† Divisor for 1 per cent. cane sugar solution in 200-millimetre tube when converted into invert sugar.

‡ *Vide* Morris, *Trans. Fed. Insts. Brewing*, 1898, p. 164.

§ Mean cupric-reducing power per 1 gramme of invert sugar. (Levulose = 2·26.)

D. *Estimation of the Matter disappearing during Fermentation.*—A few grammes of pressed yeast were added to 150 c.c. of a 10 per cent. solution of the sample, and kept at about 18° C. until fermentation ceased (about seventy-two hours). The solution was then found to have the following constants: Optical activity, 0·0; cupric-reducing power (K_{100}) (10 per cent. solution), 0·65.

The specific gravity lost during fermentation was:

Original specific gravity	1,032·10
Extract gravity after fermentation	1,010·78
	21·32

This figure, $21{\cdot}32 \times 10 \div 3{\cdot}86 = 55{\cdot}2$ per cent. sugar which has disappeared during fermentation.

This figure, 55·2, may be compared with that obtained by adding the cane sugar and reducing sugar estimation, viz.:

Cane sugar	44·0
Reducing sugar	10·17
	54·97

The residual cupric-reducing power left after fermentation may be regarded as due to unfermented dextrose and lævulose, and the mean reducing value of these two reducing sugars is 2·36 (1 gramme invert sugar = 2·36 grammes copper oxide). Consequently $0{\cdot}65 \times 10 \div 2{\cdot}36 = 2{\cdot}75$ per cent. of a mixture of the two sugars, having an optical activity of 0·0. This calculated out to a mixture of 1·78 per cent. dextrose and 0·97 per cent. lævulose.*

The composition of the fermented matter consisted therefore of:—

Reducing sugars calculated from original cupric-reducing power	12·92	per cent.
,, ,, left unfermented	2·75	,,
,, ,, disappeared during fermentation	10·17	,,

Estimation of the Reducing Sugars removed by Fermentation.—The amount of these is found by subtracting the polarimetric reading corresponding to the cane sugar from that of the original 10 per cent. solution of the sample:

	Soleil-Ventzke-Scheibler Divisions.	Laurent Degrees.
Original solution in 200-millimetre tube	16·16	5·56
Deviation due to cane sugar ($4{\cdot}48 \times 3{\cdot}84$) ...	17·20	5·92
Difference	−1·04	−0·36

The reducing sugars were found previously to have a copper-reducing value of 2·4 in a 10 per cent. solution, and, since their optical activity was −1·04, they consisted of a mixture of 4·83 parts lævulose and 5·34 dextrose. These amounts added to the same sugars which were left unfermented equal 5·80 per cent. lævulose and 7·12 per cent. dextrose. (For mode of calculation, see previous footnote.)

* The composition of the mixed sugars is calculated as follows: Let x = the dextrose and $(2{\cdot}75 - x)$ = the lævulose, then $x \times 52{\cdot}8 + (2{\cdot}75 - x) \times -95{\cdot}65 = 0$, and $x = 1{\cdot}78$.

The complete analysis was as follows :

Cane sugar	44·80
Lævulose	5·80
Dextrose	7·12
Ash	8·21
Unaccounted for = inactive matter	5·87
	71·80
Difference = moisture	28·20
	100·00

Had the results been calculated in the old way, viz., by dividing the weight about 1,000 of the 10 per cent. solution by 3·86, we should have the following :

$$\text{Specific gravity } 1{,}032{\cdot}1 \text{ and } \frac{32{\cdot}1}{3{\cdot}86} \times 10 = 83{\cdot}16 \text{ per cent.};$$

83·16 would then have been formerly taken as the true solids, and the difference as moisture, and the above analysis (excluding any question of newer methods and values used in calculating the cane sugar, dextrose, and lævulose) would have become :

SUMMARY.

E. *Determination of combined Dextrin* (*Amyloïn-dextrin*).—Any maltose existing in combination as malto-dextrin would reveal its presence by an increased reducing power after treatment of the fermented solution with cold-water malt-extract,* and this released maltose would be removed by a subsequent fermentation with yeast. To 100 c.c. of the fermented 10 per cent. solution 10 c.c. of malt-extract were added, and the mixture kept at a temperature of 55° C. for two hours.

A considerable increase in the cupric-reducing power ensued (= 18·3 per cent. of dextrin), but inasmuch as the solution after treatment with malt extract was not susceptible of fermentation to an appreciably further point than the non-treated portion, we do not consider ourselves justified in using the figure so obtained for dextrin.

The same rather curious fact has been noticed in the case of two or three other syrups which had been undoubtedly manufactured from cereals or cereal starch.

This consideration of the failure of the solution treated with malt-extract to ferment further than the untreated solution, also affects the question of the combined maltose, which should be—like the maltose produced from hydrolysed dextrin—rendered fermentable by the action of the cold-water malt-extract, and therefore the whole cupric reduction shown by the 10 per cent. solution after plain fermentation is not to be calculated as combined maltose. There is, on the contrary, every reason to believe that it is mainly due to gallisin, and it will be seen that consistent results are to be obtained if this view be adopted.

We assumed the residual cupric-reducing value of 1·46 to be due to gallisin, and 1·46 × 10 ÷ 1·01 = 14·4 per cent. of gallisin. This amount would cause a deviation in a 200-millimetre tube of 1·44 × 4·85 = 6·98 Soleil-Ventzke-Scheibler divisions, or 1·44 × 1·67 = 2·40 Laurent degrees.

The deviation observed after re-fermenting the fermented solution which had been treated with malt-extract was 22·8 Soleil-Ventzke-Scheibler divisions, or 7·84 Laurent degrees, and this, less the deviation due to gallisin, was 22·28 − 6·98 = 15·3 Soleil-Ventzke-Scheibler, or 5·26 Laurent degrees, and either (15·3 × 10 ÷ 11·56) or (5·26 × 10 ÷ 3·98) equal 13·2 per cent. of dextrin.

* Made by intimately mixing 100 grammes of finely-ground pale malt with 250 c.c. of water, and allowing the mixture to stand for twelve hours, giving it an occasional stir. The clear filtrate is used (*vide* Morris and Moritz, "Text-book of Brewing," pp. 477-480).

The matter remaining after treatment with malt-extract and re-fermentation amounted to 30 per cent., and as 27·6 per cent. was shown to be gallisin and dextrin, 2·4 per cent. was left unaccounted for.

The total matter which had disappeared during the first fermentation was 43·7 per cent., and deducting from this the 11·3 per cent. of cane sugar, 32·4 per cent. of reducing sugars were fermented. These consisted of a mixture of maltose and dextrose, having a cupric-reducing value of 6·106 (original K_{100} 7·65 – residue K_{100} 1·544), which equals 1·88 grammes of CuO to 1 gramme of substance. The deviation in a 200-millimetre tube equal to this 32·4 per cent. of substance was :—

	Soleil-Ventzke-Scheibler Divisions.	Laurent Degrees.
Original deviation	53·60	18·44
Deviation after first fermentation...	31·20	10·73
	22·40	7·70
Deviation corresponding to cane sugar estimation	4·34	1·49
	18·06	6·21

And either ($18·06 \times 10 \div 32·4 = 5·57$, divisor Soleil-Ventzke-Scheibler) or ($6·21 \times 10 \div 32·4 = 1·91$, divisor Laurent) equal the deviation in a 200-millimetre tube due to 1 gramme of substance.

These values correspond to a mixture of 16·84 parts of maltose and 15·56 dextrose.*

Discussion.

The Chairman (Mr. A. H. Allen) invited discussion, with special reference to the question of refermentation after the addition of malt-extract, and to the authors' assumption that gallisin was a substance of definite composition, possessing a definite reducing power and optical activity.

Dr. Sykes said that in all starch conversions, whether effected by acid or by diastase, undoubtedly certain bodies were present which could not be fermented by yeast alone, but which under the combined influence of yeast and diastase were readily fermentable, a fact utilized by the spirit or vinegar manufacturer, who did not boil his wort, and consequently preserved his diastase intact during the fermentation. In a glucose determination the removal of these bodies was, as mentioned in the paper, secured by fermenting the once fermented solution after the addition of malt-extract.

Dr. Dyer said he considered that, in dealing with this subject, a mistake had often been made in treating treacle, or any form of sugar syrup—a mixture of cane sugar and invert sugar—as an entity. Glucose syrup, however, for all practical purposes, could be so treated. Certain figures could be assumed as being safe outside limits to take for commercial glucose syrup, but no figures at all could be taken as representing constants for treacle or golden syrup.* Probably, indeed, some of the mixtures which had to be dealt with were not mixtures of glucose syrup with what would be called golden syrup or treacle, but consisted of commercial glucose syrup with the addition of crude sugar of some kind dissolved in water. In such cases the cane sugar was far higher in proportion to the invert sugar than would be the case in ordinary treacle or inverted syrup made from sugar. With the assistance of Mr. Sydney Steel, and from information kindly furnished to him by other chemical friends with experience in glucose syrup, he had arrived at the conclusion that it was quite safe to assume certain constants for glucose syrup: not exactly average figures, but figures representing the outside limits likely to be met with in the glucose syrup used for these mixtures—figures which would, if anything, give to the mixer the benefit of any doubt. The following were the figures assumed for glucose syrup:

Specific rotatory power $-[\alpha]_D$	$+113{\cdot}0$
Cupric oxide reducing power ("K value") ...	42

Where a polarimeter was used, which was graduated, not for angles, but for percentages of sugar, the rotation for "normal weight" dissolved in 100 c.c. of water was +170 divisions. Occasionally samples of glucose syrup were met with having a higher rotation, but such cases were exceptional. From polarization at 20° C., before and after inversion (by Herzfeld's method), and determination of the copper reducing power, the percentage of glucose syrup was calculated from the following formula, in which R stands for the specific rotatory power $[\alpha]_D$, at 20° C., of the uninverted sample, S for the + rotation due to the sucrose present, and K for the copper reducing power:

$$\text{Percentage of glucose syrup} = \frac{0{\cdot}206K + (R - S)}{1{\cdot}217}.$$

* Mr. Jones, in his paper on p. 87 of this number, suggests that, *after inversion*, sugar syrup may be regarded as an "entity." This materially reduces the liability to error through the assumption of a constant composition, but appears less satisfactory than the mode of calculation described in this paragraph.—B. D.

If a polarimeter reading percentages were used, and the observation made on "normal weight" of the syrup, R being the "percentage" reading before inversion and S the percentage of sucrose, the formula was:

$$\text{Percentage of glucose syrup} = \frac{0{\cdot}31K + (R - S)}{1{\cdot}83}.$$

The method was substantially that described some time back by Mr. Boseley for the estimation of glucose in marmalade, differing mainly in that the syrup, and not the "solids" dissolved in it, was treated as the direct basis of calculation. Mr. Chapman, after making a number of analyses of syrups more or less on the lines of those detailed in the paper of Messrs. Matthews and Hyde Parker, had also applied to his results this simple mode of calculation, and an interesting comparison was thus afforded between this method and the more elaborate and more scientific determinations which took into account the percentages of the different individual carbohydrates present.

Mr. CHAPMAN said that, whilst the rotation and copper oxide reducing power obtained, after fermentation were assumed by the authors to be due to unfermented dextrose and lævulose, modern methods of sugar analysis were to a great extent based on the assumption (which was universally believed to be justifiable) that dextrose and lævulose were, under proper conditions, entirely fermentable, and he ventured to think that the numbers referred to should rather be regarded as due to certain unfermentable bodies allied to the carbohydrates, which were well known to exist in raw sugars and in invert sugar, and to be possessed of very little optical activity, but of considerable cupric oxide reducing power. In some analyses of raw sugar recently published by Mr. Glendenning, unfermentable residues, which undoubtedly did not consist of carbohydrates, being possessed of very little optical activity, but having a cupric oxide reducing power of about 30, were shown to exist in almost all raw sugars in the proportion of from 1 to 3 per cent. With regard to the question of gallisin, he thought it a pity that definite assumptions should be made in regard to so indefinite a substance. The substance called gallisin had been obtained some years previously by a method which offered practically no guarantee as to its purity, and a body somewhat resembling it had since been obtained from glucoses and other commercial carbohydrate mixtures; but he thought there was insufficient evidence to warrant its being regarded as a body of definite composition. He had, as Dr. Dyer had mentioned, made analyses of a number of samples of adulterated treacle, four of which gave the following results:

	No. 1.	No. 2.	No. 3.	No. 4.
Cane sugar	20·63	26·10	27·40	4·10
Invert sugar	10·80	12·00	23·60	—
Dextrose	6·10	22·00	11·40	31·70
Maltose	26·40	·40	—	7·50
Dextrin	12·95	8·98	2·50	34·30
Water	19·08	20·50	22·69	21·30
Ash	1·82	5·20	7·24	1·10
Undetermined	2·22	4·82	5·17	—
	100·00	100·00	100·00	100·00
Optical activity $[a]_D$ =	+ 77·3°	+ 45·2°	+ 24·6°	+ 99·01°

From a consideration of their carbohydrate constituents, he had concluded that they contained 52, 32, 13 and 87 per cent. of glucose syrup respectively; the comparatively simple method of calculation explained by Dr. Dyer gave 56·9, 27·3, 10·5 and 86·4 as the respective percentages of glucose syrup. He was now quite satisfied that the simpler method of dealing with the subject was quite sufficient for the practical purpose of determining the approximate percentage of glucose syrup in these mixtures.

Mr. BOSELEY said that he had employed the method referred to in his paper on "The Analysis of Marmalade" (ANALYST, xxiii., 123) in the analysis of a very large number of samples of jam, and had found it to work most admirably. In determining the cupric oxide reducing power in a jam, however, it was necessary to remember that in some fruits there was present a substance which was not sugar, but which, apart from the natural invert sugar of the fruit, was capable of reducing Fehling's solution, and the results published in 1898 were probably about 2 per cent. too high owing to the influence of this substance, of the presence of which, in sufficient quantity to affect the results, he was not at the time aware. He had examined a great many samples of glucose syrup, and had not found the rotation to vary largely. The figure he had adopted for "percentage" rotation (cane sugar = 100), viz., 166

(or Sp. R. P. $[\alpha]_D = +110°$),

was an average of between 200 and 300 samples obtained from different sources, the highest result obtained being 173

(or Sp. R. P. $[\alpha]_D = +115°$).

Mr. JULIAN L. BAKER said it seemed very unsatisfactory that in the determination of cupric reducing power the method of weighing as cupric oxide should still be indulged in. It was far more accurate, and was now almost universal—at any rate, amongst Continental chemists—to weigh as metallic copper. It made a great difference whether, in speaking of gallisin, the authors meant conversion products, or whether they meant the unfermentable residues of starch conversion. On degrading starch by means of malt-extract in the cold, a substance was obtained which was practically wholly fermentable; whereas, if the operation were conducted at a higher temperature, conversion products were obtained which were not completely fermentable. Some of these unfermentable products had been examined by Mr. Ling and himself, and had been found to consist of bodies having the formula $C_{12}H_{22}O_{11}$. Their composition thus resembled that of maltose, and they were non-crystalline and had a fairly high reducing power. He was at present working, together with Mr. T. H. Pope, upon a series of polysaccharides, which occurred largely in the vegetable kingdom, and among which was probably the body mentioned by Mr. Boseley. They were non-crystalline, and yielded definite sugars on hydrolysis. He had recently isolated one of these bodies from the ivory nut, having the composition $C_6H_{10}O_5$, which on hydrolysis yielded considerable quantities of mannose, in addition to a lævo-rotatory sugar, probably lævulose, and which, while reducing Fehling's solution, decomposed at high temperatures, a peculiarity not possessed by the other members of the series which he had examined.

Mr. ARCHBUTT recommended the method of estimating cuprous oxide recently described by Messrs. Caven and Hill before the Nottingham section of the Society of

Chemical Industry,* in which the precipitate was filtered on an asbestos mat in a Gooch crucible, and transferred, after thorough washing with boiling distilled water, to a flask containing a mixture of dilute sulphuric acid and standard potassium permanganate solution, the excess of permanganate being titrated with oxalic acid or hydrogen peroxide.

FOODS AND DRUGS ANALYSIS.

The Determination of Cane-Sugar in Condensed Milk. L. Grünhut and S. H. R. Riiber. (*Zeit. Anal. Chem.*, 1900, xxxix., 19-36.)—This paper contains an account of the authors' critical examination of various methods of estimating cane sugar in the presence of milk sugar.

Of the methods based on reduction with Fehling's solution before and after inversion, they regard those in which hydrochloric acid inversion is used as of chief importance in the analysis of condensed milk.

They point out that, if a correct conclusion as to the amount of cane sugar is to be drawn from the increase in the reducing power after inversion, it is essential that the reductions before and after inversion must be made under exactly the same conditions, since every deviation, either in the concentration of the liquid or the length of time of heating, influences the amount of cuprous oxide deposited.

The only gravimetric methods known to them which fulfil this condition are those of Ost (ANALYST, xx., 259) and of Kjeldahl (ANALYST, xx., 227), and the former of these has been shown both by Ost himself and by Schmöger to be unsuitable for the determination of milk sugar. Pavy's volumetric method is not included in the investigation, since the readiness with which the ammoniacal solution undergoes alteration renders the results uncertain.

In applying Kjeldahl's method, however, in which a specially strong Fehling's solution is used and the liquid boiled for twenty minutes, there is the probability of a certain amount of decomposition of the cane sugar taking place, with the formation of decomposition products with strong reducing properties. G. Bruhns, in fact, has shown that this decomposition leads to considerable error (ANALYST, xxiii., 297).

A second source of error in the copper reduction methods in the analysis of condensed milk is that in the direct reduction too great an amount of cuprous oxide is separated, with the result that the milk sugar is overestimated. The authors' experiments show that the amount of copper reduced varies with the quantity of the milk taken. For example, a mixture of sixty parts of Passburg's dry milk (containing 21·38 per cent. of milk sugar) with forty parts of cane sugar yielded by direct

* *Jour. Soc. Chem. Ind.*, xvii. (1898), 124.

reduction in solutions of different degrees of concentration quantities of cuprous oxide corresponding to (1) 21·52 per cent. and (2) 23·20 per cent. of milk sugar.

This error depends not only on the relative proportion of milk and cane sugar, since this was the same in the above experiments, but also on the absolute quantity of sugar. In the first case a large quantity of the sugar solution was taken, and the result was nearly correct, whilst in the second much less was used and the milk sugar was too high.

The explanation given for this is that the milk sugar commences its reducing action as soon as the liquid begins to boil, and reduction is nearly completed before any decomposition of the cane sugar takes place and causes a secondary reduction. Thus, if there be much milk sugar present, so much of the copper solution is reduced that its subsequent action on the cane sugar is greatly weakened and the error will only be trifling.

The action of the solution on the cane sugar is greatest when no milk sugar is present. When both cane and milk sugar are present, less cuprous oxide is deposited than corresponds to the sum of the amounts from the two reactions.

Hence, the authors conclude that the only method of accurately estimating milk sugar in the presence of cane sugar by means of Fehling's solution is to construct an empirical table in which a correction is made for each absolute and relative amount of both sugars.

Another inherent error in these reduction methods is that it is not correct to simply calculate the quantity of cane sugar from the difference between the amounts of copper reduced by the milk sugar before inversion, and by the milk sugar and the invert sugar after inversion. For example, in the case of the prepared condensed milk mentioned above, this difference for 0·375 gramme of the mixture amounted to 0·26695 gramme of copper. This corresponded to 0·13517 gramme of invert sugar, or 34·24 per cent. of cane sugar, instead of the theoretical 40 per cent.

Somewhat better, though still incorrect, results are obtained by calculating both amounts of copper into the corresponding quantities of invert sugar and taking the difference. In this way the cane sugar (40 per cent.) in the above mixture was found to be 38·64.

This deviation is due, in the main, to the fact that the products of the reduction of two sugars causing simultaneous reduction cannot be directly added together. Kjeldahl believed that he had discovered the law underlying this reaction (*Zeit. anal. Chem.*, xxxv., 347 and 646), and gave directions for its application to the determination of two kinds of sugar. The authors, however, have been unable to obtain satisfactory results by using Kjeldahl's directions, and in the case of their prepared condensed milk found −14·23 per cent. of milk sugar and +62·81 per cent. of cane sugar.

Summing up the results of their experiments on the reduction methods, they have arrived at the conclusion that it is not possible by their means to effect an accurate determination of cane sugar in condensed milk.

A second class of methods is based on the polarization of the solution before and after inversion, and the calculation of the cane sugar with the aid of the Clerget formula.

In order to obtain correct results in this way, the authors adopt several precautions. By treating the condensed milk with boiling water and allowing the solution to cool, they state that the influence of the multirotation of the milk sugar is completely obviated. They have not met with the difficulty experienced by Richmond and Boseley (ANALYST, xviii., 141 and 171), who found that the specific rotatory power of cane sugar was considerably altered by heating the solution at 100° C.

In making a correction for the volume of the casein and fat precipitated by means of lead acetate or of mercuric nitrate as proposed by Wiley, they make use of the method of double dilution (*cf.* ANALYST, xxi., 182). For the calculation of the results they have found Herzfeld's modification of Clerget's formula (*Zeit. anal. Chem.*, xxxv., 717) more satisfactory than the original formula. Using the latter, they found 39·12 per cent. of cane sugar in their experimental mixture, whilst with the former they obtained 39·39 per cent.

The empirical factor (0·962), which has been prescribed by the *Bundesrath* for the correction of the volume, is objected to on the ground that it is only applicable to preparations of one particular chemical composition, so that when there is any considerable variation from that type the results are much less satisfactory.

C. A. M.

Gerber's Process for the Estimation of Fat in Butter. **J. Werder.** (*Chem. Zeit.*, 1899, xxiii., 1028.)—As originally devised, this process did not give trustworthy results, but it has recently been improved, and is now fit to rank as a regular laboratory method. In a small capsule, which forms the stopper of a specially graduated tube, 5 grammes of the well-mixed sample are weighed out; it is then put in position, and the tube is filled with 1 c.c. of amylic alcohol and 20 c.c. of sulphuric acid (specific gravity 1·50). After agitation and separation the volume of fat is read off. Double tests carried out on twelve samples of market butter showed maximum differences one from another of 0·42 per cent., and the mean figures, in comparison with those given by the Soxhlet process, showed maximum differences of +0·30 and −0·45 per cent., or an average difference of ±0·27 per cent. Applied to two remelted butters, the yields were between 99·6 and 100·1 per cent. F. H. L.

Contribution to our Knowledge of the Composition of Hens' Eggs. **A. Juckenack.** (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 1899, 905.)—On incinerating yolk of egg as a preliminary to the determination of the inorganic constituents, a portion of the phosphoric acid becomes reduced to phosphorus, and is therefore lost, owing to the bases being in insufficient proportion to form metaphosphates. The difficulty may, however, be overcome by the addition of alkaline carbonate and nitrate before incinerating. In white of egg, and in the combined white and yolk, mixed in the proportion in which they occur in whole eggs, the bases are present in excess, and correct results are consequently obtainable without such addition.

The following results are given:

I.	Yolk	1·279 per cent. phosphoric acid.	
II.	White	0·031	,, ,,
III.	Whole eggs:		
	(*a*) By direct determination ...	0·443	,, ,,

IV.	Average phosphoric acid contents of one egg (16 grammes yolk and 31 grammes white.)	0·214 gramme.	

Table showing the Various Combinations and Proportions in which the Phosphoric Acid exists in Yolk of Egg.

Total phosphoric acid in 100 grammes, 1·279 grammes.

Soluble in boiling alcohol, 0·823 grm. = 9·35 gramme distearyllecithin.		Insoluble in boiling alcohol, 0·456 gramme.	
Extractable direct by ether from the yolk, 0·478 gramme = 5·42 grammes free distearyllecithin.	Dissolved by alcohol after extraction by ether, 0·345 gramme = 3·93 gramme distearyllecithin combined with vitellin.	As nucleïn, 0·178 grm.	As insoluble phosphate or compounds of phosphoglyceric acid, 0·278 gramme.

The cholesterin in yolk of egg was also determined, the result showing 0·91 per cent., corresponding to 1·92 per cent. in the dry substance. H. H. B. S.

The Reliability of the Glycerin titration Method for the Determination of Boric Acid in Preserved Meats, and the Separation of Boric Acid from Borax. A. Beythien and H. Hempel. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, ii., 1899, 842-851.)—The authors have carried out experiments to test the accuracy of the glycerin titration method, which depends upon the fact that if a solution of boric acid be neutralized, using methyl orange as indicator, and then glycerin added, the solution reacquires an acid character, and can be again titrated with alkali, phenolphthalein being used as indicator. The authors followed in general the directions given by Jörgensen. The results affirmed the reliability of the process, and showed in particular that no appreciable loss takes place, either when the acidified boric acid solution is heated, or when the alkaline residue left after evaporation is ignited. The maximum loss in the experiments amounted to 1·66 per cent. of the quantity taken.

The authors also tested the process in its application to the examination of preserved meats. Weighed portions of chopped beef were mixed with measured quantities of solutions of boric acid of known strength. After the addition of water, solution of soda was added until a decided alkaline reaction was produced. The mixture was then warmed for several hours and filtered. This procedure was carried out three times, after which the various filtrates were mixed together and evaporated to dryness. The residue was then incinerated, the ash taken up with sulphuric acid, the solution gently heated to expel carbonic acid, cooled and

neutralized. Twenty-five c.c. of glycerin were then added, and the mixture titrated with standard soda. The greatest differences were: −5·06 and +1·67 per cent. of the boric acid taken.

Aspirin. F. Goldman. (*D. Pharm. Ges. Ber.*, 1899, ix., 232; through *Chem. Zeit. Rep.*, 1899, 340.)—Aspirin is a product of the action of acetic acid upon salicylic acid, its formula being $C_6H_4(O.COCH_3)COOH$. Its melting-point is 135° C. When 0·5 gramme is boiled with 10 c.c. of a 10 per cent. solution of sodium hydroxide, a clear liquid should result, in which an excess of dilute sulphuric acid produces a temporary violet colour, and precipitates the salicylic acid, which can be filtered off and identified by its melting-point and its reaction with ferric chloride. The filtrate from the salicylic acid has an odour of acetic acid, and on boiling with alcohol and sulphuric acid gives that of acetic ether. Aspirin should not contain any free salicylic acid; to detect it, 0·1 gramme is dissolved in 5 c.c. of alcohol, diluted with 20 c.c. of water, and 1 drop of ferric chloride solution is added; no violet colour should appear. F. H. L.

ORGANIC ANALYSIS.

Estimation of Benzene Vapour in Illuminating Gas. O. Pfeiffer. (*J. Gasbeleucht*, 1899, xlii., 697; through *Chem. Zeit. Rep.*, 1899, 333.)—The author suggests a modification of Harbeck and Lunge's nitration process (ANALYST, 1898, xxiii., 101) which makes it far more simple to carry out. The gas is measured and nitrated in a large separating funnel holding 3 or 4 litres; it is filled through the stopper-hole by displacement, and 10 c.c. of the mixed nitrating acids are introduced through the ordinary exit tube.* The acids are made to spread over the internal surface, and are allowed to act for an hour, when the whole of the benzene will be absorbed. The vessel is then rinsed out with 100 c.c. of water, which is brought into a small separating funnel, and neutralised with crystallised sodium hydroxide (40 grammes). It is extracted two or three times for five minutes with quantities of 50 c.c. of ether, each of which is afterwards washed two or three times with 10 c.c. of water to remove some brown substance. The solvent is finally evaporated, the residue taken up in a little anhydrous ether, filtered through freshly calcined sodium carbonate into an evaporating basin, and dried over sulphuric acid—it should neither be warmed nor placed in vacuo. To convert the weight (g) of dinitrobenzene into the percentage by volume of benzene vapour, the author gives the following simplified formula; C is the capacity of the measuring vessel, t the temperature, and b the height of the barometer:

$$\frac{36080}{C} \times g \times \frac{273+t}{b}.$$

Having a complete analysis of the gas, and knowing its specific gravity, it is also possible to calculate the proportion of benzene. Calling the specific gravity of

* The stopcocks should be "lubricated" with strong sulphuric acid.

the gas S, the specific gravity of the "heavy hydrocarbons" (C_nH_m) s, and the total volume of the latter v, we have:

$$s = 100S - \left(CO \times 0{\cdot}9621 + CH_4 \times 0{\cdot}5530 + H \times 0{\cdot}0692 + N \times 0{\cdot}9701 + CO_2 \times 1{\cdot}5197 \frac{1}{C_nH_m}\right)$$

whence the percentage by volume of benzene vapour becomes:

$$\frac{(s - 0{\cdot}9674)v}{1{\cdot}7367}.$$

As an example of this method, the author quotes a sample of gas in which the proportion of benzene was calculated to be 1·57 per cent., and that of ethylene 1·83 per cent.; by direct analysis the benzene was returned at 1·52 per cent., and the ethylene 1·88 per cent. F. H. L.

The Volumetric Estimation of Quinones of the Benzene Series. A. Valeur. *Bull. Soc. Chim.*, 1900, xxiii., 58-61.)—This method is based on the reduction of the quinones by hydriodic acid.* When the latter is replaced by an equivalent quantity of hydrochloric acid and potassium iodide, the reaction takes place in accordance with the equation:

$$C_6H_4O_2 + 2HCl + 2KI = C_6H_6O_2 + 2KCl + I_2.$$

In the determination a quantity of the pure dry quinone, sufficient to liberate from 0·20 to 0·50 gramme of iodine is dissolved in a little 95 per cent. alcohol. To this solution is added a rapidly-prepared mixture of 20 c.c. of a 10 per cent. solution of potassium iodide with 20 c.c. of concentrated hydrochloric acid previously diluted with an equal volume of 95 per cent. alcohol and cooled. The liberated iodine is titrated with standard thiosulphate, and the corresponding amount of quinone calculated.

The following results show the accuracy of the method:

	Toluquinone, $C_6H_3(CH_3)O_2$.		Thymoquinone, $C_6H_2(CH_3)(C_3H_7)O_2$.	
	I.	II.	I.	II.
Weight of substance, gramme	0·2057	0·2707	0·2130	0·1663
Iodine liberated ,,	0·4290	0·5629	0·3311	0·2574
Iodine per cent.	208·5	207·9	155·4	154·7
	(Theory 208·2)		(Theory 154·8)	

It is necessary to mix the hydrochloric acid and the potassium iodide, and not to add them separately to the quinone, since the acid would immediately react on the quinone, and the iodide would cause partial oxidation. This method appears to be applicable to the majority of true quinones. It can be used to determine their solubility in different solvents, which is not easily determined by other methods, on account of the volatility of the quinones and the difficulty of drying them without loss.

It can also be employed for the determination of quinones in somewhat unstable combinations, such as the phenoquinones and quinhydrones. In the case of

* Reduction with HI yields a mixture of hydroquinone and quinhydrone; from what is stated in the paper it appears that with KI and HCl the reduction is carried a step further, and gives only hydroquinone.

ordinary quinhydrone the following percentages of iodine were obtained: 116·6, 116·3 and 116·1, whilst the calculated percentage for $C_6H_4O_2 \cdot C_6H_6O_2$ is 116·5. The author therefore concludes that this compound, contrary to the view of Wichelhaus, results from the union of equal molecules of quinone and hydroquinone. C. A. M.

The Properties of the Oils of Lemon, Bergamot, and Orange. A. Soldaini and E. Berté. (*Boll. chim. farm.*, 1899, xxxviii., 537; through *Chem. Zeit. Rep.*, 1899, 323.)—Some constants of these three oils in the pure state are given in the annexed table:

	Lemon.	Bergamot.	Orange.
Specific gravity at 15°	0·854-0·860	0·882-0·886	0·847-0·853
Rotatory power at 20° (100 millimetres tube)	56-66°	8-20°	96-98°
Boiling-point at ordinary pressure	171-172°	—	173-174°

Lemon Oil.—In lemon oil the proportion of citral should not be below 6·5 per cent.; and when 20 grammes are fractioned at a pressure of 20 to 30 millimetres, the first 10 c.c. of the distillate should have as high a rotatory power as the original oil. The presence of orange oil is shown (*a*) by a yellow colour when a drop of the sample is mixed with 15 or 20 drops of brominated chloroform, (*b*) by a yellow flocculent precipitate instead of a white crystalline one when sodium bisulphite solution is added. To determine the percentage of citral, a 5 c.c. pipette graduated in fortieths is required, and also a pear-shaped flask, the neck of which has the same diameter as the pipette, and which has a lateral tube bent upwards at a right angle to carry a funnel. Five c.c. of the sample are run from the pipette into the flask, 25 c.c. of a solution of potassium bisulphite containing an excess of sulphur dioxide are introduced, the lower end of the pipette is connected to the neck, the whole is shaken and warmed for twenty minutes on the water-bath, then cooled and warmed again for five minutes. When finally cold, the volume of oil still remaining liquid is read off in the pipette by adding water through the side funnel; and the difference between it and the 5 c.c. taken represents the volume of the aldehyde.

Bergamot Oil.—The proportion of linalyl acetate usually varies between 21 and 22 per cent. When 15 c.c. are fractioned at the above pressure, the first 5 c.c. of the distillate should have a rotatory power 2½ times as great as the oil itself; and the next 9·5 c.c. should be almost inactive. Evaporated on the water-bath, the residue should be between 5 and 6 per cent. The oil should be soluble in ½ vol. of 90 per cent. alcohol, and the clear solution should not be rendered turbid on dilution. Schiff's reagent for aldehydes should fail, or at most give a faint tint in half an hour; an immediate colour, or a strong red in half an hour, indicates lemon oil. To estimate the linalyl acetate, 1·5 grammes are saponified with an excess of seminormal alcoholic potash, diluted with a little 80 per cent. spirit, and titrated with seminormal sulphuric acid and phenolphthalein; the volume of alkali multiplied by 0·09775 (mol. wt. of the ester, 195·5) gives the acetate.

Orange Oil.—When 20 c.c. are fractioned at a pressure of 10 or 20 millimetres, the distillate should have a rotatory power from 1° to 3° higher than the original. Schiff's reagent should give no colour. F. H. L.

Determination of the Solidifying-point of Fatty Acids. I. Freundlich. (*Chem. Zeit.*, 1899, xxiii., 1014.)—The ordinary Dalican process for determining the exact solidifying-point of fatty acids is not quite accurate, for the temperature to which the thermometer finally rises is partly dependent on that to which it was made to fall during the stirring of the fat. The following modified way of carrying it out leads to absolutely concordant results, or at the worst to differences of 0·05 to 0·1° C. At the lowest temperature above the expected solidifying-point at which the sample round the thermometer bulb remains perfectly liquid, the thermometer is moved quickly two or three times backwards and forwards through the fat, and the mercury is observed; if it falls sharply, the operation is repeated until the column remains constant for thirty or forty seconds; then the sample is stirred fifteen or twenty-five times, and if the mercury falls during the agitation and rises immediately afterwards to a maximum at which it stands unchanged for three or five minutes, that maximum is the true solidifying-point. The great thing to avoid is too prolonged stirring. F. H. L.

The Becchi and Halphen Colour Reactions for Cotton Oil. P. N. Raikow and N. Tscherweniwanow. (*Chem. Zeit.*, 1899, xxiii., 1025.)—At the present time there exist some ten different modifications of the Becchi test for cotton oil; and statements as to its utility and the best proportions for its several ingredients vary enormously. Benedikt and other authorities question whether cotton oils do not occur which cause no reduction of the silver nitrate at all; this, however, seems problematical, unless the samples have been specially treated in order to prevent their giving the Becchi reaction. It is not possible to render cotton oil indifferent to the Becchi test by blowing air through it in the cold; nor can the same object be attained by repeated extractions with alcohol, the latter fact being in contradiction to Benedikt's assertion that the true cause of the reaction is an aldehyde-like body which is readily soluble in spirit. Even the fatty acids of cotton oil after alcoholic saponification and liberation from their barium salts, or after aqueous saponification and liberation from the sodium salts, give the test, while the small proportion of unsaponifiable matter in the original oil does not give it. Treated with ordinary steam even for long periods of time, cotton oil still retains its usual properties; but superheated steam, or a simple heating of the oil to between 210° and 220°, quickly destroys its reducing power, which also vanishes more slowly at 150°, the residual material being almost unaltered, except that its colour is slightly darkened, and that it possesses a faint burnt odour. Precisely the same remarks apply to the Halphen test: one hour at 150° hardly affects the reaction, five hours reduce its intensity to one-half, ten hours to one-third; in time, probably, it would fail altogether. [*Cf.* Holde and Pelgry, ANALYST, 1899, xxiv., 214.]

After elaborate experiments, the authors find that the details of the Becchi test are most important: the proportion of silver nitrate to the oil, the proportion of free acid to the silver, ought to be kept uniform; and they decide that the method adopted by the Italian Commission (*cf.* ANALYST, 1895, xx., 222, last paragraph) should be taken as the standard. The latest modification of the Becchi test described by

Tortelli and Ruggeri (ANALYST, 1898, xxiii., 179) was not examined; in comparison with the more certain and very delicate Halphen reaction, it is too complicated to be generally useful.

It appears to be universally admitted that the Halphen reaction (ANALYST, 1897, xxii., 326; 1898, xxiii., 131) is better than Becchi's; the only points of divergence are its degree of delicacy and the best method of carrying it out. The actual temperature employed is only a matter of convenience; a cherry-red colour is produced in the cold by bright sunlight in three hours. The part played by the amylic alcohol is obscure, but it does not serve simply to retain the carbon disulphide in the hot liquid; it should, therefore, not be omitted. A faint Halphen red is manifested when the free sulphur is left out of the regular mixture; an excess of sulphur is useless, and in the testing of oils containing only a little cotton oil, it tends to decrease the delicacy of the reaction. The present authors accordingly reject Soltsien's proposals; there is no objection to the use of plain water instead of the brine bath, but in other respects Halphen's prescription should be retained in its integrity. The behaviour of olive, walnut, linseed, poppy, and arachis oils towards the test has been studied under various conditions; neither by prolonged heating on the water-bath nor in sunlight did they respond. In pale-coloured oils 0·5 per cent. of cotton oil can be readily detected, and this proportion may be taken as its limit of sensitiveness.

F. H. L.

The Determination of the Bromine Absorption of Oils. P. C. McIlhiney. (*Journ. Amer. Chem. Soc.*, 1899, xxi., 1084-1089.)—In a former communication (ANALYST, xix., 141) the author described a process for the determination of this constant in which a distinction was made between the bromine addition and bromine substitution values.

He has now simplified his process by making use of the iodometric method of Schweitzer and Lungwitz (*Journ. Soc. Chem. Ind.*, 1895, 130), and shortening the time in accordance with the fact that the addition of bromine to fats is practically instantaneous (ANALYST, xx., 146).

In the modified process a weighed quantity of the oil is dissolved in 10 c.c. of carbon tetrachloride in a stoppered bottle and 20 c.c. of one-third normal bromine in carbon tetrachloride added. Simultaneously a blank determination is made, and subsequently titrated with standard thiosulphate to determine the strength of the bromine solution. After the lapse of one or two minutes, 20 to 30 c.c. of a 10 per cent. solution of potassium iodide are introduced, the bottle shaken to insure the absorption of the bromine and hydrobromic acid, and the iodine titrated with deci-normal thiosulphate.

After the titration, 5 c.c. of a neutral 2 per cent. solution of potassium iodate are introduced, and the amount of iodine liberated, which is equivalent to the hydro-bromic acid formed, is titrated, and gives the bromine substitution figure.

In order to prevent a loss of bromine or hydrobromic acid on removing the stopper to introduce the potassium iodide, a piece of wide indiarubber tubing is slipped over the neck of the bottle, thus forming a well round the stopper. The

potassium iodide is poured into this well and the stopper slightly opened, preferably after the bottle has been cooled in ice to create a partial vacuum in the interior. The following figures were thus obtained with various representative oils. The difference between the figures given in the last column and 1·000 are intended to represent the degree of substitution which occurred in the determination of the Hübl value:

	Hübl Value.	Bromine Value calculated from Hübl Value.	Bromine Absorbed per Cent.	Bromine Addition Value.	Bromine Substitution Value.	Calculated Bromine Value divided by Bromine Addition Value.
Raw linseed oil, several years old	157·3	99·1	99·2	92·0	3·6	1·077
„ „ „ average of seven samples	183·8	115·7	112·0	106·6	2·7	1·083
Boiled linseed oil, average of eight samples	—	—	109·5	103·0	3·2	
Third run rosin oil	63·9	40·3	92·3	7·7	42·3	5·231
"Java" boiled rosin oil	73·3	46·2	101·9	8·3	46·8	5·685
Menhaden oil, average of three samples	174·9	110·2	110·6	95·6	7·5	1·154
Maize oil, average of three samples	—	—	75·8	72·9	1·5	
Cotton-seed oil	—	—	65·8	62·2	1·8	
Turpentine			266·1	166·1	50·0	
Ceylon cocoanut oil			5·36	4·7	0·33	
Tallow rendered in laboratory			24·0	21·48	1·26	
Hard paraffin			3·55	1·43	1·06	
Black rosin	—	—	135·4	5·4	65·0	

The advantages claimed for this method are that the bromine solution is readily prepared and does not change on keeping, that it is exceedingly rapid, and that it distinguishes between the halogen absorbed by addition and by substitution.

C. A. M.

INORGANIC ANALYSIS.

Bromine and Alkali Hydroxides as a Test for Copper. D. Vitali. (*Boll. Chim. Farm.*, 1899, xxxviii., 665; through *Chem. Zeit. Rep.*, 1899, 349.)—It is well known that when a solution of copper sulphate is mixed with potassium or sodium hydroxide, and an excess of bromine water is added, the original blue precipitate soon becomes black. This substance consists of copper dioxide; it evolves oxygen on warming or on treatment with sulphuric acid, and it gives off chlorine with hydrochloric acid. The reactions proceed thus:

$$CuSO_4 + 2NaOH = Cu(OH)_2 + Na_2SO_4.$$
$$2NaOH + Br_2 = NaBr + NaBrO + H_2O.$$
$$Cu(OH)_2 + NaBrO = CuO_2 + H_2O + NaBr.$$

Other oxidizing agents, such as hydrogen peroxide or manganese dioxide, also convert copper hydroxide into dioxide.

By evaporating 1 c.c. of a solution containing copper to dryness, treating the residue with the yellow mixture of alkali and bromine, a black precipitate will be produced if the proportion of copper was 1 : 100,000. If the residue is more simply moistened with saturated bromine water and again dried, a black deposit is obtained, consisting of $CuBr_2$, which becomes blue on being touched with water. This test will show copper in 1 c.c. of a 1 : 1,000,000 solution, and it is therefore more sensitive than sulphuretted hydrogen or potassium ferrocyanide. The black bromide is rendered more visible when moistened with strong sulphuric acid.

Other metallic salts yield black precipitates with alkali hydroxides and bromine, *e.g.*, $Co_2(OH)_6$, $Ni_2(OH)_6$, MnO_2H_2O. Mercurous salts give a yellow precipitate of mercuric oxide. Bismuth salts give a reddish-brown precipitate of Bi_2O_4. Lead salts in the cold finally yield an orange-yellow precipitate of lead oxybromide, which changes into peroxide on warming. F. H. L.

The Separation of Tungsten and Molybdenum. F. Ibbotson and H. Brearley. (*Chem. News*, lxxxi., 13-15.)—Two modes of procedure are recommended :

(*a*) The tungsten and molybdenum are precipitated together by lead acetate, the precipitate washed slightly with hot, very dilute acetic acid and ignited. The ignited precipitate is then dissolved in concentrated hydrochloric acid, using about as many c.c. of acid as there are centigrammes of the lead salts. Two or three times the bulk of boiling water is then added, the solution boiled, allowed to settle, filtered by decantation through a small pulp filter, the precipitate redissolved in about half the quantity of acid previously used, reprecipitated with water, and filtered through the same pulp. The molybdenum is determined in the filtrate as $PbMoO_4$. The greater the amount of acid used to dissolve the lead salts, the more water is required for the complete precipitation of the tungstic acid, and the greater the dilution, the greater the liability to contamination with molybdic acid.

(*b*) When the quantity of tungsten is small in comparison with that of the molybdenum, the former is not completely precipitated. Under these circumstances the following procedure is recommended : A few drops of nitric acid are added to the hydrochloric acid solution of the lead salts, which is then evaporated to a pasty consistence. The mass is diluted with 200 to 300 c.c. of dilute hydrochloric acid (1 : 3), the solution boiled, and the tungstic acid filtered off. The precipitate adhering to the sides of the vessel can be removed by dissolving in a few drops of dilute ammonia, which may then be absorbed with a piece of filter-paper, and the latter ignited with the precipitate. H. H. B. S.

Estimation of Tellurium Dioxide in Presence of Haloid Salts. F. A. Gooch and C. A. Peters. (*Zeits. anorg. Chem.*, 1899, xxi., 405.)—Brauner has shown (*J. Chem. Soc. Trans.*, 1891, 238) that tellurous acid cannot be determined by oxidation with permanganate if it be dissolved in hydrochloric acid ; and he has also stated that if the oxidation take place in sulphuric acid solution a small correction is

necessary, which is not required when the oxide is dissolved in alkali. If, therefore, the tellurous acid is dissolved in sodium hydroxide, and if the final titration between the oxalic acid and permanganate is carried out under those conditions which are desirable to avoid the interfering action of hydrochloric acid—*i.e.*, presence of manganous chloride—tellurium dioxide can be accurately determined in the manner indicated, even if it be accompanied by chlorides. About 0·1 gramme of TeO_2 is dissolved in a little sodium hydroxide, and mixed with permanganate solution (standardized on ammonium oxalate) till it remains pink; the liquid is heated, and 5 c.c. more of 1 : 1 sulphuric acid than are needed to neutralize it are added; excess of standard ammonium oxalate is introduced to destroy the higher oxides of manganese and the excess of permanganate; and finally the excess of oxalate is titrated with permanganate. If the proportion of hydrochloric acid is quite small, *e.g.*, such as is produced by the decomposition of the original tellurium chloride, addition of manganous chloride is not necessary; but it is better always to employ it (0·5 to 1 gramme), as the last titration can then be conducted in the cold.

In the presence of a bromide fairly satisfactory results can be obtained, provided that the excess of sulphuric acid is not greater than 5 c.c. of a 12·5 per cent. acid, that sufficient manganous chloride (0·5 to 1 gramme) is used, and that the liquid is titrated at ordinary temperatures.

The process is obviously not available in the presence of an iodide. The method described by Norris and Fay (ANALYST, 1898, xxiii., 249) gives excellent results. Instead, however, of titrating the iodine liberated from the iodide and sulphuric acid by means of thiosulphate, it can be determined with decinormal arsenious acid, this modification possessing the advantage that the arsenic serves also to standardize the original permanganate used to oxidize the tellurium dioxide. About 0·5 or 1 gramme of potassium iodide dissolved in 100 c.c. of water is added to the alkaline solution of the tellurium, then standard permanganate is run in till the green colour disappears (about 30 c.c. of the decinormal liquid per 0·1 gramme of TeO_2); next a few c.c. of sulphuric acid are added to clarify the liquid, and the free iodine is titrated in presence of potassium bicarbonate. It is important to have a sufficient excess of iodide, and it is perhaps better to run in some of the arsenious acid before acidifying with sulphuric acid. All the examples quoted by the authors are reasonably satisfactory, and they agree closely with theory when the atomic weight of tellurium is taken at 127. F. H. L.

Determination of Sulphur in Bitumens. S. F. and H. E. Peckham. (*Journ. Amer. Chem. Soc.*, vol. xxi. [9], pp. 772.)—The authors have modified their deflagration method by taking such an amount of the assay as will correspond to about 0·2 gramme of bitumen, and mixing it with 15 grammes each of pure, dry sodium carbonate and potassium nitrate, the mixture being then deflagrated in small successive portions in a 2-ounce platinum crucible at dull red heat. No blast lamp is necessary, the fusion being complete without; the excess of flux reduces the violence of the operation and the risk of loss by spattering.

The mass is dissolved by immersing the crucible in water over night, and the silica, iron, alumina and sulphuric acid determined in the solution in the usual manner. C. S.

REVIEWS.

DETERMINATION OF RADICLES IN CARBON COMPOUNDS. By Dr. H. MEYER (Prague). Authorized translation, by Dr. J. BISHOP TINGLE (Chicago). New York: J. Wiley and Sons; London: Chapman and Hall, 1899. Price 4s. 6d.

This small book is a valuable addition to literature, containing as it does within the limits of 120 pages much useful information and many valuable hints. Its scope is broader than might be inferred from the title; it really deals with the principles of methods for the proximate analysis of organic compounds. Although it might appear at first sight to appeal more particularly to the investigator in organic chemistry than to the technical analyst, it must not be forgotten that the problems with which both are confronted very frequently differ only in the form in which they are presented. Methods which depend on the determination of certain atomic groups and radicles find in point of fact frequent application alike in purely scientific investigations and in the technical analysis of organic products. Some of these have, in their technical application, become quite stereotyped, and are perhaps too often used by analysts without regard to the scientific principles on which they are based. The use of such terms as "acetyl value," "iodine value," convenient though they may be, are doubtless largely responsible for this, yet the analyst should in all cases consider what he is actually measuring. Thus, that the acetyl value is a measure of displaceable hydrogen in the groups – OH, = NH, etc., and that the iodine value indicates the presence of unsaturated compounds.

To briefly summarize the contents of the book, it describes methods for the determination of the following groups: $-OH$, $-OCH_3$, $-OC_2H_5$, $-COOH$, $=CO$, $-NH_2$, $-CN$, $-CONH_2$, $=NH$, $=NCH_3$, the diazo, hydrazine, iodoso, iodoxy, and peroxide groups. Instructions are also given for the determination of the "iodine value."

Methods for the determination of the basicity of acids, and for the introduction of acid radicles, notably acetyl and benzoyl, and of alkyl groups are fully described, and wherever chemicals rarely met with in laboratory practice are referred to, details for their preparation are given. The arrangement of the matter and the style of writing are all that could be desired, and the numerous references to original papers cannot but add to the utility of the book. The only typographical error noticed is on page 41, where the group carboxyl is represented as CHOH instead of COOH.

A. R. L.

DAIRY CHEMISTRY: A PRACTICAL HANDBOOK FOR DAIRY CHEMISTS, ETC. By H. D. RICHMOND, F.I.C. London: Charles Griffin and Co., Limited. Price 16s.

If the question were raised as to the necessity for a work specially treating on the chemistry of milk, it should certainly be answered in the affirmative. Not only is the public analyst called upon to examine large numbers of samples of milk and milk products with the object of detecting and checking adulteration, but other chemists are also frequently called upon to analyse and pass opinions on materials directly or indirectly connected with the dairy, and last, but not least, practical dairy work nowadays demands a considerable amount of scientific knowledge if it

is to be performed in a satisfactory and successful manner. The days are gone for ever in which a very limited amount of experience was considered either sufficient to judge whether a milk was pure or sophisticated, or to support and aid the practical dairyman with scientific counsel, or to fill up a responsible position in the dairy industry. If, then, a work on dairy chemistry must be considered highly desirable—nay, necessary—nobody could be better fit for producing such a work than the author of the book lying before us. Mr. Richmond has for nearly eight years superintended the Aylesbury Dairy Company's laboratory, which was erected in the year 1880. Although established to serve the special requirements of that large firm in exercising an extended and minute control over the milk and milk products there dealt with, Mr. Richmond, like his predecessor, has not confined himself to exercising control alone, but has taken good care to make extensive use of the opportunities given to work out as many questions as possible which in one way or another are connected with the chemistry of milk, milk products and dairy work generally. In the course of twenty years a vast amount of facts and experiences has been thus accumulated, which in itself would have been quite sufficient to form a valuable publication. But the author has done much more. By collating and studying the respective publications of others, and reproducing them in a digested form, he has succeeded in putting before the reader a complete work on dairy chemistry. It would take up far too much space merely to indicate the contents of the various chapters of the book, to draw attention to the useful tables, and to enumerate the numerous illustrations. Less still could justice be done to Mr. Richmond's work by an attempt to specially mention the most important parts and statements. In fairness we must also abstain from noticing the weaker portions of the book, and as these are scant and of little importance we can do so without remorse. Suffice it to say that Richmond's "Dairy Chemistry" forms a complete résumé of theoretical and practical knowledge, written in easily intelligible language, and is a work useful to everyone desiring instruction in the chemistry of milk and milk products, a work which the attentive reader will study with the greatest satisfaction. P. V.

A Text-book of Physical Chemistry. By Dr. R. A. Lehfeldt. London: Edward Arnold. Price 7s. 6d.

This branch of general chemistry has developed so enormously during the past twelve years or so that it now constitutes a department of considerable size and importance; and as its teachings already to some extent exert on analytical problems an influence which in all probability will become more marked as time rolls on, it behoves every analytical chemist to become acquainted with the general principles of this subject, especially as analytical processes depend ultimately on a knowledge, not only of chemistry in the restricted sense, but of the physical behaviour of the materials dealt with. The work before us is eminently adapted for this purpose; it forms a well-written digest, couched in terse but intelligible language. Although mathematical formulæ are indispensable in illustrating a subject of this nature, the work is ingeniously arranged so as to be intelligible to the non-mathematical reader who is content to take the mathematical proofs on trust. The general get-up of the book is good; it is printed in clear, bold type, contains numerous illustrations and has a copious index. W. J. S.

MISCELLANEOUS.

QUALIFICATIONS OF PUBLIC ANALYST.

THE following extracts are taken from an Order and accompanying Circular, dated March 7, 1900, issued by the Local Government Board to those local authorities who are required by law to appoint a Public Analyst:

"Every person appointed on or after the first day of January, one thousand nine hundred, to the office of Public Analyst shall furnish such proof as we may deem sufficient of his competent skill in, and knowledge of, (*a*) analytical chemistry, (*b*) therapeutics, and (*c*) microscopy.

"Such proof shall in every case comprise documentary evidence that such person holds the requisite certificate, diploma, license, or document conferring the qualification, or attesting his possession of the skill or knowledge to which the same applies, and granted or issued by any person or body of persons for the time being recognised by us as competent to confer such qualification, or to test such skill or knowledge. Such proof shall also comprise such further evidence as we may in any particular case require.

"All such documentary evidence as is hereinbefore mentioned shall be furnished by such person to the local authority by whom he is appointed, and shall be transmitted to us by the local authority when applying for our approval of the appointment.

"Provided that nothing in this regulation contained shall, in the case of any person who was appointed to the office of Public Analyst with our approval, between the first day of January, one thousand eight hundred and ninety-one, and the date hereof, or of any person who is so appointed for the first time after such last-mentioned date, apply upon any subsequent appointment of such person to the said office."

"As regards the reference in the Order to a person or body of persons whom the Board may from time to time recognise as competent to confer the requisite qualification, or to test the skill or knowledge of which proof is required by the Order, the Board may state that it would accord with their existing practice to accept as sufficient documentary evidence of the requisite qualification under the Acts the Diploma of Fellowship or Associateship of the Institute of Chemistry of Great Britain and Ireland, together with the Certificate granted by the Institute after an examination, conducted by them on lines approved by the Board, in therapeutics, pharmacology, and microscopy."

"The possession of a diploma as a registered medical practitioner is accepted as sufficient proof of competency in microscopy and therapeutics, and it would only be necessary that a medical practitioner appointed as a public analyst should furnish evidence of competent skill in, and knowledge of, analytical chemistry."

"Evidence of skill or knowledge on the part of a candidate in respect of any of the qualifications referred to as requisite, which is tendered by an individual, must be from a person recognised as entitled to speak with authority as to proficiency in the particular qualification in question."

THE ANALYST.

MAY, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, April 4, in the Chemical Society's Rooms, Burlington House. The President, Mr. W. W. Fisher, M.A., occupied the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. T. E. Hill, M.B., B.Sc., F.I.C., T. Macara, and W. E. F. Powney were read for the second time; and certificates in favour of Messrs. John Richard Brooke, A.I.C., Analytical Chemist, 36, Mincing Lane, London, E.C.; Thomas Henry Lloyd, Analyst and Bacteriologist, The Laboratory, Penygraig, Rhondda; and George Harris Morris, Ph.D. (Würzburg), F.I.C., Analytical and Consulting Chemist, 72, Chancery Lane, London, W.C., were read for the first time.

Messrs. Arthur Alexander Ramsay, James Eugene Kirkpatrick, and A. J. Murphy were elected members of the Society.

The following papers were read: "Note on the Influence of Temperature and Concentration on the Saline Constituents of Boiler Waters," by Cecil H. Cribb, B.Sc.; "On an Improved Absorption Apparatus for Use in the Analysis of Essential Oils," by Alfred C. Chapman and Herbert E. Burgess; and "On the Composition of Danish Butters," by Harold Faber.

BUTTERS FROM VARIOUS COUNTRIES COMPARED.

BY C. ESTCOURT, F.I.C.

(*Read at the Meeting, February* 7, 1900.)

DURING the last twelve months I have analysed a considerable number of samples of butter for the direct importers of such produce, representing shipments from Ireland, Denmark, Sweden, Germany, Canada, and Finland.

I am able to give the following results of the analyses of about 250 samples, the origin of each of which I ascertained and noted:

Water in Butter.

Origin of Samples.	Total Samples.	Average Percentage of Water.	Highest Percentage of Water.	Lowest Percentage of Water.
Finnish	85	12·3	18·0	8·0
Danish	89	13·5	18·0	9·0
Irish	39	14·1	20·0	9·0
Swedish	14	13·75	17·8	11·8
Canadian	10	13·2	19·4	10·0
German	8	13·5	14·8	11·4

Water.

The percentages of water, as will be seen from the tables just given, vary considerably in the produce of every country with the exception of Germany.

I give in the foregoing tables the average, as well as the highest and lowest figures.

On reviewing the results, I find in Irish butter that, of the thirty-nine samples examined, only four contained more than 18 per cent. of water, three contained more than 16 but less than 18 per cent., as many as twenty-three contained from 12 to 16 per cent., and the results obtained from nine samples gave figures falling below 12 per cent.

In the case of the Danish samples only nine contained more than 15 per cent. of water, while six contained less than 12 per cent.

The produce from Finland showed that only three samples of the eighty-five analysed contained more than 15 per cent. of water, twenty-six contained between 13 and 15 per cent., and the remainder, fifty-six, were all under 13 per cent. The Finnish butter, therefore, must be deemed a most satisfactory article as regards the quantity of water.

Of the Swedish samples, six showed water to the extent of 14 per cent. and above, the highest being 17·8 per cent.

The Canadian samples gave results varying from 10 to 15 per cent. of water, with the exception of one sample which was found to contain as much as 19·2 per cent.

The German produce gave results much more constant: six of the eight samples analysed contained from 12 to 14 per cent., and one 14·8 per cent. of water. The exceptional one contained 11·4 per cent.

It will appear from the results obtained with the Irish butters that where care is exercised, as it is at the creameries, no great excess of water is found.

Samples Examined for Preservatives.

Origin of Samples.	Total Samples Examined.	Samples not containing Preservatives.	Samples containing Boric Acid.		
			Average in Grains, per pound.	Highest in Grains, per pound.	Lowest in Grains, per pound.
Finnish ...	74	73	8·3	—	—
Danish ...	85	82	5·3	8·0	4·0
Irish ...	37	2	24·7	46·0	5·0
Swedish ...	13	13	—	—	—
Canadian ...	10	9	9·0	—	—
German ...	8	8	—	—	—

Preservatives.

As regards the examination of the samples for preservatives, it will be seen from the tabulated results that not a single sample of the German and Swedish imports was found to contain any.

Of the ten Canadian butters, one contained boric acid, and that only to the extent of 9 grains per pound.

Eighty-five specimens of Danish butter were examined, and in three samples only could any preservative be found, namely, boric acid, and the highest quantity contained in a sample was 8 grains per pound.

Of the seventy-four samples from Finland, only one was found upon examination to contain boric acid, namely, 8·3 grains per pound.

Therefore the percentage of the samples of Danish and Finnish butter containing preservative is very low and scarcely worthy of notice.

The same cannot be said of the Irish production, of which all the samples were found to contain boric acid, varying in quantities from 5 to 46 grains per pound.

Of the thirty-five samples in which preservative was found, eight contained upwards of 35 grains per pound of boric acid, including two containing above 40 grains.

Nineteen showed results between 20 and 35 grains per pound, and seven samples contained quantities below 12 grains of boric acid.

These results are rather surprising following upon those of the analyses of the produce of other countries, which rather tend to show that a preservative is not absolutely necessary.

Figures obtained by the Reichert Process.

Origin of Samples.	Total Samples.	Average Figure.	Highest Figure.	Lowest Figure.
Finnish	85	13·8	17·6	11·9
Danish	90	15·2	17·0	12·5
Irish	39	14·0	15·5	12·8
Swedish	14	14·4	16·2	13·7
Canadian ...	10	14·1	15·5	13·0
German	8	15·3	16·2	13·5

Results obtained by the Reichert Process.

Coming to the composition of the fats of these different butters, the results obtained by submitting them to the Reichert test are given below; and a few notes I have made may be of some interest to the members of this Society.

Taking the Finnish butters first, the fats of eighty-four samples were examined, and gave an average Reichert figure of 13·8; only eight gave Reichert figures of 16 and over; whilst twenty-one samples showed results below 13, including two results of 11·9.

These two samples I returned as adulterated, and they accordingly were sold as confectionery butter.

With regard to the Irish butters, only four gave Reichert numbers below 13, and

seventeen samples were lower than 14; there was not much variation among the remainder of these thirty-nine samples, the figures of which ranged from 14 to 15·5.

Of the Danish samples, ninety were analysed, and as many as twenty-two gave Reichert figures of 16 and above, including two of 17, showing a very large percentage having a high Reichert number. There were only three giving numbers of 13 and lower, the general figure for the remaining sixty-five samples being about 15.

Denmark may be said to produce a butter of very good quality, and the Reichert figure of which is fairly constant.

The butters of German and Swedish origin appear to be of even composition, as evidenced by the results obtained by the Reichert test.

Of the Swedish, only one of the fourteen samples gave a figure so low as 13·7, the next lowest being 14·4, and this is the average figure for the whole of these samples.

The results of the German butters were higher on the whole than the Swedish, though the lowest in this case was 13·5.

Although the Canadian and Irish agree practically as regards the average Reichert figure, the former have a greater percentage of samples whose figures come as low as 13 to 13·5. Four out of the ten are below 13·5, while the remainder agree fairly with the Irish.

NOTES ON SOUR MILK.

By H. Droop Richmond, F.I.C., and J. Bristowe P. Harrison, A.I.C.

(*Read at the Meeting, February* 7, 1900.)

I. The Determination of the Specific Gravity of Sour Milk.

Weibull (*Chem. Zeit.*, 1893, xvii. 1679) proposed, in order to determine the specific gravity of sour milk, the addition of a known volume of ammonia; the density of the mixture, corrected for the volume of ammonia added, of which the density is known, gives the density of the milk.

It has been our practice to slightly modify this method; we add to each 100 c.c. of sour milk 5 c.c. of strong ammonia, and to the density of the mixture we apply a constant correction deduced from the change of density on adding 5 c.c. of strong ammonia to 100 c.c. of fresh milk; this correction has varied from 0·0065 to 0·0070 with different samples of strong ammonia.

We can fully confirm Weibull's statement that the density of sour milk can be accurately determined by this means, and have used the method extensively.

De Koningh (Analyst, xxiv. 142) has substituted a solution of caustic soda (specific gravity 1·030) for the strong ammonia; he finds that a constant correction of 0·0008 must be added to the results, this being the mean figure by which the density is lowered on mixing 5 c.c. of soda solution with 100 c.c. of milk. He accounts for the lowering of density by the assumption that calcium phosphate is rendered insoluble; we neither entirely confirm his figure nor are we satisfied with his explanation; as we propose to show, the correction is not constant, but varies

with the "acidity" of the milk, and can be, we think, explained when the action of acids on alkalies is considered.

In Table I. we give the densities of solutions of caustic soda, ammonia, and sulphuric and hydrochloric acids, and the salts resulting from their mutual action.

The figures are obtained by interpolation from well-known tables, which we have taken from the *Chemiker Kalender*, and are expressed in terms of $\frac{N}{5}$, $\frac{N}{10}$, and $\frac{N}{20}$ solutions; they are probably correct to the fourth place of decimals.

TABLE I.

Densities of Solutions of Bases, Acids, and Salts.

Substance.	$\frac{N}{5}$.	$\frac{N}{10}$.	$\frac{N}{20}$.	Authority
NaOH ...	1·00920	1·00465	1·00235	Lunge.
NH_3 ...	0·99856	0·99928	0·99964	Carius.
HCl ...	1·00372	1·00186	1·00093	Lunge and Marchlewski.
H_2SO_4 ...	1·00774	1·00387	1·00193	Lunge and Isler.
NaCl ...	1·00846	1·00423	1·00212	Gerlach.
NH_4Cl ...	1·00338	1·00169	1·00085	,,
Na_2SO_4 ...	1·01266	1·00639	1·00322	,,
$(NH_4)_2SO_4$	1·00752	1·00376	1·00188	Schiff.

If a salt in solution had a density which was the sum of the densities of the acid and base of which it was composed, the density of a solution of a salt should be equal to the sum of the densities of corresponding strengths of its acid and its base, less 1. This is not, however, the case, and the difference between the sum of the densities of the acid and base (less 1), and the density of the salt is given in Table II.:

	NaOH.		NH_3.	
	HCl.	H_2SO_4.	HCl.	H_2SO_4.
$\frac{N}{5}$ ...	−0·00446	−0·00428	+0·00110	+0·00122
$\frac{N}{10}$ ...	−0·00228	−0·00213	+0·00055	+0·00061
$\frac{N}{20}$ ...	−0·00116	−0·00106	+0·00028	+0·00031

As the acidity of fresh milk is about $\frac{N}{50}$, and that of sour milk about $\frac{N}{20}$ to $\frac{N}{10}$, it is seen that the change of density on neutralization will go a long way towards explaining the change noticed by De Koningh.

Thinking that it would not be quite correct to compare the acids such as sulphuric and hydrochloric, with milk, we have made a few experiments with weaker acids.

We prepared a solution of caustic soda of density 1·032, which was 0·666 N., and determined the densities of various dilutions of this with water. There were:

No. of c.c. diluted to 100 c.c. $= x$.	Density found.	Density calculated.
4·10	1·00138	1·00138
7·96	1·00266	1·00265
11·81	1·00388	1·00391

Formula: Density $= 1 + 0{\cdot}000339x - 0{\cdot}0000007x^2$.

The determinations show that when 5 to 20 c.c. of this solution are added to 100 c.c. the density is about 0·0001 higher than that calculated proportionally.

A solution of citric acid, 1·0064 N., was prepared; the densities of various dilutions were determined:

No. of c.c. diluted to 100 c.c. = x.	Density found.	Density calculated.
2·39	1·00059	1·00064
4·80	1·00135	1·00130
7·47	1·00200	1·00201

Formula: Density = $1 + 0{\cdot}0002688x$.

Solutions were now made up containing varying quantities of citric acid and a slight excess of soda solution:

No. of c.c. of Citric Acid in 100 c.c.	No. of c.c. of Soda in 100 c.c.	Density found.	Density calculated.
2·41	4·04	1·00174	1·00200
4·82	8·48	1·00361	1·00412
7·41	11·99	1·00524	1·00595

The calculated density was obtained by adding together the figures obtained by calculating the densities due to the citric acid and soda by the formulæ given above, and subtracting 1.

Fifty c.c. of a solution of lactic acid diluted to 100 c.c. (making 0·0256N) had a density of 1·00060; 50 c.c. of this solution + 4·76 c.c. solution of caustic soda, diluted to 100 c.c., had a density of 1·00195. The calculated density was 1·00220.

Calculated to a strength of $\frac{N}{10}$, the differences are for citric acid 0·00105, 0·00104, and 0·00095, or a mean of 0·00100, and for lactic acid 0·00098, figures which are less than half that given by the stronger acids. As citric acid, in addition to being a weak acid, is a tribasic acid, we thought that the lower figure obtained might be partly due to the three hydrogen atoms not having the same value. It was convenient to test this question in the first instance with oxalic acid on account of the ease with which normal and acid salts could be prepared.

We made a quantity of each salt, the purity of which is shown by the following figures:

	Normal Salt $Na_2C_2O_4$		Acid Salt $NaHC_2O_4{\cdot}OH_2$	
	Found	Theory	Found	Theory
Total C_2O_4	65·55, 65·48	65·67	67·58, 67·82	67·69
C_2O_4 (as acid)	none	none	33·61	33·85
Loss in water-bath	none	none	13·92	13·85
Further loss at 105° to 110°	none	none	none	none

The following densities were determined:

(i.)	Oxalic acid 0·0406 N.	1·00082
	,, ,, 0·10 N.	1·00217
	,, ,, 0·2597 N.	1·00563
(ii.)	*$Na_2C_2O_4$ 0·10 N.	1·00556
(iii.)	*$NaHC_2O_4$ 0·20 N.	1·00720
(iv.)	Oxalic acid 0·10 N., to which 14·43 c.c. soda solution per 100 c.c. had been added = 0·0961 N.	1·00572

* These two solutions contained the same amount of sodium.

From the above figures we calculate the following losses of density for $\frac{N}{10}$ solutions:

When the total acidity is neutralized	from i., ii.,	and density of NaOH	0·00126
,, ,, ,, ,,	from i. and iv.	... ...	0·00124
When the first hydrogen atom is neutralized	from i., iii.,	and density of NaOH	0·00179
When the second hydrogen atom is neutralized	from i., ii., and iii.	... ...	0·00053
,, ,, ,, ,, ,,	from i., iii., and iv.	... ...	0·00068
,, ,, ,, ,, ,,	from ii., iii.,	and density of NaOH	0·00073
,, ,, ,, ,, ,,	from i., ii., iii., and iv.	... ...	0·00071

From the above results it appears that the first hydrogen atom in oxalic acid is the more powerful.

It is seen from the above that although neutralization of an acid by soda always produces a loss of density, the figure varies not only with the acid, but also with the hydrogen atom neutralized in a polybasic acid. For this reason it is useless to apply any theoretical correction for milk, and we have made some experiments to see if we can find a value which may be used in milks.

To milk of density 1·0319 increasing quantities of soda solution were added and the densities taken. Three c.c. of the solution rendered this milk exactly neutral to phenolphthalein.

Quantity added.	Density.
1 c.c. to 100 c.c.	1·03175
2 ,, ,,	1·0316
3 ,, ,,	1·0316
4 ,, ,,	1·0316

Five c.c. of soda solution was added to 100 c.c. of different milks, and the densities determined.

Original ...	1·0325	1·0327	1·0319	1·0328	1·0339 1·0338	1·0309	1·0328
Alkaline ...	1·0322	1·0321	1·0316	1·0324	1·0334 1·0335	1·0306	1·0325

The third milk in the above table was allowed to get sour; when the acidity was equal to 9 c.c. of the soda solution for 100 c.c., it still was liquid, and had a density of 1·0319. On the addition of 5 c.c. soda solution the density fell to 1·0316, and to 1·0310 by the addition of 10 c.c.; when 15·1 c.c. were required to neutralize it, the addition of 20 c.c. of soda dissolved the precipitated curd, and the density was 1·0298. In each case Weibull's method, applying the correction found for fresh milk, gave a density of 1·0320.

The following additional experiments were performed:

Original Density of Milk.	Acidity.	Soda added.	Density of Alkaline Milk.
1·0331	136°	21 c.c.	1·0300
1·0326	124°	19 c.c.	1·0302

Fresh milk has, according to our experience, an average acidity of 20°, and we assumed that all the milks tested in a fresh condition had this acidity.

Tabulating the acidities and the lowering of density, we get:

Original Density.	Acidity Neutralized.	Lowering of Density.	Calculated Original Density.
1·0319	6·7°	0·00015	1·0319
,,	13·3°	0·0003	1·0319
,,	20·0°	0·0003	1·0320
1·0325	20·0°	0·0003	1·0326
1·0327	20·0°	0·0006	1·0325
1·0319	20·0°	0·0003	1·0320
1·0328	20·0°	0·0004	1·0328
1·03385	20·0°	0·0004	1·03385
1·0309	20·0°	0·0003	1·0310
1·0328	20·0°	0·0003	1·0329
1·0319	33·3°	0·0003	1·0323
,,	60·0°	0·0009	1·0321
,,	101·0°	0·0021	1·0318
1·0326	124·0°	0·0024	1·0327
1·0331	136·0°	0·0031	1·0327

The figures calculated are obtained on the assumption that each degree of acidity causes a lowering of the density of 0·00002, and with this correction the results are fairly accurate.

On referring to Table II. we see that with strong acids the change of density on neutralizing with ammonia is very much smaller than with soda, and in the opposite direction, and our results with milk indicate that it may practically be neglected. This is due partly to the fact that dilution of strong ammonia produces a small change in density in the direction opposite to that due to neutralization, and partly to the fact that there may be a small loss in solids when milk becomes sour, and the small errors in the one case tend to neutralize the small errors in the other.

With De Koningh's method the errors are larger, and tend in the same direction, and though an approximate correction depending on the acidity of the milk can be worked out, it appears preferable to use Weibull's method.

II. The Point at which Milk may be considered Sour, and the Rate of Souring in the Presence or Absence of Preservatives.

There is considerable divergence of opinion as to the degree of acidity at which milk may be considered sour. Thus Stokes (Analyst, xvi., 122) states that milk which has not yet reached an acidity of 0·3 per cent. lactic acid (33·3°), but is near it, will coagulate on boiling; he records, however, the fact that three samples did not coagulate when the acidity had reached 0·54 per cent. lactic acid (60°). He also gives figures which show that milk tastes sour at an average acidity of 0·396 per cent. lactic acid (44°). Thorner (*Chem. Zeit.*, 1891, 1108) gives 23° as the acidity at which milk curdles on boiling, and gives the normal acidity of milk as 12° to 16°.

Rideal and Foulerton (*Public Health*, May, 1899) say that milk turns sour at an acidity of 0·5 per cent. lactic acid (55·6°), but Rideal (*Lancet*, January 27, 1900, 228) finds that milk curdles on boiling at 28° acidity, while with other samples slight coagulation was noticed at 25·6° and 21·6°.

We have made a series of experiments, and our figures confirm almost absolutely

the figures of Stokes. On the average we find that milk tastes sour at 45°, though the variations are fairly wide. The following experiments show the point at which milk curdles on boiling:

	Acidity.	Remarks.
i.	33·3°	Faintly curdles on boiling.
ii.	28·0°	Does not curdle on boiling.
iii.	52·0°	Curdles on warming.
iv.	32·7°	Curdles on boiling.
v.	33·3°	Faintly curdles on boiling.
	34·0°	Curdles on boiling.
vi.	24·7°	Does not curdle on boiling.
vii.	37·8°	Curdles on boiling.
viii.	34·9°	Just curdles on boiling.
ix.	32·5°	Just curdles on boiling.

The acidity at which milk curdles on boiling is about 33°, and as we find that milk, when fresh, has an acidity of 20°, this corresponds to an increase of 13°. We have tried to ascertain the amount of acid added to milk which will curdle it on boiling; aqueous solutions of various acids were added little by little with constant shaking, till a faint coagulation on boiling was observed. The results were:

Acid.	Volume necessary expressed as $\frac{N}{10}$ c.c. to 100 c.c.
Sulphuric	8·8
Hydrochloric	8·6
Oxalic	29 and 28
Lactic	9·7

We find that milk curdles at about 85°, or an increase of 65°, without boiling; this was the figure found at 17° to 35°, and between these limits does not appear to vary appreciably; it is difficult to determine the point with accuracy.

It is quite certain that the "acidity" of milk is not wholly due to lactic acid; indeed, the "acidity" of fresh milk is due to the mono- and di-basic phosphates, and not to free acid at all. Seeing that 9·7 c.c. $\frac{N}{10}$ lactic acid will curdle milk on boiling, while it requires a development of about 13° "acidity," it is highly probable that another acid very much weaker than lactic is produced, and we venture to think that carbonic acid is responsible for a portion of the acidity of sour milk; we know that carbonic acid is produced, and we have found that when milk is sufficiently sour to develop gas about half the acidity, as indicated by phenolphthalein, is shown to litmus (to which both milk and carbonic acid are approximately neutral).

We have based a hypothesis on the facts that different acids do not give the same result, that salts of polybasic acids are present in milk, that both casein and albumin have acidic functions, and that the coagulation of milk at temperatures between 17° and 35° does not appreciably vary with the temperature; it appears to us that curdling of milk is due to an amount of acid being present to set up an equilibrium between the acids and bases present, such that certain acids, *e.g.*, casein and albumin, are liberated. At a boiling temperature we are inclined to think that the curdling is determined by the coagulation of the albumin, the equilibrium being destroyed by the removal of one acid (albumin) from solution, and fresh amounts of albumin, and finally perhaps casein, are liberated.

When milk tastes sour, it would appear that the equilibrium is such that a sour-tasting free acid exists in solution; while when milk curdles spontaneously the equilibrium is such that the insoluble acid casein is produced.

We have mentioned this hypothesis to emphasize the fact that the point at which milk must be considered sour is a purely arbitrary one; the three points we have mentioned are determined by the coagulation of albumin, the production of a sour-tasting acid, and the formation of insoluble casein respectively, and others could doubtless be found.

We have made some experiments to determine the rate of souring of milks with and without preservatives. The preservatives used were a mixture of borax and boric acid, in the proportion of one part borax to three parts boric acid, from which sufficient water had been driven off to raise the percentage of B_2O_3 to 56·3 per cent. (this is a mixture largely sold under fancy names), and a solution of formaldehyde.

Our results are, with boric preservative (the figures represent degrees of acidity):

Temp. 17·5° C.	Milk alone.	Milk + 0·05 per Cent.	Milk + 0·10 per Cent.
52 hours	69·9°	31·3°	35·3°
76 ,,	95·0°	67·3°	52·6°
Temp. 24·5° C.			
24 hours	32·6°	31·3°	35·0°
48 ,,	99·2°	97·1°	82·6°
Temp. 34·5° C.			
22·5 hours	93·6°	71·3°	45·3°
46 ,,	116·6°	114·8°	108·2°

The acidity of the milk when fresh was:

Milk alone	19·7°
,, + 0·05 per cent.	25·3°
,, + 0·10 ,, ...	31·3°

With formaldehyde:

Temp. 17·5° C.	Milk alone.	Milk + 0·0023 per Cent.	Milk + 0·0047 per Cent.	Milk + 0·0093 per Cent.
24 hours	22·9°	—	—	—
48 ,,	72·7°	29·3°	23·3°	22·0°
72 ,,	93·6°	99·2°	33·3°*	24·0°
Temp. 27° C.				
24 hours	58·7°	26·7°	23·3°	—
48 ,,	106·3°	115·3°	81·3°*	27·3°
72 ,,	118·0°	120·8°	123·3°	56·7°
Temp. 36° C.				
24 hours	83·3°	80·0°	28·0°	22·7°
48 ,,	116·7°	141·6°	129·2°	52·0°*
72 ,,	158·3°	152·4°	139·2°	132·0°

The acidity of the fresh milk was in all cases 20·7°.

In the samples marked with an asterisk we could only obtain a very slight formaldehyde reaction with Hehner's tests. All the samples with an acidity below 30° gave a strong reaction, and the others a most indefinite one.

We would draw attention to the fact that when a milk treated with formaldehyde

begins to develop acidity, the rate of souring is greater than that of untreated milk, and this is noticed also, to a smaller extent, with boric preservative.

By drawing a curve including the results at 17·5°, we get an expression of the rate of souring, and we find that the same curve with a different time factor applies without great error to the other temperatures, and to the results with boric preservative; a second slightly differing curve applies to the formaldehyde results.

By means of these curves we have constructed tables of the time which milk takes to arrive at the three points of "sourness"—*i.e.*, an increase of 13°, 25°, and 65° acidity. These tables are, of course, only approximate, but we do not think that the deviation exceeds 10 per cent. of the values stated.

Table of the Time in Hours taken by Milks to reach 13° Additional Acidity.

		Boric Preservative.		Formaldehyde.		
Temp.° F.	Milk alone.	Milk + 0·05 per Cent.	Milk + 0·10 per Cent.	Milk + 0·0023 per Cent.	Milk + 0·0047 per Cent.	Milk + 0·0093 per Cent.
60	42	71	93	51	85	119
70	29	36	46	34	49	78
80	19	22	31	25	34	56
90	13	15	23	15	26	44
100	7·5	10	20	9	23	37

Time in Hours to reach 25° Additional Acidity.

		Boric Preservative.		Formaldehyde.		
Temp.° F.	Milk alone.	Milk + 0·05 per Cent.	Milk + 0·10 per Cent.	Milk + 0·0023 per Cent.	Milk + 0·0047 per Cent.	Milk + 0·3093 per Cent.
60	50	84	110	60	100	140
70	34	43	54	40	58	92
80	22	26	36	29	40	66
90	15	18	27	18	31	52
100	9	12	23	11	27	44

Time in Hours to reach 65° Additional Acidity.

		Boric Preservative.		Formaldehyde.		
Temp.° F.	Milk alone.	Milk + 0·05 per Cent.	Milk + 0·10 per Cent.	Milk + 0·0023 per Cent.	Milk + 0·0047 per Cent.	Milk + 0·0093 per Cent.
60	75	126	165	84	140	192
70	51	64	81	56	81	129
80	33	39	54	41	56	92
90	22	27	40	25	43	73
100	12·5	18	34	15	38	62

The only results we have been able to find which are comparable with ours are those of Rideal (*loc. cit.*). Applying the same methods to his results, we obtain practically the same figures as those given above.*

We would draw attention to the fact that at high temperatures (say 80° hot summer weather) preservatives are comparatively useless unless added in relatively

* We assume that as Rideal does not notice the increased acidity when boric acid is added to milk, he has subtracted a constant amount for this throughout his series.

large quantities; the minimum quantities used by us, and also by Rideal, only increase the life of milk a few hours, and are equivalent only to a lowering of temperature of about 5° F. Unless milk can be made to keep at least twelve hours longer than without preservatives, we do not think much is gained by their use, and to do this in summer we think that the minimum amounts are 0·09 per cent. boric preservative and 0·004 per cent. formaldehyde.

We would also draw attention to the increased rate of souring as time goes on, when preservatives are added. This indicates a possible danger in using preservatives in milk, as it seems far from improbable that succeeding generations of micro-organisms become in the presence of preservatives more active and more virulent, and if the use of preservatives were universal, there is a probability that they would cease to act.

The work of Effront on yeast grown in the presence of sodium fluoride shows that this view is not a mere hypothesis.

Discussion.

The Chairman (Mr. Allen) inquired whether there was any reason to suppose that milk contained carbonic acid or carbonates. If this were the case, the reliability of titrations with phenol-phthalein would be seriously affected.

Mr. Richmond said that a portion of the acidity of sour milk was undoubtedly due to carbonic acid, and the question had been considered in connection with this paper. The figures, however, were not given as representing the acidity absolutely, but were only intended for comparative purposes. The question of carbonic acid would not affect the immediate object of the determinations, which was to ascertain the time required for the acidity to reach a certain point. If different samples contained different proportions of carbonic acid, there would, of course, be a distinct error; but these samples had been treated as nearly as possible under the same conditions, and the ratio of carbonic acid to other acids was probably not sufficiently divergent to affect the conclusions.

Mr. Chapman asked whether the experiments took place in the winter or summer months. The effect of a temperature of 80° F. in the summer and in the winter would probably not be the same.

Mr. Richmond said that the experiments were conducted during the winter. If any difference occurred, it would be rather in the autumn months—September and October—when an increase in the rate of souring might be expected. He did not think there would be any increase in the summer.

ORGANIC ANALYSIS.

The Detection of Cotton-seed and Sesame Oils in Fats. J. Wauters. *Bull. de l'Ass. belge*, 1899, xiii., 404-416.)—From the results of his experiments on the detection of these oils in butter, lard and other oils, the author has arrived at the following conclusions:

Halphen's reagent is preferable to Becchi's reagent for the detection of cotton-seed oil. It does not produce any coloration with other oils or fats, and is capable of detecting 0·25 per cent. of cotton-seed oil in mixtures. The reaction, which is also given by old oils, gains in sensibility by decolorizing the fat by heating it at about 50° C. with animal charcoal. Butter, both naturally and artificially coloured, and margarine are completely decolorized in this way.

The fatty acids do not give the coloration after being dried at 100° C., but with the undried acids the reaction is obtained with even greater intensity than with the fat itself.

Butters prepared from the milk of cows partially fed on cotton-seed cake give the reaction, but the intensity of the colour does not appear to exceed that produced by a fat containing 1 per cent. of the oil. On the other hand, feeding the cow with cotton-seed cake does not appear to have any influence on the chemical or physical constants of the butter. Decolorization by means of animal charcoal does not remove from sesame oil the active principle which gives the coloration in the Baudouin test. It removes foreign colouring matters, however, and notably turmeric. By applying the test to the decolorized fat it is possible to detect as little as 0·25 per cent. of sesame oil in butter or margarine. C. A. M

Notes on the Constitution of Train Oils. H. Bull. (*Chem. Zeit.*, 1899, xxiii., 996.)—By suitable treatment with alkalies dissolved in absolute alcohol, the fatty acids in train oils can be divided into four groups: (*a*) those whose potassium salts crystallize out of alcohol, (*b*) those whose sodium salts are crystallizable, (*c*) those whose sodium salts are very soluble in ether, and (*d*) a small residue. From 1 kilo. of Baltic cod oil the fractions were as follows:

	Weight in Grammes.	Acid Number.	Iodine Number.
A	334	194·2	67·5
B	375	190	135·6
C	120	167	322·4
D	69	169	347

A contains practically all the saturated acids and some belonging to the oleic series; B contains acids of the oleic and linolic series; C consists chiefly of acids of the

formulæ $C_nH_{2n-8}O_2$ and $C_nH_{2n-10}O_2$ ($C_{20}H_{32}O_2$ and ? $C_{23}H_{30}O_2$). For the latter an iodine value of 369 and an acid value of 165·2 were found, which agree satisfactorily with theory.

An imperfect separation of the fatty acids of the original oil can also be attained by distilling them at 200° C. in a sharp current of steam heated to the same temperature, recovering the distillates by fractional condensation in a set of receivers maintained at 180°, 160°, 140°, 120°, and 100°. The same process may also be applied to the acids previously separated by crystallization; fraction A above gave the following results:

Temperature of Receiver.	Weight of Fraction.	Acid Number.	Iodine Number.
160°	83·3	182	102·6
140°	95·5	200	62·4
120°	115·7	209	40
100°	14·2	212	33

Saturated acids were present in all fractions: stearic acid only in the first; stearic acid with a little palmitic in the second; palmitic almost alone of the saturated acids in the third; in the last palmitic and its lower homologues.

The ordinary processes for separating fatty acids which depend on the use of lead are not suited for the investigation of train oils. In all the samples examined, except torsk,* erucic acid, $C_{22}H_{42}O_2$, was met with, and also a new acid, $C_{20}H_{38}O_2$, melting about 20° — both of which (especially the former) yield lead salts slightly soluble in ether. In liver oil a new acid of the oleic series containing 21 atoms of carbon was found, which melted at 24·5°, and had the acid value 171·6 (theory, 172·8); this gave a lead salt very soluble in ether, and was therefore no mere mixture of the two former. In herring oil two unsaturated liquid acids with melting-points below – 20° were discovered, which gave the annexed analytical results:

Formula.	Acid Value.	Iodine Value.
$C_{20}H_{32}O_2$	179·0	344·5
$C_{24}H_{40}O_2$	154·9	279

F. H. L.

Estimation of Unsaturated Fatty Acids in Train Oils. H. Bull. (*Chem. Zeit.*, 1899, xxiii., 1043.)—This process depends, as already mentioned (*cf.* preceding abstract), on the solubility in ether of the sodium salts of the unsaturated acids of train oil. Seven grammes of the oil are weighed into a 200 c.c. flask, mixed with 25 c.c. of sodium ethylate (23 grammes of metal dissolved in 1 litre of absolute alcohol), and boiled on the water-bath for half an hour under an inverted condenser, shaking at intervals. The flask is closed and set aside for two hours; the soaps are thoroughly broken up with a rod, and 144·2 c.c. of ether free from alcohol and water (which has stood at least twenty-four hours over a large quantity of calcium chloride) is introduced. After agitating several times at intervals of half an hour, the mass is thrown on a dry 150 millimetre filter, the funnel of which is covered with a plate moistened with glycerin, and is connected by a rubber cork

* A fish allied to the cod.

to the flask, a piece of string being inserted between paper and funnel to permit circulation of air. One hundred c.c. of the filtrate (equivalent to 4 grammes of oil) are removed and extracted three times with 20 c.c. of water, a little free alkali being added each time in presence of phenolphthalein to prevent dissociation of the soaps. Any emulsion is broken down by means of a trace of alcohol or a few drops of alcoholic potash. The fatty acids are then liberated from the soaps, and the unsaponifiable matter extracted.

A very long table is appended giving the various constants of different varieties of train oil. Excepting the Japanese kinds, torsk oils, especially if pale, show a high proportion (12 to 21 per cent.) of unsaturated acids belonging to the series $C_nH_{2n-8}O_2$. The whale oils of the Northern Seas contain much less (4 to 9 per cent.); the antarctic "right" whale oil gives 19·5 per cent. Sardine oils contain 14 to 26 per cent. A turbid Japanese sample, however, gave only 5·75 per cent. The figures yielded by American porpoise-jaw oil show that an almost saturated acid of low molecular weight in it has a soluble sodium salt. Treated similarly, linseed, olive and rape oil give 2·37, 1·32, and 1·35 per cent. of soluble sodium salts respectively. F. H. L.

Estimation of Sugar in Transparent Soaps. F. Freyer. (*Oesterr. Chem. Zeit.*, 1900, iii., 25.)—The expression "glycerin soap" is used in trade to designate all transparent soaps, whether they contain glycerin or not. Materials intended for exportation to hot climates are nearly always prepared with cane-sugar, instead of glycerin, as the former enables them to bear high temperatures without sweating; and the proportion of sugar usually lies between 10 and 15 per cent. 16·28 grammes (a quarter of the normal weight per 250 c.c. for the soleil-ventzke-scheibler polarimeter) are dissolved on the water-bath in 50 or 100 c.c. of water, and a small excess (about 40 c.c.) of 10 per cent. barium chloride solution is added. The mixture is brought into a graduated flask, and diluted to 260 c.c., allowing 10 c.c. for the volume of the precipitated soap. The filtrate is tested with Fehling's solution for reducing sugars, polarized in the S-V-S instrument as it is, and polarized again after inversion with acid. F. H. L.

The Determination of Tannin and Gallic Acid. F. Jean. (*Rev. de Chim. Ind.*, 1900, xi., 35-38.)—This is an iodometric method based upon the fact that iodine combines with tannin or gallic acid to form compounds which do not give a blue coloration with starch. The iodine is dissolved in a solution of potassium iodide, and standardized on 0·1 per cent. solutions of tannin and gallic acid dried at 100° C. In each case 20 c.c. of the 0·1 per cent. solution are mixed with 5 c.c. of a concentrated solution of sodium bicarbonate, and the iodine run in drop by drop with continual circular agitation until a drop of the liquid gives a blue coloration when applied to paper covered with powdered starch.

The iodine solution is then strengthened or diluted according to the results of the titration until 10 to 10·5 c.c. are equivalent to 10 c.c. of the tannin solution. Gallic acid requires about 3 c.c. more of the iodine solution than tannin.

A blank determination is made to obtain the correction (usually about 0·4 c.c.) for the sodium bicarbonate.

In extracting the tannin substances from wood, leaves, etc., about 1 gramme of the sample is finely powdered, and heated for about thirty minutes with 15 c.c. of water at 50° C. The extract is decanted, the residue boiled for ten minutes with a fresh portion of water, and the aqueous solution again decanted, this treatment being repeated until the total extracts amount to nearly 100 c.c., to which volume it is finally made up when cold.

In the case of liquid extracts a solution is prepared containing 0·5 per cent. of the sample.

Ten c.c. of the solution are titrated with the standard iodine solution in the manner described above, the titration being repeated until the amount corresponding with 10 c.c. of the iodine solution is found. From the result the total amount of astringent matter is calculated.

For the separation of the tannin a solution of albumin is employed. This is prepared by triturating 2 grammes of dried egg albumin with sufficient glycerin (28-30° Ré.) to form a thin paste, leaving this for thirty minutes, and then making up to a litre with tepid water. It is preserved by the addition of a few fragments of camphor and by closing the flask with cotton wool impregnated with formaldehyde.

In the analysis 50 c.c. of the astringent solution are mixed with 15 c.c. of the albumin solution and 20 grammes of powdered sodium chloride, and the liquid made up to 100 c.c. with water, well shaken and filtered, the first portions being rejected.

A quantity of the filtrate, double that required in the first titration, is rendered acid by the addition of one drop of acetic acid and boiled to coagulate the excess of albumin. The filtrate and washings from this precipitate are cooled, mixed with 5 c.c. of sodium bicarbonate, and titrated with the standard iodine solution, a correction (usually about 0·7 c.c.) being made for the albumin from the result of a blank titration.

The amount of gallic acid is calculated from the iodine consumed, and the tannin is obtained from the difference in the results of the two titrations.

When the tannin material contains amylaceous substances soluble in water, the extraction should be made with alcohol. In the case of liquid extracts the absence of sulphites should be ascertained. C. A. M.

Detection of Nicotine. J. Schindelmeiser. (*Pharm. C. H.*, 1899, xl., 703; through *Chem. Zeit. Rep.*, 1899, 361.)—If unresinified nicotine is mixed with a drop of 30 per cent. formaldehyde, and a drop of strong sulphuric acid is added, an intense rose-red colour is produced, which becomes dark red in the presence of 0·005 or 0·01 gramme of the alkaloid. Concentrated formic acid may equally replace the formalin. F. H. L.

The Determination of Phosphorus in Organic Compounds. C. Marie. (*Bull. Soc. Chim.*, 1900, xxiii., 44, 45.)—One gramme of the substance is dissolved in 15 to 20 c.c. of concentrated nitric acid, the liquid gently heated, and finely divided potassium permanganate added in successive small portions until the colour of the solution remains pink for some minutes after the last addition. In the case of com-

pounds of the fatty acid series the destruction of the organic matter is very rapid; but with aromatic compounds it is more tedious, and it is necessary to add the permanganate in very small portions at a time, and to wait until the reaction is completed before adding the next portion.

A 10 per cent. solution of an alkali nitrite is added drop by drop to the oxidized liquid when cold until it becomes quite clear. It is then boiled for some time to expel the nitrous gases and to concentrate the solution, and the phosphoric acid precipitated in the usual manner with molybdate solution, care being taken to wash the precipitate completely free from manganese.

The author has tested this method on a large number of compounds, including some which, like Baeyer's ammonium calcium aceto-diphosphite, are extremely difficult to oxidize, even with fuming nitric acid in a sealed tube at 200° C., and has obtained results absolutely identical with those yielded by the ordinary method.

By the use of this method the analysis of glycero-phosphates may be greatly simplified. C. A. M.

A Simple Method of Estimating Mercury in Urine. Schumacher and W. L. Jung. (*Zeit. anal. Chem.*, 1900, xxxix., 12-17.)—A litre of the urine under examination is mixed with 15 to 20 grammes of potassium chlorate and about 100 c.c. of concentrated hydrochloric acid, and heated in a 2-litre flask on the water-bath until chlorine commences to be evolved. The flask is then allowed to stand for twelve hours. After expelling the excess of chlorine by gentle heating, the mercury is precipitated by the addition of 100 c.c. of a clear solution of stannous chloride, and the liquid filtered through purified asbestos. The precipitate, which contains a little organic matter, is washed by means of water and potassium hydroxide solution into a 300 c.c. flask, and gently heated so as to dissolve the organic matter; the solution is again treated with potassium chlorate and hydrochloric acid.

After filtration, the solution, while still warm, is treated with 10 to 20 c.c. of a concentrated solution of stannous chloride, and filtered through a Soxhlet-tube containing a layer of asbestos, and above it asbestos impregnated with metallic gold, which retains the mercury.

The asbestos is washed with dilute hydrochloric acid and water, then with alcohol and with ether, and the tube dried to constant weight in a current of dry air. The mercury is then expelled from the asbestos by heating the tube strongly and conducting a current of air through it until the weight again becomes constant. The difference between the two weights gives the amount of mercury.

The gold asbestos is prepared by dissolving pure gold in *aqua regia*, and evaporating the solution until nearly the whole of the free acid has been expelled. Fine threads of purified asbestos are soaked in this solution, and, after the liquid has drained off, heated in a porcelain crucible in a current of hydrogen for about fifteen minutes, when the reduction will be complete. Finally, the asbestos is washed with dilute hydrochloric acid and hot water, and dried.

In illustration of the accuracy of the method, the authors quote the following analyses among others: To a litre of pathological urine, which, according to the mean results of numerous analyses, contained 20 decimilligrammes of mercury, 30, 40·5,

and 67 decimilligrammes were added, and the amounts respectively found were 60, 55, and 77·5 decimilligrammes. C. A. M.

INORGANIC ANALYSIS.

The Analysis of Tungsten Compounds. F. Ibbotson and H. Brearley. (*Chemical News*, vol. lxxx., pp. 293, 294.)—On adding strong nitric acid, drop by drop, to a boiling solution of lead tungstate until the colour begins to turn yellow, then running in a few c.c. of the acid, and boiling a short time, a precipitate of tungstic acid is obtained corresponding in weight with the known quantity present. As, however, from 2 to 3 milligrammes of tungstic acid are found in the filtrate, the accuracy of the method depends on small compensatory errors. The colour change not being developed in presence of ammonium salts, the latter must be previously eliminated with caustic alkali.

Again, the acid lead tungstate thrown down by lead acetate from faintly (acetic) acid solutions can be dissolved in warm concentrated hydrochloric acid, and tungstic acid completely precipitated therefrom by the addition of water. No interference in this precipitation is exercised by barium, strontium, calcium, magnesium, zinc, cadmium, manganese, nickel or cobalt. In the case of *arsenic*, a few grammes of ammonium nitrate are added before precipitating the tungsten; any lead arsenate thrown down is redissolved in the hydrochloric acid, and may be disregarded, as may be also the precipitate formed with tungstates by *mercury*.

Uranium forms insoluble tungstates, which can be dissolved in a slight excess of sodium carbonate, and the clear solution should be heated to near the boiling-point and then poured into 6 or 7 c.c. of hot acetic acid, with an excess of lead acetate, the whole being well shaken. After just boiling the mixture the precipitate is washed by decantation, etc., and will then be free from uranium.

Iron comes down with the lead tungstate precipitate. To remove it the mixture is rendered faintly alkaline and then slightly acidified with acetic acid, the bulky precipitate furnished by lead acetate being washed thoroughly by decantation, ignited, and treated with hydrochloric acid as though it were pure lead tungstate. Small quantities of aluminium can be similarly dealt with.

Tin and *silicon* prevent the accurate precipitation of tungsten by this method, the former producing compounds insoluble in hydrochloric acid, whilst the silico-tungsten compounds are imperfectly thrown down by lead salts. They may, however, be precipitated by mercurous nitrate, from a neutral solution, the silica being removed by hydrofluoric acid after igniting the residue. C. S.

A New Method of Separating the Gadolinite Earths, and of Obtaining Pure Yttria. W. Muthmann and R. Böhm. (*Berichte*, 1900, xxxiii., 42-49.)—This is based on the fact that the normal chromates of the rare earths are considerably more insoluble than the corresponding sulphates. On precipitating a dilute neutral solution of the salts of the cerite or gadolinite earths with potassium chromate, the precipitates, when crystalline, have a composition corresponding to the general

formula $R_2(CrO_4)_3 + nH_2O$. The amount of water varies with the temperature and the metal, but most of these chromates crystallize with 8 molecules.

The authors have found that the most rapid method of fractionally precipitating these rare earths is to treat their readily soluble dichromates with potassium chromate. For the separation of the commercial yttria material into its six or more components they have proved that the following precautions are necessary:

1. The solutions of the rare earth salts and of potassium chromate must both be very dilute.

2. The liquid must be kept boiling throughout the precipitation.

3. The resulting precipitates must be kept in a fine state of division, and brought into intimate contact with the liquid. In carrying out these conditions they heat the liquid to be precipitated in a large retort nearly to the boiling-point, and then conduct a current of steam into it, the neck of the flask being slanted upwards to avoid loss by spurting. Besides the steam tube a second tube provided with a tap passes through the tubulure of the retort, and is connected by means of a siphon arrangement with the potassium chromate solution which is contained in a graduated flask. As each drop falls from the tube the resulting precipitate is distributed throughout the rapidly-boiling liquid. After the precipitation of each fraction the liquid is evaporated to its original volume, so that the conditions are the same throughout.

The following experiment is described to illustrate the method: The mixture of earths used was bought as "Yttrium oxydat. pur.," but in reality was found by spectrum analysis to contain oxides of most of the other rare earths. Forty grammes of this were triturated with about 90 grammes of chromium trioxide, and the mixture treated with a litre of water. The resulting solution of the dichromates was treated with potassium chromate until a turbidity resulted, and was then transferred to the retort and precipitated into six fractions as described above.

Fraction I. precipitated in two hours by 250 c.c. of 10 per cent. potassium chromate solution yielded only 1·1 gramme of oxides owing to the solution still containing polychromates. The oxides contained about 25 per cent. of erbian earths.

Fraction II(a). obtained in the same manner yielded 13·6 grammes of the oxides, of which about 20 per cent. were erbian earths. The spectrum showed that there was a considerable increase in the proportion of gadolinium as compared with the original substance.

Fraction II(b). was deposited on evaporating the mother liquid to the original volume. It yielded 6·04 grammes of oxides containing about the same amount of erbian earths as Fraction *II(a)*.

Fraction III. was precipitated with 300 c.c. of 5 per cent. potassium chromate solution and yielded 7·04 grammes of oxides, of which about 10 per cent. consisted of erbian earths.

Fraction IV., obtained in the same manner as *III.*, yielded 5·35 grammes of oxides containing only about 5 per cent. of erbian earths. On concentrating the liquid the chromate of a lighter earth was deposited. The oxide (2·065 grammes) was almost pure white, and showed only traces of erbium.

Fraction V. consisted of chromate of yttrium and yielded nearly pure yttria (4·2 grammes).

Fraction VI. gave 1·5 grammes of oxide, which was also practically pure yttria.

The residual solution, from which nothing more could be precipitated by potassium chromate, yielded on treatment with sodium hydroxide a slimy precipitate consisting of magnesia, calcium hydroxide, silica, and traces of yttria.

C. A. M.

Estimation of Calcium Carbonate in Soil. Immendorff's Process for the Determination of Total Calcium. H. Schütte. (*Zeit. angew. Chem.*, 1899, 854.)—The process already described by Stutzer and Hartleb (ANALYST, xxiv., 275) for estimating the proportion of calcium and magnesium carbonates, as distinguished from ferrous carbonate, in soil, yields perfectly accurate results when it is carried out on the pure carbonates of the alkaline earths; but when it is applied to natural soils, especially such as are poor in chalk, it leads to quite erroneous conclusions. In the first place, zeolites are present in larger or smaller quantities in most soils, and silicates of this nature react with the ammonium chloride, liberating ammonia, which neutralizes part of the standard acid placed in the receiver of the apparatus. The influence of such easily decomposed silicates is shown by the fact that if a soil giving only a slightly higher proportion of "carbonates" by distillation than by direct estimation of the carbon dioxide is repeatedly extracted with water saturated with carbon dioxide so as to dissolve and remove part of the true calcium carbonate, and is then again tested by the two processes, the difference between the yields is considerably increased. Secondly, Stutzer and Hartleb have stated that ferrous carbonate can be wholly decomposed by boiling the earth with water alone before the distillation is begun; this is quite true of fresh artificially precipitated ferrous carbonate, but the natural substance is far more stable, and, indeed, it can neither be broken up entirely in the manner indicated, nor correctly estimated by the authors' method. Moreover, the process does not give even concordant results when it is conducted according to the directions already specified; it is necessary to distil the liquid almost to dryness to ensure complete decomposition of the carbonates, or to use a larger excess of ammonium chloride; it is perhaps better to start with 25 c.c. of a 25 per cent. solution of chloride and 200 c.c. of water, distilling until only 25 c.c. of liquid are left in the retort, *i.e.*, till the residual liquid has again a concentration of 25 per cent.

Nevertheless, in the case of soils rich in alkaline earth carbonates, but free from ferrous carbonate, the method should prove of some value, for the errors are then relatively insignificant; but when the carbonates form but a small percentage of the total material it is no longer of service. For instance, a sample of marl containing 36·97 per cent. of carbon dioxide or 84·02 per cent. of calcium carbonate by gravimetric analysis gave 37·56 per cent. or 85·36 per cent. respectively on distillation; whereas a mud with 0·05 per cent. of carbon dioxide or 0·11 per cent. of calcium carbonate gravimetrically, was represented to contain 0·16 per cent. or 0·36 per cent. respectively by the Stutzer and Hartleb process.

To assume that the question whether a soil would be improved by the addition of chalk can be answered simply by noting the proportion of calcium carbonate already in it is not universally correct; earths rich in humus occasionally contain no calcium carbonate, yet they are not improved by introducing chalk. In many cases, therefore, it is desirable to estimate the total calcium, which is best done by Immendorff's process. The sample is extracted with hot hydrochloric acid, a portion of the solution is rendered just alkaline with ammonia, warmed and clarified by the cautious addition of more acid, then brought to the boil. A large excess of a strong solution of ammonium oxalate is next introduced, and after boiling some time the whole is made alkaline with ammonia, and faintly acid with acetic acid. The calcium oxalate can then be titrated, but it is preferably (if the soil contains much iron) ignited and weighed. Manganese in the precipitate is thus shown by the dark colour, and can be removed by a second precipitation, or by the use of bromine as usual. If the operation is properly conducted, iron and aluminium never contaminate the calcium oxalate. Passon's method for the estimation of calcium (*Zeit. angew. Chem.*, 1898, 776) is more troublesome to use, and does not give more accurate figures than that just outlined. F. H. L.

Separation of Chlorine and Iodine. L. Vanino and O. Hauser. (*Berichte*, 1900, xxxii., 3615-3617.)—This method is based on the behaviour of these halogens towards an alkaline solution of formaldehyde, the chloride being rapidly reduced to metallic silver whilst the iodide is not attacked.

The solution containing the mixed salts is precipitated with silver nitrate and the precipitate washed as far as possible by decantation, the washings being passed through a filter. It is then treated in the beaker with 25 c.c. of a solution of 50 grammes of potassium carbonate in 100 c.c. of water and 5 c.c. of a 42 per cent. solution of formaldehyde, and allowed to stand until carbon dioxide ceases to be evolved. Initial heating to 30° or 40° C. accelerates the reaction, which is usually complete in about thirty minutes. Any particles of chloride on the filter are also reduced to silver by repeated washing from a jet with the reagent previously heated to 40° C.

The precipitate in the beaker is washed with hot water, as far as possible by decantation, and after being treated with hot dilute nitric acid the liquid is repeatedly filtered through the same paper as used before, until the filtrate is perfectly clear. The silver iodide left upon the filter is washed, dried, ignited in a porcelain crucible and weighed.

The silver in the filtrate is precipitated with hydrochloric acid, and from the weight of silver chloride obtained the amount of the chlorine originally present can be calculated.

The results obtained in test experiments are given in tabular form, and show a close agreement with the theoretical quantities.

This method cannot be used for the separation of bromine from chlorine or from

iodine, since silver bromide is more or less reduced by the author's reagent under varying conditions, though not completely reduced like silver chloride. C. A. M.

A New Reaction for the Detection and Estimation of Nitrous Acid. **H. Erdmann.** (*Berichte*, 1900, xxxiii., 210-215.)—In the author's opinion the methods used for the detection of nitrites in water leave much to be desired. He states that in his experience well and surface water in which the nitrites correspond in quantity to a $\frac{1}{100000}$ N solution contain large numbers of bacteria. In exceptional cases the bacterial production of nitrites in natural water may reach a concentration corresponding to a $\frac{1}{10000}$ N solution. When the amount of nitrite nitrogen does not amount to 1 centigramme in a cubic metre of water, he considers that it may be ignored, but that when it amounts to from 1 centigramme to 1 gramme per cubic metre an, at least, approximate estimation is necessary in order to form a correct judgment of the character of the water.

If the nitrous acid in the water can be quantitatively converted into a coloured azo compound, it should be possible to make a colorimetric estimation. Metaphenylene-diamine, and similar substances, however, cannot be used for this purpose, since the brown colorations obtained are not sufficiently characteristic; and, on the other hand, they also give somewhat similar colorations with oxidizing agents.

After numerous experiments, the author has finally fixed upon 1-8-amido-naphthol 4-6-disulphonic acid as the most suitable substance. This is prepared from 1-3-5-naphthalene-sulphonic acid (*Berichte*, xxxii., 3186) by nitration, reduction, and heating with sodium hydroxide. It has the property of combining in acid solution with diazo compounds to form mono-azo colouring matters which are readily soluble and have a characteristic tint.

In using the reagent, 50 c.c. of the water are treated with 5 c.c. of a hydrochloric acid solution of sulphanilic acid (2 grammes of sodium sulphanilate per litre), and after about ten minutes about 0·5 gramme of 1-amido-8-naphthol-4-6-disulphonic acid in the solid state is introduced. In the presence of nitrous acid a brilliant Bordeaux red colour is produced, and reaches its maximum intensity in about an hour.

For a quantitative estimation, the colour is compared after that lapse of time with that given by standard solutions under the same conditions. The solutions used are $\frac{1}{1000000}$ N, $\frac{1}{100000}$ N and $\frac{1}{10000}$ N, and should be freshly prepared in order to avoid bacterial alteration.

As a proof of the superiority of this test over bacteriological methods, the author cites a case in which a well-water, which had given rise to an epidemic of anthrax, gave a pronounced nitrite reaction after a year, although the bacteria had long disappeared. He points out that it is seldom possible to actually isolate anaërobic pathogenic bacteria on account of their short life.

As regards other tests for nitrites, that of Griess with α-naphthylamine (*Berichte*, xii., 427) is said to be not sufficiently sharp or characteristic for water analysis, and to be unsuitable for a colorimetric estimation.

Still less satisfactory is Riegler's reagent, naphthionic acid (ANALYST, xxii., 305),

since, as is the case with many other readily diazotized bodies, its fluorescence interferes with the comparison. The author's reagent is stated not to fluoresce under the conditions given above. With oxidizing agents, such as ferric chloride, it gives a yellow coloration, which cannot possibly be confused with the red colour obtained with nitrites.

The author has made arrangements with J. F. Schwarzlose Söhne (Berlin, S.W., Markgrafenstr. 29) to forward specimens of his new reagent gratis on application.

C. A. M.

The Estimation of Sulphydric, Sulphurous, and Thiosulphuric Acids. W. Feld. (*Chem. News*, lxxxi., 40.)—The methods recommended by the author are applicable to the salts of the alkalies and of the alkaline earths.

For *sulphides* the sample is boiled with a concentrated solution of magnesium chloride in an atmosphere of carbonic acid, when (assuming barium sulphide) the following reaction takes place:

$$BaS + MgCl_2 + CO_2 + H_2O = BaCl_2 + MgCO_3 + H_2S.$$

The sulphuretted hydrogen evolved is absorbed in a solution of iodine, which is afterwards titrated.

For *sulphites* the same procedure is adopted, but substituting hydrochloric acid for magnesium chloride.

Thiosulphate is first converted into tetrathionate by titration with iodine. The solution is then subjected to the action of aluminium and dilute hydrochloric acid in an atmosphere of carbonic acid, when the following reaction takes place:

$$Na_2S_4O_6 + 20HCl + 6Al = 2NaCl + 3Al_2Cl_6 + 6H_2O + 4H_2S.$$

This method is also applicable for the determination of thiosulphate in the presence of sulphite which becomes oxidized to sulphate.

For the determination of sulphite in the presence of thiosulphate, the latter is first decomposed by the addition of mercuric chloride, thus:

$$Na_2S_2O_3 + HgCl_2 + H_2O = Na_2SO_4 + HgS + 2HCl.$$

The process recommended for sulphites is then applied.

In the case of mixtures of sulphide, sulphite, and thiosulphate, the sulphide is first determined by the magnesium chloride method, after which the thiosulphate is decomposed by mercuric chloride, and the sulphite determined by boiling with hydrochloric acid. The thiosulphate is determined in a fresh portion by titration with iodine and treatment with aluminium and dilute hydrochloric acid. H. H. B. S.

Determination of Nitrogen in Fertilizers containing Nitrates. F. P. Veitch. (*Journ. Amer. Chem. Soc.*, vol. xxi., p. 1094.)—The author modifies Field's variation of the Gunning method, in which potassium sulphide alone is used in place of potassium sulphate and sodium thiosulphate (ANALYST, xxii., 166), by adding to the nitrate in the digestion flask 35 to 40 c.c. of sulphuric acid, containing 34 grammes of salicylic acid per litre, the whole being allowed to stand in the cold until the nitrate is dissolved, whereupon 6 or 7 grammes of powdered potassium sulphide is

added, and gentle heat is applied for a quarter of an hour, followed by heating over the full flame till clear. C. S.

Valuation of Alkali Persulphates and of Hydrogen Peroxide. B. Grützner. (*Arch. Pharm.*, 1899, ccxxxvii., 705; through *Chem. Zeit. Rep.*, 1900, 21.)—About 0·3 gramme of an alkali-metal persulphate is gradually warmed to the boiling-point with 50 c.c. of decinormal arsenious acid and a few c.c. of potassium hydroxide solution, and kept hot for a short time. When cold, the liquid is faintly acidified with sulphuric acid, a large excess of sodium bicarbonate is added, and the whole is titrated with iodine and starch. One c.c. of decinormal arsenic is equal to 0·0119 gramme of sodium persulphate. Hydrogen peroxide can be similarly treated, 1 c.c. of acid being equivalent to 0·0017 gramme of H_2O_2. F. H. L.

Valuation of Clays for Brick Manufacture. W. Cronquist. (*Oesterr. Zeits. Berg. u. Hüttenw.*, 1899, xlvii., 522, *nach Teknisk Tidsskrift;* through *Chem. Zeit. Rep.*, 1899, 322.)—A mere chemical analysis of a clay is not sufficient alone to indicate its value to the brick-manufacturer; the proportion of silica in an air-dried aluminium silicate may range between 37 and 45 per cent., but a determination of this ingredient is practically useless. The amount of sand in Swedish clays varies from 47 to 72 per cent., but all are employed for making bricks; this sand, however, should be investigated for foreign matter, since the presence of mica, for instance, weakens the bricks. The air-dried sample is boiled with 1·12 hydrochloric acid till the residue is white; it is then filtered off and treated in a silver crucible with sodium carbonate solution to dissolve gelatinous silica, and the final insoluble sand is washed, ignited, and weighed. The author suggests two physical tests. A thoroughly representative sample is kneaded with water, and pressed into a wooden mould to yield a plate $20 \times 4 \times 1$ centimetres in size, on which a line exactly 150 millimetres long is drawn. After drying, the line is observed to find the distortion and contraction; a shrinkage of 8 per cent. indicates a well-binding clay. To ascertain the strength of the material, a crucible 45 millimetres high and 2·5 millimetres thick in the walls is constructed with suitable moulds; this is dried for four or six days in the air, then for two days at 100° C. It is next placed in an oven with similar crucibles made from standard clays, and burnt as usual. Finally it is broken in a specially-designed apparatus by means of lead shot. F. H. L.

A New Method of Titrating Potassium Iodide. E. Vincent. (*Journ. Pharm. Chim.*, 1899, x., 481-483.)—This is based upon the well-known fact that iodic acid acts upon the iodide in accordance with the equation:

$$6HIO_3 + 5KI = 5KIO_3 + 3I_2 + 3H_2O.$$

One gramme of the iodide under examination is dissolved in a litre of water, and 100 c.c. of the solution mixed with the same quantity of a solution of iodic acid (2 grammes per litre).

Five to ten c.c. of a standardized solution of thiosulphate, containing 2·48 grammes of thiosulphate in 100 c.c. and potassium bicarbonate in the pro-

portion of 2 grammes per litre, are measured into a beaker, and the mixed solutions of iodide and iodic acid run in from a burette drop by drop until the liquid assumes a faint yellow tint. Five-sixths of the iodine found are derived from the iodide originally present.

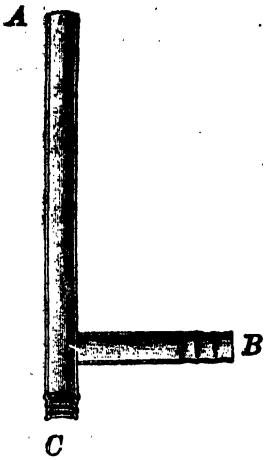
The potassium bicarbonate is added to the thiosulphate with the object of preventing the oxidation of the latter by the excess of iodic acid.

The following results were obtained by this method and by the more complicated method of Falières, in which the iodine is liberated by ferric chloride:

	Falières' Method. Per Cent.	Iodic Acid Method. Per Cent.
I.	96	95·87
II.	97·2	97
III.	94·5	94·4

It is essential that the thiosulphate solution should be titrated with the iodine solution, and not *vice versâ*. C. A. M.

On the Use of Iceland Spar as a Standard in Volumetric Analysis. O. **Masson.** (*Chemical News*, vol. lxxxi., pp. 73-75.)—Compact fragments weighing about 1 to 3 grammes each should be broken from a crystal of the spar, then freed from powder by rinsing with dilute acid, washed with distilled water, dried at over 100° C., and stored in a stoppered bottle.



For use, about 2·5 to 3·5 grammes are weighed in an 80 to 100 c.c. beaker, the total weight alone being required, and exactly 20 c.c. of approximately normal hydrochloric acid are run in from a burette, the beaker being covered and precautions taken to prevent loss by spurting. After three to four hours the evolution of gas will have ceased, and the contents of the beaker are kept at about boiling temperature for an hour, to drive off dissolved carbon dioxide and complete the reaction. The clear solution is then decanted, and the residual lumps of spar are well washed, dried at about 110° C., cooled and weighed. The loss in weight gives the amount of spar dissolved by, and exactly equivalent to, the 20 c.c. of hydrochloric acid taken; and also furnishes direct the "factor" of the acid, since, the molecular weight of calcium carbonate being 100, 20 c.c. of strictly normal acid dissolve exactly 1 gramme.

The author discusses several possible sources of error, but regards them all as negligible. C. S.

APPARATUS.

A Mortar Cover for Use in Grinding Hygroscopic Substances. R. Scholl. (*Chem. Zeit.*, 1900, xxiv., 15.)—This consists of a rubber cap or plate with a central hole or short flexible sleeve to admit the pestle-stem, and a flange to fit air-tight round the upper edge of the mortar. The flange is made of considerable width, so that the cover is raised somewhat above the top of the mortar, thus leaving more space for the movements of the pestle. The cover is equally useful in grinding hygroscopic materials, or such as are brittle or possess an unpleasant odour.

F. H. L.

A Simple Bunsen Burner. F. Allihn. (*Chem. Zeit.*, 1899, xxiii., 996.)—In this apparatus the usual injector gas-jet attached to the base and the radial air-holes surrounding it are done away with, so as to gain simplicity and cheapness in construction. The burner consists essentially of a plain T-piece, open at all three ends. At the spot where the horizontal (gas inlet) tube joins the vertical, the wall of the latter is drilled centrally with a small hole pointing upwards towards the end where combustion takes place; and this hole being the substitute for the ordinary jet, the bore of the vertical pipe is clear throughout, so that if liquids, etc., are spilt over the burner no choking can ensue. The bottom of the upright is provided with a male thread, which screws into a cast-iron base; and the air thus enters from underneath the stand.

This latter should manifestly be cast with a milled or fluted bearing edge, or on a level table the supply of air might be insufficient.

The burner can be used equally well without the base, being supported by any convenient clamp. The apparatus is patented, and may be obtained from Warmbrunn, Quilitz and Co., Berlin. F. H. L.

REVIEWS.

LEXIKON DER KOHLENSTOFF-VERBINDUNGEN. By M. M. RICHTER. London: Williams and Norgate. Pp. 2482. (Published in thirty-nine parts, at 1s. 10d. each.)

This work is the second edition of the "Tabellen der Kohlenstoff-Verbindungen nach deren empirischen Zusammensetzung geordnet," which appeared in 1883. It contains a register of about 67,000 compounds.

Taking into account the fact that organic chemistry is a highly systematized branch of the science, the indexing of compounds by their empirical formulæ appears at first sight a retrograde step. However, that the expedient has gone far towards meeting the demands for a scheme of registering organic compounds is plain from the fact that the Executive of the German Chemical Society now publishes an index based on this system in addition to the ordinary annual index to the well-known "Berichte." A few considerations will, indeed, show that, judged on its merits, the system is the best yet proposed in many respects. Thus, even if chemists had universally agreed upon the best nomenclature for organic compounds, which is by no means the case, it must be admitted that the names denoting the constitution of chemical compounds are not in themselves well adapted to indexing purposes. They are extremely long, besides which opinions are constantly altering with regard to the constitution to be assigned to a given compound: moreover, there are the so-called tautomeric compounds to which definite constitutions cannot be assigned (*Cf.* Jacobsen and Stelzner, *Ber.*, 1898, 31, 3368). The best established property of a compound, and at the same time the one least liable to alterations, is therefore its composition which finds expression in its empirical formula.

In the system under consideration the compounds are arranged in an ascending series depending on the number of carbon atoms they contain; the elements other than carbon follow in an order which may be denoted the alphabet of the system, thus —H, O, N, Cl, Br, I, F, S, P. The remaining elements come after these in the alphabetical order of their symbols. The work includes an index of names which gives the corresponding empirical formulæ. The "Lexikon" forms a collective index to Beilstein's well-known "Handbuch der Organischen Chemie," the third edition of which has just been completed, and as such, references are given to the latter for all the compounds—about 57,000—therein dealt with. As, however, the "Lexikon" is of later date than the last edition of Beilstein, about 8,000 more compounds are referred to in the former than in the latter. In the case of very well-known compounds, besides giving the reference to Beilstein, the words "literature abundant" are added, whilst in other cases references are to be found to the principal papers dealing with the compounds in question.

It is a very common occurrence in researches in organic chemistry that in the case of certain compounds nothing beyond the composition, *i.e.*, the empirical formula, is determined. Under no other system of indexing but Richter's can these substances be registered, and consequently hitherto their record has been as good as lost. A. R. L.

SQUIRE'S COMPANION TO THE BRITISH PHARMACOPŒIA. Seventeenth Edition. London: J. and A. Churchill. Price 12s. 6d.

This work, which has attained a large circulation amongst pharmacists, is not so well known to analysts as it should be.

Although the number of examinations of drugs and their preparations made under the Food and Drugs Acts is at present small and inadequate, there is every sign that it will be increased in the near future. This being so, it behoves analysts to make a fuller study of drugs than many of them have had occasion to do in the past, and there is no work more suited to their requirements than the one under consideration.

Although this work is primarily designed for pharmacists, it contains much information of value to analysts. Thus, the normal amounts of ash are given in the case of a large number of substances; comments on official processes, with suggestions or amendments of a practical nature, are included. To cite two instances, we may take the remarks on the analysis of pepsin and the examination of malt extracts. The table in the beginning of the book dealing with the materia medica of the Pharmacopœia is of high merit, and probably the most accurate published. A prolonged study of the work serves to increase one's appreciation of the infinite care expended on the collection and presentation of the vast array of facts that have been accumulated. The writer has noticed but one misprint in the book of 850 pages.

On examining the information given below the official tests in each monograph, we find either abstracts or references to almost every recent research of importance, so that the analyst may feel confident of getting assistance in the case of nearly every drug that may come into his hands. Among the many valuable pieces of information, only two have been found that seem questionable—namely, the statements that

"nutmegs yield about 5 per cent. of ash"; and, secondly (although this is not a statement of the author's), that the difference in the petroleum spirit extracts of true and false pareira is so marked as is indicated by the difference between the figures 8 and 0·3 per cent. Analysts will find the latest edition of this work a valuable acquisition.

C. G. M.

BAYLEY'S CHEMISTS' POCKET-BOOK. Seventh Edition. London: E. and F. N. Spon. Price 5s.

The author states that this seventh edition of his well-known Pocket-Book has been rearranged and to a large extent rewritten. The book contains various numerical tables for rapid calculations, which are useful to all technical workers, whether chemists or not. The more strictly chemical part includes tables of the principal properties of the elements, various analytical factors, and tables of weights and measures, with means for translating one kind into another. We would suggest the addition of a selection of the heats of combination most frequently needed in practical calculations. Tables of specific gravity of solutions and of sundry salts are given, and are certainly acceptable, as are also records of the melting and boiling points and solubility of a number of substances, and the tables of the behaviour of salts with different indicators. Altogether, there is a great mass of matter clearly arranged and readily accessible. The fact that the book has been long before a critical public and has been received with favour implies that the data contained in it are substantially accurate. Its use may save many a search in bulkier tomes. B. B.

MILK STANDARDS.

The following letter has been received from Dr. Thorpe by Mr. P. A. E. Richards, Public Analyst for St. Martin's-in-the-Fields:

Government Laboratory,
Clement's Passage, London.
November 2, 1899.

DEAR MR. RICHARDS,

In the early days of the working of the Food and Drugs Act, when it was necessary to have regard to the character of much of the milk supplied, which, although genuine, was, as regards its fat, of no very high quality, the "standard" was fixed at 2·5 per cent. of fat.

By the operation of the Food and Drugs Act, and the weeding out of certain classes of cows, there has been a gradual improvement in the general character of the milk-supply of the country, as was shown by the investigation undertaken by Dr. Bell shortly before his resignation, and published as a Local Government Board paper.

As a result of this inquiry, I raised the standard of fat in 1894 to 2·75 per cent.

The causes above alluded to have continued to operate, as shown by the evidence taken by the Committee which more recently reported on the working of the Food and Drugs Act. In consequence of this, and in view of the fact that under Section 4 of the new Act, which comes into force on January 1, 1900, a *presumption* of non-genuineness may be raised by the analyst should the amount of fat fall below a certain figure, whereas the onus of *proof* of the genuineness will fall upon the seller, I have felt justified in raising the limit to 3 per cent., and, as you may have noticed, this number has been given in recent certificates.

This limit is, however, not to be held to anticipate or prejudge in any way the regulations as to standards which the Board of Agriculture may issue under the section of the Act referred to.

Yours very truly,
(Signed) T. E. THORPE.

THE ANALYST.

JUNE, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, May 2, in the Chemical Society's Rooms, Burlington House. The President (Mr. W. W. Fisher, M.A.), occupied the chair.

The minutes of the previous meeting were read and confirmed.

Certificates of proposal for election to membership in favour of Messrs. J. R. Brooke, T. H. Lloyd, and G. H. Morris, Ph.D., were read for the second time.

Messrs. Thomas Eustace Hill, M.B., B.Sc., Thomas Macara, and William E. F. Powney were elected members of the Society.

The following papers were read: "The Composition of Milk and Milk Products," by H. Droop Richmond; "A New Colour Reaction for Citral and certain other Aromatic Compounds," by Herbert E. Burgess; and "On the Detection of Zirconia in the Presence of Thoria," by Otto Hehner.

THE DETERMINATION OF CARBON AND SULPHUR IN STEEL.

BY BERTRAM BLOUNT, F.I.C.

(Read at the Meeting, March 7, 1900.)

EXISTING methods in common use for the determination of carbon and sulphur in steel are curiously roundabout. The obvious course is to oxidize the whole mass of metal, so that all its constituents—iron, carbon, sulphur, phosphorus, manganese, and minor impurities—are brought to their highest state of oxidation consonant with the conditions, and to collect and separate those products which are volatile—viz., the oxides of carbon and sulphur. This method has been propounded with many elaborations for carbon. As a rule, the analytical description begins by requiring that the steel shall be reduced to fine powder to aid its combustion, a proceeding hopelessly impracticable in the case of mild, tough metal used for structural purposes, and sufficiently difficult with any grade of steel. An alternative plan is to remove the iron by volatilization in a stream of chlorine, which must be free from oxygen, and to burn the carbon thus disentangled from iron in oxygen. The difficulty of insuring the freedom of the chlorine from oxygen is the chief obstacle to the wider use of this method.

I have tried to work out a process for determining both carbon and sulphur by direct combustion of steel of all grades in oxygen. In this endeavour I have encountered certain difficulties which are not yet wholly overcome; but the work has reached a stage at which it may be usefully recounted. The process employed was extremely simple. The steel was heated in a porcelain tube in a current of oxygen, and the gaseous products absorbed and estimated by the usual means. As the method was intended for use in ordinary practice, no attempt was made to divide the metal finely; turnings or drillings, such as are commonly taken from a sample for analysis, were employed in all my experiments.

1. *Determination of Carbon.*—Various experiments were carried out to determine the conditions necessary to be observed in order to oxidize completely fairly thick fragments of steel, such as ordinary turnings or drillings. As it was an obvious advantage to work at a moderate temperature, the attempt was made to oxidize the steel at the temperature attainable in a porcelain tube heated by a good Fletcher combustion furnace. The temperature which can be reached thus may be taken as between 700° C. and 800° C. It was found that oxidation took place readily at first, but that the steel soon became coated with a layer of magnetic oxide so dense and adherent that the rate of oxidation rapidly fell off. This layer doubtless acts as a carrier of oxygen to the core of unoxidized metal; but the speed of translation of oxygen is so low that complete combustion cannot be effected in a reasonable time, and the process is impracticable. It is evident that the rate of oxidation would be greatly increased if the combustion could be effected in the presence of some flux which would slag off the iron oxide as fast as it was formed. A mere solvent flux such as boric acid would be useless, because the glass formed by it would protect the unoxidized metal even more effectually than the layer of magnetic oxide. The flux should be an oxidizing agent as well as a flux, and preferably one capable, not only of supplying, but of carrying, oxygen. Lead oxide fulfils these conditions; but, unfortunately, no ordinary material which can be used to make a boat will withstand the attack which it, or the lead reduced from it by the iron, may cause. Pending the construction of a boat of fused alumina or some similar material, the use of lead oxide as an oxidizing flux must be set aside.

Oxidation of the steel at a higher temperature was then tried. It was found that at a temperature of about 1,100° to 1,200° C. (well above the fusing-point of copper), such as can easily be attained in a small Fletcher lecture furnace, oxidation proceeded fairly fast, and for a quantity of 3 to 5 grammes of metal was usually complete in about one hour, reckoning from the time when the furnace became fully hot. The rate of oxidation was at first so rapid that the oxygen passing through the tube was almost completely absorbed; as soon as a crust of magnetic oxide had formed the rate naturally fell off. Occasionally there remained a slight core of metal, but analysis of this showed it to be free from carbon. The core had been decarburetted by a kind of reverse cementation.

Ultimately the method arrived at was as follows: 3 to 5 grammes of steel in the form of drillings or turnings, which may be quite thick,* are placed in a porcelain boat, and heated in a porcelain tube for at least one hour at a temperature of 1,100°

* Evidently, if thin turnings are available, they will present the advantage of oxidizing more rapidly.

to 1,200° C.—*i.e.*, to about as high a temperature as a good porcelain tube will bear. [The process of oxidation may be watched through a glazed spyhole by the use of the little device described in a paper of mine on "The Determination of Oxygen in Copper," ANALYST, xxi., 57]. The oxygen before it enters is purified by the usual train of absorption tubes, and the gases as they leave the porcelain tube pass through a glass tube kept at a dull red heat, and containing a column of copper oxide and one of lead chromate. This is necessary to insure the oxidation of small quantities of CO which might arise from a momentary defect of oxygen, and also to stop sulphur, which is the only element other than carbon in the steel yielding a gaseous oxide. Direct experiment has proved that no sulphur escapes from this tube into the absorption bulbs. The purified CO_2 is dried, absorbed, and weighed in the usual manner.

Now, although the advantages of this direct method over the usual lengthy process of dissolution in potassium cupric chloride, filtration and combustion of the residue are so manifest that their discussion would be tedious, yet there are certain difficulties and defects which arise, chiefly from the high temperature needed for oxidation. The life of the porcelain tubes is unduly short, and there is some risk of cracking in the course of an experiment. I am inclined to think that tubes—and, in fact, porcelain generally from the Royal Berlin porcelain factory—is now somewhat inferior to that which was made some years since; I have noticed many small signs of a lowering of quality. The necessarily high temperature of the air in the neighbourhood of a small but vigorous injector furnace makes the task of the absorption tubes unusually difficult, unless they are elaborately screened from radiation or kept at a distance; in the latter case the connections are inconveniently long. Lastly, it is almost a necessity for practical work that the blast of air should be obtained by power; the use of a foot-blower is too laborious, and the risk of unduly rapid heating is too great to allow of the ordinary bellows being conveniently employed. In my own case I use a Root's blower driven by a gas-engine for all such operations.

On account of these difficulties, which sometimes cause errors, I cannot recommend the method as being in its present state capable of replacing generally the older process; it is, however, useful as a completely independent method of checking a result which may appear to be in doubt. What is needed in order to make it generally applicable is some modification that will allow of the complete oxidation of the metal at a temperature not exceeding a moderate red heat—say, 800° C.

2. *Determination of Sulphur.*—This is the only other element commonly present in steel which, on the complete oxidation of the metal, yields a gaseous oxide. It seemed reasonable to suppose from general considerations that a fragment of steel heated in oxygen until fully oxidized would yield the whole of its sulphur as SO_2 (or partly as SO_3). Granting this, the estimation of the sulphur would be extremely simple, consisting merely in combustion of the steel in oxygen and reception of the products of combustion in any suitable absorbent. In my experiments I used apparatus similar to that employed for carbon. The steel, in the form of drillings, was heated in a porcelain tube to nearly 1,200° C. and a current of oxygen passed over it; the products of combustion were at once led into baryta-water. After the operation, the baryta-water, containing barium carbonate, sulphate, and sulphite in suspension, was

made acid with hydrochloric acid, saturated with bromine, and the resulting barium sulphate estimated in the usual way. But an unexpected difficulty arose. It was found easy to catch and estimate all the sulphur which was evolved as oxides, but quite impracticable to expel the last trace from the magnetic oxide left in the boat. As much as 20 per cent. of the total sulphur in the steel might thus remain; in what form it can be fixed is by no means clear. It would probably be feasible to expel this residual sulphur by fusion of the magnetic oxide with an acid oxide such as silica or boric anhydride but the proceeding would need an operation successive to and distinct from the combustion proper, and would so complicate the method as to destroy its chief ground for consideration. Moreover, it was found that any small fragment of unoxidized metal (which is harmless in the determination of carbon) means serious loss of sulphur, that element being segregated and gradually driven in towards the centre as combustion proceeds. The core, though small, may therefore contain a sensible proportion of the total content of sulphur.

These facts are well illustrated by the figures obtained in the following experiment: A mild steel containing 0·064 per cent. of sulphur was used; 10 grammes of this were oxidized; the sulphur passing into the absorption bulbs, that remaining in the crust of magnetic oxide and that remaining in the small metallic core (weighing 0·4075 grammes), were severally determined. The results are appended:

	Per Cent.	
Sulphur volatilized	0·006	
Sulphur from magnetic oxide ...	0·041	Calculated on the original steel.
Sulphur from metallic core ...	0·017	
Total sulphur...	0·064	

This particular experiment was stopped at a point when there was still a sensible weight of unoxidized core. Had it been proceeded with until oxidation was complete and the whole mass of magnetic oxide had been strongly heated for some hours, no doubt the bulk of the sulphur would have appeared in the absorption bulbs. Even then, however, an appreciable fraction would have remained with the magnetic oxide. The large quantity of sulphur left in the core becomes more evident when it is calculated on the weight of the core itself; in this instance it amounts to 0·4 per cent.

These facts go to show that, whereas the method which I have indicated may prove useful and, with some modification, convenient for the determination of carbon in steel, the corresponding method for sulphur is not likely to be found practically available.

Discussion.

Mr. Allen said that the greater number of the steels with which he had to deal contained chromium and nickel, constituents which were not taken into account in the author's investigation, but which probably would not interfere with the success of the method proposed. As a check upon the usual method of dissolving the metal in ammonio-cupric chloride and burning the carbonaceous residue, a method based on direct combustion of the steel itself would have many advantages. The chlorine method was a good one, but, as had been pointed out by the author, the chlorine must be free from oxygen, and dry, which constituted the great difficulty of the

method. He once tried to avoid this difficulty by using bromine, which could easily be obtained dry and free from oxygen. He understood that Mr. Archbutt had successfully used chromic acid for oxidizing the carbon, but he (Mr. Allen) had not been able to get sufficiently good results with this process. The method of dissolving the iron in cupric chloride was perhaps the one most suited for practical work, and if a simple direct combustion process could be satisfactorily turned to account for checking purposes, it would be of considerable value.

Mr. ARCHBUTT said that he had tried the method of direct combustion at a red heat, but had abandoned it as being too cumbrous. The chief difficulty of Mr. Blount's method, he imagined, was to find apparatus that would stand the very high temperature. He had long ago abandoned the chromic acid method because it also was too tedious, although it was sufficiently accurate if proper precautions were observed. His present method was to dissolve the steel with the double chloride of copper and potassium, burning the residue in oxygen. Results were obtained rapidly, and duplicates were very close; but it was desirable to have an alternative method based on a different principle, by which the results could be checked. The only really reliable method of determining sulphur in steel was by oxidizing the steel with aqua regia, and precipitating the sulphur with barium chloride.

Mr. ALLEN said that his difficulty with the chromic acid method had not been that it was too tedious, but that the sulphuric acid used for dissolving the chromic acid was liable to dissolve carbon dioxide.

Mr. BEVAN suggested that a correction might be obtained for this once for all by determining the quantity of carbon dioxide dissolved by the sulphuric acid in a blank experiment.

Mr. ARCHBUTT said that as, when the carbonaceous matter was placed in a flask with chromic acid, a much larger quantity of oxygen was evolved than was necessary for oxidizing the carbon, he would have expected all the carbon dioxide to be driven off. Besides, it was customary to aspirate air through the flask and tubes after the combustion was complete.

Mr. ALLEN said that he had been anxious to measure the carbon dioxide in the nitrometer instead of weighing it. It was not possible to blow air through, but the chromic acid mixture was heated until oxygen was evolved, and the carbonic acid was absorbed. The difficulty, however, caused by the solubility of the carbon dioxide in sulphuric acid prevented the satisfactory working of the process in this way.

Mr. JENKINS observed that in such a method of determining carbon, if the combustion were carried out at a lower temperature, the core of metallic iron remaining would presumably still retain some carbon: and the difficulty would be to insure, in the case of any metallic core left after combustion, that it no longer contained any carbon.

The PRESIDENT suggested that the sulphur collected in the core might perhaps be obtained by cracking the core and picking out the middle, somewhat in the same way in which the nodules of sulphide of copper were extracted from burnt pyrites.

Mr. BLOUNT said that the segregation of the sulphur in the manner described was a phenomenon of quite general occurrence; as the crust of oxide was brittle, it

was of course possible to separate the core mechanically, and to oxidize it separately, but the process would cease to be a simple one, and there would still remain the obstacle that the sulphur lurked to a comparatively enormous extent in the crust, which was a fully oxidized product. If a core were left in the carbon process, there would of course always be room for some doubt, though it did not follow necessarily that carbon was left behind. But he did not propose so to limit the process that any core remained; properly there should be no core. He would have thought that the simplicity of the use of bromine mentioned by Mr. Allen would have balanced any disadvantages which might have attended it.

Mr. ALLEN said that the experiments with bromine had been made a good many years ago, when the question of rapidity of working was not of so much consequence as at present; but as a volatilizing agent, which could be easily insured to be dry and free from air, bromine would certainly seem to be worth considering.

Mr. BLOUNT, continuing, said that 1,200° C., although appreciably above the melting-point of copper, was by no means an impracticable temperature. A good porcelain tube would certainly stand it, and the only serious difficulty was that porcelain tubes had lately been of indifferent quality and liable to crack. He was quite of Mr. Archbutt's opinion that the aqua regia method was the only one of any practical utility for determining sulphur in steel.

MAIZE OIL.

By ROWLAND WILLIAMS, F.I.C.

(*Read at the Meeting, March 7, 1900.*)

THIS oil has attracted a considerable amount of attention during the last few years, and its properties have been investigated by several well-known chemists. Among others, Archbutt has published an interesting paper on the subject (*Jour. Soc. Chem. Ind.*, vol. xviii., p. 346). Maize oil is, I understand, largely used in the manufacture of soap, especially of soft-soap, and I am informed that it is also employed in the United States for making paints and varnishes.

It was, indeed, as a possible drying oil that maize oil was first brought under my notice, and during the last two or three years I have examined a good many samples of the oil, both analytically in the laboratory and also practically on a larger scale, with a view to determine whether its drying properties are sufficiently marked to enable it to be used, either partially or entirely, as a substitute for linseed and other drying oils.

According to Lewkowitsch ("Oils, Fats, and Waxes," p. 372), "Maize oil is, notwithstanding its high iodine value, almost devoid of drying powers. No decided drying properties are imparted to it by subjecting it to the process of 'boiling,' or by addition of lead oxide. If, however, a current of air is passed through it at 150° C. [? for how long], it will, on addition of manganese borate, acquire to a small extent drying properties, and a thin film on lead dries in ten to twenty hours, but not completely." My own experiments have led me to the conclusion that, although maize

oil does possess drying properties to a certain degree, which may be increased by suitable treatment, it is not at all likely to take the place of linseed and similar oils in the manufacture of paints and varnishes.

One advantage claimed for maize oil is the comparative paleness of a film of the oil when dry, in consequence of which it is said to be more suitable than linseed oil for mixing with white and delicate pigments in general; but I have not found its slight superiority in this respect to counterbalance its undoubted disadvantage as regards slowness of drying.

I find that a thin layer of maize oil (about ½ gramme), when heated on a watch-glass to 100° C. for some considerable time, gradually increases in weight for perhaps twenty-four hours, after which it usually begins to lose slowly, until at the end of three or four days the weight is generally less than that originally taken. The maximum increase in weight does not, as a rule, exceed 1·5 per cent., whereas good linseed oil under similar conditions will generally gain at least 4 per cent.

On heating in the way described above maize oil thickens slowly, and eventually becomes solid if the oil is of good quality and the heating is continued long enough (usually two or three days); but the film thus obtained is inferior in many respects to a linseed-oil film.

In the following table I have recorded some of the figures obtained in the examination of several samples of maize oil. These were procured from most reliable commercial sources, and I have no reason to doubt their genuine character:

	Specific Gravity (15·5° C.).	KOH Absorption, per Cent.	Free Fatty Acids (as Oleic), per Cent.	Bromine Thermal Value, ° Centigrade.	Iodine Value.		Unsaponifiable Matters, per Cent.
					Hübl (15 hours).	Wijs (15 minutes).	
No. 1	·9252	18·88	3·50	23·7	123·97	124·74	1·46
No. 2	·9268	19·07	3·02	24·4	127·27	127·48	—
No. 3	·9244	18·96	3·18	23·3	122·57	123·54	1·71
No. 4	·9256	18·62	3·64	23·4	127·36	128·02	—
No. 5	·9284	19·00	2·39	23·3	120·85	122·21	—
No. 6	·9246	18·79	1·52	23·3	125·56	126·62	—
No. 7	·9262	18·74	1·50	23·2	121·99	122·68	1·66
No. 8	·9248	18·81	2·27	23·5	123·98	125·05	—

It will be observed that the iodine value was determined by Wijs' as well as by Hübl's solution, with essentially the same results.

The bromine value of three of the samples was also determined by the bromine absorption method described by McIlhiney (*Jour. Amer. Chem. Soc.*, December, 1899). The figures obtained were about 2 per cent. lower than the theoretical bromine values calculated from the iodine values.

Discussion.

The President having invited discussion,

Dr. Lewkowitsch said that he was not altogether responsible for the passage which the author had quoted. It was, in fact, itself a quotation from the original paper of Smith. It would have been interesting to ask the author whether he had examined the unsaponifiable matter. Recently, by American chemists, the unsaponi-

fiable matter of maize oil had been variously stated to consist of cholesterol and of phytosterol, but, as a matter of fact, the unsaponifiable matter of vegetable oils had been shown invariably to consist of phytosterol, and that of the animal fats and oils to consist of cholesterol. To admit, therefore, the presence of cholesterol in maize oil would be to upset a classification which was well founded on observations. According to his experience, such an admission would be erroneous.

Mr. ALLEN observed that the percentages of unsaponifiable matter were very high as compared with those of most vegetable oils.

Dr. LEWKOWITSCH said that a high percentage of unsaponifiable matter was one of the special characteristics of maize oil.

Mr. ARCHBUTT said that the question of whether maize oil was capable of being satisfactorily blown had recently been tested for him on a practical manufacturing scale, and the result was to show that it yielded an excellent blown oil without any difficulty whatever.

ON THE ASSAY OF CREOSOTE.

BY A. D. HALL, M.A.

(*Read at the Meeting, March* 7, 1900.)

BEING not infrequently called upon for advice as to the most suitable kind of creosote for the preserving of hop-poles and other kinds of timber used agriculturally, I was led to examine a number of different samples of creosote in commerce. The authorized method for the examination of creosote, introduced, I believe, by Dr. Tidy, seemed to afford considerable scope for improvement, and, after some experiment, I have adopted the following method as more rapid in execution and less liable to errors of manipulation:

1. The creosote in bulk is warmed, and well mixed till all crystals of naphthalene, etc., are dissolved.

2. A portion is dipped out into a measuring glass marked at 100 c.c., and thence transferred to the distilling flask. The glass is rinsed out with 5 c.c. of benzene, which is added to the flask. For the distillation I prefer to use a nickel flask, holding about 500 c.c., as a glass flask can rarely be used a second time.

3. To the flask is connected by a cork a straight glass tube of $\frac{1}{2}$ inch bore about 2 feet long, which serves as a condenser. A thermometer reading to 350° also passes through the cork.

4. The condensing tube passes into the receiver, a cylindrical separator of about 300 c.c. capacity, stoppered at the top and terminating in a tap at the bottom. The cylinder is graduated from the tap upwards.

5. The distillation is begun gently, then pushed till a temperature of 325° C. (600° F.) is reached, and maintained till no further distillate passes over. It may be necessary from time to time to warm the condensing tube to prevent it blocking with naphthalene.

6. When no more comes over, the volume of distillate is read off in the receiver, 5 c.c. is deducted for the benzene used, and so the percentage of "residue non-volatile at 600° F." is obtained.

7. To the receiver 100 c.c. of caustic soda solution are now added (alkali of specific gravity 1·2 is specified in the old method, but there is no objection to the use of the alkali of specific gravity 1·3, commonly used for ammonia distillations). The mixture is well shaken and put in a water-oven for an hour at least, being well shaken from time to time. Finally, it is allowed to stand till cool, the volume read, and the greater part of the caustic soda solution is drawn off by the tap. There will be more than 100 c.c., owing to the phenols absorbed.

8. The caustic soda solution is boiled for a few minutes, to expel any traces of hydrocarbon, etc., it may retain, and allowed to cool. When cold, 10 c.c. are withdrawn by a pipette, and run into the bottle of a Leffmann-Beam centrifugal milk apparatus; dilute sulphuric acid is added carefully till the alkali is neutralized and the so-called "tar acids" are liberated, then the bottle is whirled for a few minutes in the machine, allowed to cool, and the quantity of "tar acids" in the neck of the bottle read off. A preliminary calibration of the divisions on the neck of the bottle is, of course, necessary to obtain their value in c.c. From these data the percentage of "tar-acids" in the original creosote is calculated.

9. To the contents of the receiver 100 c.c. of dilute sulphuric acid (1 : 5) is now added, and the heating and shaking of 6 is repeated. The contents of the receiver are allowed to cool, and the volume of the acid extract is read off (it is greater than 100 c.c., because some of the caustic soda solution was not drawn off). Ten c.c. of this are pipetted off into a Leffmann-Beam bottle, the "tar bases" liberated by alkali, and their volume measured after whirling, just as in the last operation. After correcting for the volume of the acid solution, the proportion of "tar bases" in the original creosote is calculated. The "tar bases" sometimes solidify, making it difficult to read their volume with accuracy.

The disadvantages inherent in the old process are the necessity of complete separation of the oil from the caustic soda solution and of the "tar acids" after acidifying, and the filtration of the latter through asbestos. By taking an aliquot part of the soda solution, the losses inevitable in the attempt to collect the whole of the "tar acids" are avoided, while the use of the small bottle and the centrifugal method enables the "tar acids" to be separated and measured with accuracy and speed. The ease of the method also enables the "tar bases" to be estimated, which is desirable, because of their preservative power. In the old method the distillate, etc., has to be transferred from vessel to vessel four times before it is actually measured as "tar acids"; in the method suggested there is no such transference of a liquid that has to be finally measured.

Example.

Readings :		
Distillate	66 c.c.	67·5 c.c.
Volume of soda solution	110 ,,	110 ,,
"Tar acids" in bottle	47 ,,	47 ,,
Volume of acid solution	103 ,,	100 ,,
"Tar bases" in bottle	15 ,,	10 ,,
Calculated :		
Residue non-volatile at 600° F.	39 per cent.	37·5 per cent.
"Tar acids"	9·3 ,,	9·3 ,,
"Tar bases"	2·8 ,,	3·2 ,,

It may not be out of place here to give a brief account of some experiments instituted to ascertain in which constituent of the creosote its preservative power mainly resides, as no sound information seems to be available on the point. The "tar acids" are always referred to in creosote specifications, and they have been supposed to act by combining with albuminoids in the wood; others, again, lay stress on the injection of the heavy oils into the pores of the wood, thus mechanically preventing the entry of water, and therefore of decay; while, again, I find many users of hop-poles prefer "creosote salts," which consist practically of naphthalene.

It was decided to institute some experiments to throw light on the relative preservative powers of the various constituents of ordinary creosote, and the first trial was carried out by Mr. H. H. Cousins, M.A., of the South-Eastern Agricultural College at Wye, upon a good sample of hemp-string, which had an average breaking strain when fresh of 33 pounds.

Lengths of this string were soaked in various extracts from creosote and other pure materials, as set out below, at a water-bath temperature; the string was partly buried for two months in ordinary garden soil, dug up, and its strength redetermined.

The results set out in Table II. gave a low value either to pure phenols or the homologous phenols extracted from commercial creosote by alkali; naphthalene was little better; while the non-volatile portion of the creosote, the "tar bases" extracted from it by acid, and the bone oil, which is rich in similar bases, had preserved the string. It does not, however, follow that string will behave in the same way as wood, and other experiments were begun upon wood. In one set small blocks of wood, sawn transversely to the grain, were soaked for half an hour in 5 per cent. solutions in benzene of the constituents to be tested, the solutions poured off, and the blocks dried. One of my colleagues, Professor J. Percival, then seeded each block with a pure culture of penicillium and also with fragments of rotting wood; the blocks were kept in a moist chamber in the dark. The experiment, however, did not succeed; most of the substances entirely inhibited the growth of penicillium, etc., though the wood was repeatedly seeded, and even streaked over first with a nutrient medium.

In the other trial a series of small rods of deal were carefully selected; they were 8 inches long by $\frac{3}{8}$ inch square, and were soaked in the various materials for one and a half hours at a temperature of 90° C. They were then buried in about three-quarters of their length for ten months in ordinary garden soil, taken up, washed and slowly dried, and then broken transversely under similar conditions, with the result set out in Table III.

The results show that the creosote itself, and particularly the non-volatile constituents, had considerable preservative power, as also had the bone oil; the tar "acids" and "bases" had a real but smaller preservative power; but pure cresol had little or none.

As far as the experiments go, they seem to show that the preservative action of creosote lies in its power to fill the cells of the wood with a fixed moisture-resisting material rather than in any chemical antiseptic action; the preservative qualities of cresol and naphthalene are small, for thin pieces of wood at any rate, because the one evaporates and the other dissolves, leaving the wood open to attack. It also

seems desirable in the commercial examination of creosote to estimate the pyridine "tar bases" and rate them as of equal preservative value to the "tar acids." Further experiments on large pieces of wood are in progress, which I hope to lay before the Society at some future time.

TABLE II.

Breaking Strain of String after Two Months' Exposure (original Breaking Strain, 33 Pounds).

Treatment.	Condition.	Breaking Strain, Pounds.
Untreated	Rotten	0
With "tar acids"	Rotten	0
volatile distillate from creosote ...	Rotten	0
phenol	Rotten	0
cresol	Rotten	0
naphthalene	Partly rotten	3
"tar bases"	One in six rotten	16
bone oil	Sound	18
non-volatile residue from creosote	Sound	16
creosote in the cold	——	4
same creosote, hot	——	13

TABLE III.

Breaking Strain (transverse) of Deal Rods exposed Ten Months (original Breaking Strain, 630 Pounds).

Treatment.	Condition.	Breaking Strain, Pounds.
Untreated	Much decayed ...	... 300
"Tar acids"	A little decayed ...	... 430
"Tar bases"	Surface good ...	... 360
Naphthalene	Surface decayed, sound within	... 410
Non-volatile residue	Sound	... 570
Animal oil	Surface fair ...	... 440
Creosote	Sound	... 470
Cresol	Much decayed ...	... 230

DISCUSSION.

The PRESIDENT having invited discussion,

Dr. LEWKOWITSCH said it seemed very probable indeed that the alkaline solution would contain some proportion of the bases, which it would be important to collect and duly take into account in the analysis.

Mr. BLOUNT said that while the methods described in the paper were certainly more refined than the older ones, nevertheless the latter, when properly worked, yielded equally satisfactory results. The practical experiments of the author seemed to indicate that one of the constituents which engineers were most careful to exclude from creosote—namely, the heavy oils—possessed considerable preservative value for wood.

Dr. DYER desired to join in thanking Mr. Hall for a very interesting paper. The

latter part of the paper confirmed the views held by the late Dr. Tidy, who used to maintain that a high percentage of tar acids was by no means a necessary index of the preservative properties of creosote. Specifications used to stipulate that not more than a certain proportion of non-volatile matter should be left after distillation at 600° C.; but Dr. Tidy exactly reversed this, maintaining that at least a certain proportion of non-volatile matter ought to be present. With regard to the determination of the tar acids, he (Dr. Dyer) would like to hear whether Mr. Hall had tried, after exhausting with a large quantity of alkali, subsequently exhausting with repeated small quantities. The usual process was to exhaust with repeated small quantities of alkali, probably for the reason that, although carbolic acid (or phenol proper) dissolved in alkali of any strength, yet the higher acids—cresols, etc.—were singularly capricious, being liable, while dissolving in a certain volume of alkaline solution, to separate out if the volume of solution were increased.

Mr. ALLEN said that cresol, the immediate higher homologue of phenol, dissolved readily in a solution of sodium cresylate, so that, if there was sufficient alkali to form sodium cresylate, it would stand dilution without separation, while if there was an insufficient quantity of alkali, the cresol dissolved in it if it was strong, being thrown out of solution on dilution. If sufficient alkali were used, the various tar acids would all dissolve, but not with equal facility. It was a case of fractional neutralization, the phenol going first, as the stronger acid. But if too much alkali were used, probably some of the hydrocarbons would go into solution as well. Creosote was very largely employed for the preservation of timber-piles, piers, etc., exposed under water, which in the tropics were destroyed very rapidly owing to the action of the teredo and other worms. A method was much to be desired for the determination of acridine, which was probably the constituent most objectionable to such animal pests.

Mr. CHAPMAN suggested that the use of cork in place of wood in laboratory experiments such as those which the author had made would probably lead to more conclusive results, owing to the greater readiness with which cork would be penetrated by fungoid growths. The difficulties experienced in determining phenols by extraction with alkaline solutions were also met with in the analysis of essential oils containing phenolic bodies. In the case of clove oil, for instance, the determination of eugenol by treatment with caustic potash solution was vitiated owing to the sesquiterpene, caryophyllene, being also appreciably soluble in the alkaline liquid. With regard to the statement as to the non-occurrence of albuminoids in wood, it was, he thought, a very general belief that, but for the presence of those substances in the wood, the cellulose would undergo little or no change.

Mr. ARCHBUTT said that the author's experiments confirmed the conclusions arrived at by Mr. Boulton, and embodied in a paper read by him before the Institution of Civil Engineers in 1884. Mr. Boulton brought forward a good deal of evidence to show that the value of creosote oil for preserving timber lay in the higher and less volatile fractions, and especially in the tar bases, much of this evidence being based on the experiments of the late Dr. Tidy. That paper led to the abandonment of the late Dr. Letheby's specification, in which the phenol was regarded as the most important constituent, and the substitution for it of Dr. Tidy's specification, in which

a certain proportion of less volatile constituents was required, the exact percentage of phenol being of less importance. Personally he had found no difficulty in using a glass retort over and over again, provided that the distillation was not carried to coking. The advantage of using very strong soda was that, when the soda was mixed with dilute sulphuric acid, a supersaturated solution of sodium sulphate was produced, in which the phenols became insoluble, so that the whole of the phenols were thrown out on adding excess of acid. For removing neutral oils and naphthalene dissolved in the soda, filtration through asbestos had been recommended by Dr. Tidy, but he (Mr. Archbutt) had found it simpler to shake the caustic soda solution with ether. In estimating the tar bases he had adopted the method of distilling a separate portion down to coking and shaking with dilute sulphuric acid. The acid liquid is then evaporated to a small volume, and the bases are thrown up by adding pieces of solid stick soda or potash.

Mr. HALL said that he had a good many times tried the effect of boiling the caustic soda solution, comparing the quantities of tar acids obtained with boiled and unboiled solution ; but he had never found any notable difference, though it was possible that differences might occur in some samples, and therefore he had suggested the boiling of the solution as a precaution. He had occasionally tried, after removing everything possible by means of alkali, what could be obtained by means of acid. The effect of second and third extractions with alkali had been tried, but as far as his experience went a single treatment with alkali extracted all the phenolic substances. With regard to the question of the presence of albuminoids in wood, it was very hard to say that anything quite of the nature of an albuminoid existed in wood, but the analogy had been pressed strongly that the preservative power of creosote was due to the sort of antiseptic action which carbolic acid, for instance, had upon a substance like true albumen, namely, coagulation. There was nothing in wood exactly equivalent to true albumen, coagulable by phenol. It was the starch always that was affected. Decay was always quickest in fresh sap wood, where the cells contained a good deal of starch. He had been trying to ascertain how far the fungi penetrated the treated wood, but could not get the fungus to start into the wood except in one case, when it had been saturated with cresol, though where the other materials mentioned were present the growth was arrested at the surface.

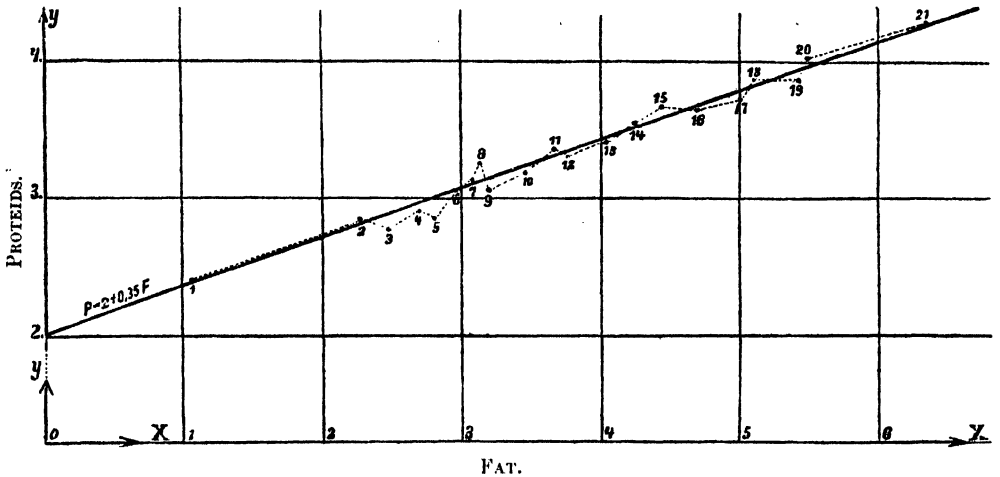
FOODS AND DRUGS ANALYSIS.

The Influence of Certain Alcohols, Acids, and Sugars on the Digestion of Proteids by Pepsin and Trypsin. E. Laborde. (*Journ. farm. Chim.*, 1899, x., 484-488.)—In his comparative experiments on this subject the author digested a definite quantity of coagulated egg albumen with acid pepsin or alkaline trypsin in the presence of 50 c.c. of a 20 per cent. and 5 per cent. solution of the given alcohol, and also as a check with the enzymes in 50 c.c. of water. The flasks were kept at a temperature of 40° C. for four hours in the pepsin digestions, and for three hours in the trypsin digestions, and at the end of those periods the amount of albumoses and peptones in the filtered liquids was determined by precipitating the former with ammonium sulphate and estimating the organic nitrogen in the solution before and after removal of the albumoses.



In the experiments with pepsin it was found that isobutyl alcohol, glycerol, and malic acid favoured the digestion when present in small quantity, whilst methyl alcohol appeared to have a very slight accelerating influence. On the other hand, the digestion was markedly retarded by the presence of ethyl and propyl alcohols, by lactic and tartaric acids, and by mannitol and glucose.

In the case of trypsin the activity of the enzyme was accelerated by methyl and isobutyl alcohols, by glycerol, and by glucose, and retarded by ethyl and propyl alcohols, by lactic, malic, and tartaric acids, and by mannitol. C. A. M.

The Ratio between Proteids and Fat in Milk. H. Timpe. (*Chem. Zeit.*, 1899, xxiii., 1040.)—In Table I. (p. 158) are given the analytical results obtained on examining milk derived from cows of different breeds and different localities, the samples being placed in order according to the amount of fat they contain. These figures bring to light various relationships between the several constituents in the normal secretion which are apt to be overlooked when the milk of only one description of cattle is tested, since the composition of the liquid produced by each breed is too uniform to show these ratios distinctly. Calculated per 100 parts of total solids, it will be seen that the sugar varies inversely with the fat, so that within certain limits the proportion of sugar plus fat is constant. The ash (calculated on the solids) also decreases as the fat rises, so that, with five exceptions, the value sugar divided by ash is always between 6·04 and 6·84. On the other hand, the amount of proteids (calculated on the solids) is remarkably uniform: the largest difference among the fats is 27·43 per cent.; among the sugars, 22·92 per cent.; but among the proteids it is only 2·88 per cent., and even the ash varies within wider limits. Therefore per 100 parts of total solids the amount of fat, sugar, and ash together is essentially constant. This fall in sugar and ash as the fat rises, when calculated on the solids, finds a simple explanation if the two former ingredients remain practically the same, however the fat varies, when the calculation is made upon the original milk. The table shows signs

of this: the fat in No. 21 is 520 per cent. of that in No. 1; the greatest increase in sugar is only 13 per cent., and that in ash 26 per cent. of their lowest proportions respectively. In contradistinction to the fat, therefore, it may be said that the amount of sugar and ash in milk is roughly constant.

Matters are different in the case of the proteids. If these were constant in amount in the milk itself, they should fall, like the sugar and ash, as the fat rises when calculated on the solids. It appears, however, that they are remarkably constant in the total solids; therefore they must increase (calculated on the milk), though on a far smaller ratio, with increases in the fat. Although there is no ratio between the percentage of proteid and of fat in the milks, there is a distinct ratio

between their several variations; for it will be observed that when the latter rises 5·36 per cent., the former rise 1·89 per cent., which is roughly 3 : 1; and this ratio obtains not only between the extreme samples, but also practically throughout them all. It is evident, therefore, that the ratio may be expressed by the formula $P = a + bF$, where P is proteid, F fat, and a and b two constants. From Table I. a is shown to equal 2, b to equal 0·35; and the formula thus becomes:

$$P = 2 + 0{\cdot}35F.$$

The figures in column 8 record the amount of proteid calculated from the fat by this formula, and column 9 gives the differences between the theoretical and analytical results. The coincidence is brought out more clearly in the accompanying diagram, where the thick line marks the theoretical value of P. The maximum difference is ±0·12 per cent.; only in three cases does it exceed ±0·08 per cent.

It may also be imagined that the proteids are divisible into two classes, α and β. The β-proteid perhaps is formed from the same original substance which yields the fat, and the ratio β-proteid : fat equals 0·35 : 1. The α-proteid is produced independently of the fat, and is present constantly in the proportion of 2 per cent. Thus, it may be said generally that ash, sugar, and α-proteid are approximately constant in normal milk; β-proteid and fat vary in the ratio mentioned.

These observations apply only to the milk of healthy cows fed with normal food;

illness and exceptional feeding lead to different results. In Table II. (p. 159) are collected various more or less abnormal milks. Nos. 1 to 3 are from stall-fed cattle; Nos. 4 to 8 from experimentally-fed cows; No. 9 is not described; Nos. 10 to 12. represent the milk of a cow suffering from foot-and-mouth disease; No. 13 onwards record the history of a Simmenthal cow ill, and recovering, from a severe attack of gastric catarrh ("Magenkatarrh"). [The ash figures are omitted; they appear unaffected except in Nos. 10 to 12, where they stand at 1·01, 0·88, and 0·90 per cent. respectively.] With the exception of No. 9, special feeding has caused the amount of proteids to be less than the theoretical—that is to say, has produced an excess of fat, which is the more noticeable seeing that the fat and one portion of the proteids have a common origin. This increase of fat must therefore be regarded as abnormal, if not pathological—a view which is strengthened by the phenomena of foot-and-mouth disease and gastric catarrh in its acute stages (Nos. 10 to 16). The sudden change from a deficiency to an excess of proteids on the fourth day of the latter ailment may be explained by the complete alteration in character of the milk during disease, which causes the ordinary ratios to be no longer valid; by November 6, when the catarrh had disappeared and only the animal's body-weight was still reduced, the secretion may be said to have become normal again. It should be noticed that, with five exceptions, even when the cows were ill, the amount of sugar remained within its proper limits of 4·4 to 5 per cent. This matter is of great importance in the valuation of milk samples.

To show that the ratio of fat to proteids is a constant, and is affected only by disease or by sudden changes in the conditions of life, but not by the influence of the food itself, some experiments made by Landbeck may be quoted. Three cows were fed specially during four periods of twenty days with a diet rich in proteid and fat. The proportions of the latter in the food were higher during the second period than during the first, higher during the third than during the second; during the fourth they were the same as at first. Each period was divided into a preliminary and a second stage of ten days each (the food being the same in both stages of the same period). One of the cows remained practically constant in weight throughout the whole experiment, having so good a constitution as not to be deranged by the sudden alterations in diet. The analyses of its milk were as follows:

		Proteids.		
	Fat.	Found.	Calculated.	Difference.
Period I., first stage	4·20	3·13	3·47	−0·34
second stage	4·10	3·40	3·44	−0·04
Period II., first stage	4·29	3·33	3·50	−0·17
second stage	4·15	3·44	3·45	−0·01
Period III., first stage	4·52	3·49	3·58	−0·09
second stage	4·29	3·51	3·50	−0·01
Period IV., first stage	4·35	3·43	3·52	−0·09
second stage	4·32	3·45	3·51	−0·06

It will be evident that it was the sudden changes in food, and not the food itself, which affected the ratios, for otherwise the "differences" which rose at each alteration would have remained of the same dimensions during the second stage of each period. The other two cows gained in body weight during the investigation, and their milk was constantly abnormal,

Inasmuch as commercial milk is always a mixed product derived from a large number of cows, the disturbing influence on the ratio of proteids to fat which is produced by the stall-feeding of a few individuals is practically eliminated; and it may be said that the difference (D) between the proteids obtained by analysis and by calculation (calculated amount deducted from that recovered by analysis) in such mixed milk will scarcely ever exceed ±0·06 per cent. The factor thus becomes of great value in judging the quality of ordinary milk samples; and the effect of the various methods of sophistication may consequently be studied.

Removal of Cream.—If cream has been removed from a milk, D becomes positive, while sugar and ash remain normal. When, for example, milk No. 11, Table I., was skimmed till it contained only 3·02 per cent. of fat, it gave on analysis 11·74 per cent. of total solids, 4·63 per cent. of sugar, 0·74 per cent. of ash, and 3·35 per cent. of proteids. The theoretical proteids were 3·01 per cent., therefore D equalled +0·34. From the amount of proteids found, the original proportion of fat (or the degree of fat removal) could be calculated by the formula $F = \frac{P - 2}{0{\cdot}35}$, and gave 3·85 per cent.—an error of 0·13 per cent.

Addition of Water.—When the proportion of fat falls through natural causes, the β-proteids are reduced correspondingly, while the α-proteids remain unaltered; but if water is added, all the constants are lowered, and their ratios one to another are the same as in whole milk. Addition of water thus causes D to be negative. A negative D, however, by itself does not prove addition of water; it is necessary to consider the proportion of sugar and ash. By adding fat to a skimmed milk, a negative D is produced, the fat and sugar remaining normal; dilution with water would diminish the percentage of the latter bodies as well. On mixing 100 c.c. of milk No. 11 with 20 c.c. of water, the following figures were obtained: 10·37 per cent. of total solids, 3·13 per cent. of fat, 3·84 per cent. of sugar, 0·63 per cent. of ash, 2·77 per cent. of proteids by analysis, 3·10 per cent. by calculation, D being accordingly −0·33. By using the formula $\frac{-D \times 100}{P - 0{\cdot}35\ F}$, the amount of added water could be deduced, and gave 19·7 c.c.

Removal of Cream and Addition of Water.—Detection of this method of sophistication is more difficult, but in the majority of cases it can be effected with certainty. As the former process yields a positive D and the latter a negative one, if the exact amount of water is added which compensates for the removal of fat, D remains at its proper value; but as the quantity of fat removed cannot be ascertained except by analysis, it is impossible for a milk-dealer to know how much water to add, and probably D will be either too high or too low. If, however, the two processes were carried out successfully, so that D gave no sign, the deficiency in ash and sugar would be apparent. Only if the degree of dilution were so small that the percentage of sugar remained above the minimum would detection be impossible; but if the analytical results are recalculated to a basis of an average sugar-content, the figures for fat and proteids so obtained will show the removal of cream. For example, Milk No. 11 was skimmed and mixed with one-sixth its volume of water. On analysis it showed 10·36 per cent. of total solids, 2·93 per cent. of fat, 3·93 per cent. of sugar, 0·64 per cent. of ash, 2·86 per cent. of proteids (found), 3·03 per cent.

by calculation. D was equal to −0·17, for too much water had been used, the presence of which was also indicated by the lowness of the sugar. Recalculating to a basis of 4·7 per cent. of sugar, the fat was 3·50 per cent., and the proteids 3·42 per cent. Calculating the proteids from the 3·50 per cent. of fat gave 3·23 per cent., D being +0·19. This proved the removal of cream. By the formulæ given above, the added water was represented to be 19·6 (instead of 16·7) c.c., and the original proportion of fat to be 4·05 (instead of 3·72) per cent. Therefore the falsification can not only be detected, but even estimated with some degree of accuracy—at any rate, more safely and conveniently than by "an appeal to the cow."

In practice the following cases have to be considered: (1) Sugar and ash normal. If D is less than ±0·06, manipulation cannot be detected. If D exceeds +0·06, cream has been removed, the original amount of fat being $\frac{P-2}{0{\cdot}35}$. If D exceeds −0·06, the milk has been loaded with cream. (2) Sugar and ash at or below the minimum. The amounts of fat and proteids are recalculated to the normal basis of 4·7 per cent. of sugar, in order to yield their respective proportions before addition of water. If then the recalculated D is approximately correct, only water has been added; if D is positive, cream has been removed as well, and the magnitude of the sophistication can be ascertained as above.

[Judged solely on these rules, the average normal morning milk quoted by Richmond (ANALYST, 1899, xxiv., 199) would appear as though it had been partly skimmed, for it gives D = +0·226; the evening milk gives D = +0·025, and accordingly would be regarded as genuine. Even if the morning and evening figures are combined, D = +0·125, and the mixed milk would be regarded as skimmed.—ABS.]

ORGANIC ANALYSIS.

Iodometric Determination of Small Quantities of Carbon Monoxide. **L. P. Kinnicut and G. R. Sanford.** (*Journ. Amer. Chem. Soc.*, vol. xxii., pp. 14-18.)—The apparatus used is a modification of that employed by Nicloux. Twenty-five grammes of purified iodine pentoxide are placed in a small U-tube, supported in an oil-bath at 150° C., and connected to a Wolff blood-absorption tube containing 0·5 gramme of potassium iodide in 5 c.c. of water. The air to be examined is freed from unsaturated hydrocarbons, hydrogen sulphide, sulphur dioxide, and similar reducing gases by passing it through U-tubes containing sulphuric acid and solid caustic potash respectively, and is then passed through the iodine pentoxide tube, the liberated iodine being retained in the Wolff tube and estimated by $\frac{1}{1000}$ N sodium thiosulphate. The rate of flow of the air-current is regulated by dry mercury to about ½ litre per hour. The method will detect as little as 0·0025 per cent. by volume of carbonmonoxide in air. C. S.

The Separation of Formic, Acetic, Propionic, and Butyric Acids by Haberland's Method. **J. Schütz.** (*Zeit. anal. Chem.*, 1900, xxxix., 17, 18.)—The method of separation proposed by Haberland (*Zeit. anal. Chem.*, 1899, 217) consisted in liberating the acids by means of phosphoric acid, distilling them in a current of steam, and evaporating the distillate to dryness with an excess of lead oxide. The basic lead propionate, being insoluble in water, was removed; the filtrate, after removal of the lead, was evaporated to dryness with zinc oxide and the zinc acetate, and butyrate separated from the zinc formate in virtue of their different solubilities in alcohol.

In examining this method, the author has made experiments with the three acids separately by evaporating on the water-bath titrated amounts with an excess of zinc oxide and a small quantity of zinc sulphate, liberating and distilling the acids from the residue, and again titrating.

The loss increased with the molecular weight of the acids, and amounted to 10·5 per cent. with the formic acid, 73·9 per cent. with the acetic acid, and 82·3 per cent. with the butyric acid.

Similar, though somewhat more favourable, results were obtained in the case of the lead salts of these acids, and the author therefore concludes that these bases are not suitable for the estimation of these acids by the method described by Haberland.

C. A. M.

The Composition of Geranium Oils of Different Origin. **Jeancard and Satie.** (*Bull. Soc. Chim.*, 1900, xxiii., 37-39.)—The samples examined by the authors were selected from oils distilled in 1898 and 1899, and were known to be pure.

A direct determination of the esters by the ordinary method gave the following results, calculated as $C_{12}H_{20}O_2$: Cannes oil, 19·11; Spanish oil, 23·03; Corsican oil, 21·07; African oil, 23·03; Bourbon oil, 25·95; and Indian oil, 15·05 per cent.—figures in substantial agreement with those of Charabot, Dupont, and Pillet (*cf.* ANALYST, xxii., 193).

Taking into account the fact that geranium oil invariably contains free acids, the authors determined the degree of acidity in the following manner: Three grammes of the oil were mixed with 10 c.c. of 96 per cent. alcohol and 10 c.c. of semi-normal potassium hydroxide solution. After two minutes the oil was precipitated by the addition of water, and the excess of alkali titrated with standard sulphuric acid.

It is essential not to prolong the contact of the alkali with the oil beyond the two minutes, since otherwise a partial saponification takes place. Under the conditions given above the author considers that there is hardly any saponification, and that the figure obtained in milligrammes of potassium hydroxide per gramme o oil is equal, or but slightly higher than that corresponding to the free acids actually present.

In the case of a sample of African geranium oil the results thus obtained were: After two minutes, 42·93; after five minutes, 43·06; ten minutes, 43·86; twenty minutes, 45·73; forty minutes, 48·53; one hour, 49·35; two hours, 49·93; and by hot saponification, 65·80 milligrammes.

By this method of cold saponification the authors have found that geranium oil becomes oxidised on contact with the air. Thus, a sample of Bourbon oil with a cold saponification value of 56·00 gave a value of 66·73 after being left for two months in a partially filled flask. On the other hand, a Cannes oil became oxidised much less readily, the figures only varying in a year from 26·6 to 29·66.

In the subjoined table of the characteristics of the different varieties of geranium oil the esters were calculated as $C_{12}H_{20}O_2$ (allowance being made for the free acids) and the alcohols as $C_{10}H_{18}O$:

Oil of Geranium.	Density at 15° C.	Rotatory Power at 15° C. in 100 mm. tube.	Saponification Value.		Esters, per Cent.	Alcohols, per Cent.
			Hot.	Cold.		
Cannes ...	0·8972	−9·40	54·60	26·60	9·80	61·31
Spanish ...	0·9073	−7·30	65·80	43·40	7·84	66·23
Corsican ...	0·9012	−8·00	60·20	40·13	7·00	68·55
African ...	0·9006	−8·06	65·80	42·93	8·08	63·19
Bourbon ...	0·8905	−8·20	74·00	56·00	6·65	71·28
Indian ...	0·8960	−0·48	43·00	9·60	11·30	84·62

The solubility of the different oils in dilute alcohol was practically the same, 1 volume of oil dissolving in 0·9 to 1 volume of 80 per cent. alcohol, or in 2 to 2·3 volumes of 70 per cent. alcohol at 15° C.

The authors consider that it may be possible to base a method of distinguishing between oils from different sources on the fact that those containing much free acid undergo oxidation more rapidly than oils containing a smaller amount, such as palmarosa oil (Cannes oil). C. A. M.

Detection of Ionone in Violet-scented Preparations; and Separation of the Two Varieties thereof. R. Schmidt. (*Zeits. angew. Chem.*, 1900, 189.)—If the original substance is an alcoholic solution, it is poured into twenty times its volume of water, and extracted twice with ten volumes of ether; the ether is washed two or three times with water, filtered through a double paper, and distilled off. If the

substance is a solid, it may be thoroughly distilled in a current of superheated steam as long as any volatile matter passes over, extracting the distillate with ether. Pomades may be treated with warm 80 per cent. alcohol two or three times, separating the fat by solidification, then distilling the alcoholic extract (after removal of the solvent) as before. The crude material thus obtained is ready for quantitative analysis, or it can be purified for qualitative purposes only by a distillation at a pressure of 12 millimetres, collecting the liquid which comes over between 125° and 135° C.

Melting-point Determination.—0·5 gramme of the oil is mixed with a cold solution of 0·5 gramme of parabromophenylhydrazine in 2·5 grammes of glacial acetic acid. According to the amount of ionone present, the mass either solidifies directly, after an hour or two, or after the addition of a drop of water; the crystals are dried on a porous tile. The melting-point of the parabromophenylhydrazone of crude β-ionone lies between 110° and 115°; the presence of α-ionone may raise the observed temperature to 140°. By repeated recrystallization from hot alcohol or light petroleum the α-ionone derivative may be isolated, and will give the proper melting-point of 142° to 143°. Contamination of the ionones with other ketones or aldehydes will either greatly lower the melting-point, or prevent the formation of crystals.

Separation of the Ketones from other Substances (Von Baeyer's Process).—Fifty grammes of the oil are agitated mechanically for ten hours with 83 grammes of *p*-hydrazobenzene sodium sulphonate dissolved in 500 c.c. of water, and 2 grammes of strong sulphuric acid diluted with 50 c.c. of water. The mass is made alkaline with 3 grammes of anhydrous sodium carbonate, and mixed with enough ammonium sulphate (200 or 250 grammes) to cause the liquid to separate into three layers when treated with ether. The whole is extracted twenty times with ether, and the two aqueous layers are distilled with 150 grammes of phthalic anhydride in steam, taking up the volatile oil in ether. The solvent is boiled off under reduced pressure, and the residue is fractioned at 12 millimetres pressure, retaining the distillate between 125° and 135°, which contains the ionone. This process is not quantitative.

Separation and Identification of α- and β-Ionone.—This method is the one described in *Ger. Pat.*, 106, 512 [*cf. Eng. Pat.*, 1944, 1899; *J. Soc. Chem. Ind.*, 1900, 69—Abs.]. If only a qualitative identification of the two ketones be desired, the operation may be conducted on the crude oil recovered as above; but if a quantitative separation be necessary, the product of Von Baeyer's process must be used. Seventy-five grammes of commercial bisulphite solution are warmed on the water-bath, neutralized with 10 per cent. soda solution (about 25 grammes), and acidified again with 10 or 12 grammes of bisulphite. This mixture is boiled under an inverted condenser with 15 grammes of alcohol and 25 grammes of ionone for ten to twenty-five hours, according to the purity of the ketone, until a small sample of the liquid gives only a faint turbidity with water. It is then diluted with 2 volumes of water, the undissolved ionone extracted by three agitations with ether, and the aqueous portion distilled in a current of steam as long as oily drops pass over, and until the contents of the retort begin to froth. The β-ionone in the distillate is collected with ether; to the retort are added 30 grammes of sodium hydroxide, and the α-ionone recovered by distillation as before. To identify the α-ionone, its parabromophenylhydrazone is

prepared, which melts before purification at 138° to 140°, after recrystallization from hot alcohol at 143° or, if heated fast, sometimes at 145° C. It crystallizes from petroleum in hexagonal plates, from alcohol in rhomboids. The β-ionone is identified by means of its semicarbazone, which, from alcohol, gives firm white crystals, becoming yellowish in air, and melting at 148°. The compound is readily broken up by warming with dilute hydrochloric acid, and the β-ionone may be converted into its parabromophenylhydrazone, which crystallizes in large rhombs from alcohol, and melts at 118° C.

If the mixed ketones consist mainly of β-ionone, as will be shown by the first melting-point test coming out between 110° and 116°, a qualitative separation may be effected more rapidly as follows: 10 grammes of the original oil fraction are mixed with a solution of 7 grammes of semicarbazide hydrochloride and 10 grammes of sodium acetate in 40 c.c. of water, and sufficient alcohol to insure dissolution; and the whole is allowed to rest twelve or fifteen hours. It is then precipitated with water, the semicarbazone collected, washed with water, and dissolved in about 50 grammes of spirit. After a time the bulk of the β-ionone derivative crystallizes out, and much of the remainder can be recovered by stirring with a rod, starting the crystallization again with a crystal from the first yield. This β-ionone-semicarbazone is filtered off, washed with weak alcohol, and recrystallized; it melts at 148° C. The alcoholic mother liquors containing the α-ionone are warmed for two minutes on the water-bath with a little dilute sulphuric acid, poured into water, and the oil collected by means of ether. From this the parabromophenylhydrazone of α-ionone may be prepared, and recognised by its appearance. F. H. L.

Volumetric Estimation of Tannin. L. Specht and F. Lorenz. (*Chem. Zeit.*, 1900, xxiv., 170.)—This process depends on the precipitation of safranine as a tannin-antimony lake, using an excess of dye, and determining that excess by titration with a standardized hydrosulphite. The reagent is prepared by suspending 50 grammes of zinc dust in 100 c.c. of water, and adding, at a temperature not exceeding 36° C., 600 c.c. of a 20° Beaumé solution of ammonium bisulphite previously neutralized with ammonia. When the precipitate has settled, 75 c.c. of the clear supernatant liquor are diluted to 2 litres, and the solution is again clarified by subsidence. To standardize the hydrosulphite, it is titrated against (1) a weak aqueous solution of safranine "T extra," of the badische Anilin Fabrik, twice recrystallized from alcohol, and (2) against the same volume of water just tinted pink with the dye solution. From the figures so obtained are calculated the value of the hydrosulphite in terms of safranine, and the amount of reagent destroyed by the oxygen dissolved in the water. To carry out the analysis, about 0·16 gramme of tannin, 0·2 gramme of tartar emetic, and 0·33 gramme of safranine are dissolved separately, mixed together, diluted to 2 litres, and allowed to stand for five or six hours, with occasional agitation. A portion of the clear liquid is finally titrated with the hydrosulphite till the colour disappears. Deducting from the volume of reagent used the quantity decomposed by the oxygen dissolved in the water, the remainder indicates the amount of safranine unprecipitated; and thus the weight of dye in the lake, or the value of the tannin, may be deduced.

In order to express the latter in figures, parallel experiments with a pure tannin, or with a tannin of known degree of purity, must be conducted simultaneously. The titration should be done in a beaker under a layer of oil, the jet of the burette entering the aqueous liquid; and the hydrosulphite should be stored in a reservoir, connected as usual to the base of the burette, and also covered with oil. The reagent thus retains its strength practically unchanged for twelve hours. All the water employed should be thoroughly boiled. When using pure tannin as the standard, the substance should be air-dried merely, the proportion of moisture in it being determined in a separate portion. F. H. L.

Estimation of Uric Acid by Precipitation as Ammonium Urate. E. Wörner. (*Zeits. physiol. Chem.*, xxix., 70; through *Zeits. angew. Chem.*, 1900, 141.)—This process depends on Fischer's statement (*Ber.*, 1899, xxxii., 3266) that uric acid can be heated with dilute caustic soda without losing ammonia. 150 c.c. of urine are warmed to 40° or 45° C., and 30 grammes of ammonium chloride are dissolved in it. After standing for about an hour the precipitated ammonium urate is filtered off and washed with a 10 per cent. solution of ammonium sulphate till it no longer gives a chlorine reaction. The residue is dissolved in hot 1 or 2 per cent. caustic soda, and the paper is washed with hot water. The filtrate is then heated on the water-bath until all free ammonia has disappeared, and finally kjeldahled with 15 c.c. of strong sulphuric acid and a little copper sulphate. One c.c. of decinormal sulphuric acid corresponds to 0·0042 gramme of uric acid.

It seems improbable that other substances should be thrown down from the urine by this treatment. Small amounts of albumin are without effect; larger quantities are objectionable. Urines containing urate or phosphate deposits can be used directly. F. H. L.

INORGANIC ANALYSIS.

Lead Assay. J. Flath. (*Chem. Zeit.*, 1900, xxiv., 263.)—The author states that the process of determining lead in ores, residues, etc., by reduction under fluxes in a wrought-iron crucible is more accurate than is often imagined. He quotes results obtained with fourteen products found to contain by wet analysis from 1·25 to 76·15 per cent. of lead, which show a maximum deficiency of 1·48 (mean −0·79) per cent. in the yield calculated on the samples when treated by the fusion method. The best composition of the flux either for an acid or a basic material is sodium carbonate, 70 parts; borax, 28 parts; and potassium bitartrate, 2 parts; but the proportions need not be maintained exactly. F. H. L.

Determination of Thallium as Normal or Acid Sulphate. P. E. Browning. (*Zeits. anorg. Chem.*, 1900, xxiii., 155.)—Thallium can be determined as acid sulphate by heating its chloride with sulphuric acid to a temperature between 220° and 240° C., or as normal sulphate by igniting it similarly at a dull-red heat. Both processes are perfectly satisfactory. F. H. L.

The Rapid Evaluation of Metallic Tungsten Powders. F. Ibbotson and H. Brearley. (*Chemical News*, vol. lxxx., pp. 294, 295.)—The following method is more rapid than the usual one, and gives as near an approximation to the truth:

Three grammes of the substance are weighed in a tared platinum dish, then ignited to tungsten trioxide and weighed (A). After treating the mass with hydrogen fluoride it is re-weighed (B), the loss indicating silica. To the residue is added water and pure sodium hydroxide, and the whole is diluted to 200 to 300 c.c., boiled, filtered through paper pulp, ignited, and weighed (C), then treated with a little hydrochloric acid, diluted, filtered, and the precipitated trioxide ignited, and weighed (D).

B = tungsten trioxide and its iron and manganese compounds, which in turn are represented by C – D; therefore B – C + D = the amount of tungsten trioxide.

The residue D and the filtrate from the sodium hydroxide treatment contain the whole of the tungsten, which may be estimated direct if required; and the filtrate obtained previous to the final weighing (D) contains the iron and manganese.

Sulphur, if not removed during the hydrochloric acid treatment or in roasting, makes the results too high. It should not, however, be present in tungsten powders used for steel-making.

Carbon may be estimated by roasting in a current of oxygen, or by combustion with lead oxide. C. S.

The Action of Ammonia upon Magnesium Salts. W. Schieber. (*Oesterr. Chem. Zeit.*, 1900, iii., 83.)—According to the text-books, magnesium salts are not quantitatively precipitated by ammonia, while if sufficient ammonium salts are present no precipitate is formed at all. These phenomena are explained by the production of a double compound of the typical formula $(MgCl_4)(NH_4)_2$, which is not decomposed by ammonium hydroxide. It is noticeable that the authorities say nothing about the influence of temperature; these statements refer only to cold solutions; in hot liquids, even in presence of 4 molecules of an ammonium salt per 1 molecule of magnesium, sufficient ammonia will cause a turbidity, if not a precipitate. The matter is important in water analysis, where alumina is thrown down by boiling with ammonia, for the deposit may also contain magnesia, which is scarcely capable of re-solution under the working conditions. From a special series of experiments the author finds that to insure all magnesium remaining in solution in such separation it is necessary to have an excess of ammonium chloride, and to use as little ammonia as possible. Employing normal solutions of magnesium sulphate, ammonia, and ammonium chloride, the following ratios show the maximum proportion of ammonia and the minimum proportion of ammonium chloride which will allow the mixtures to be raised safely to the boiling-point:

$MgSO_4$	NH_3	NH_4Cl
1	2	1
1	10	2

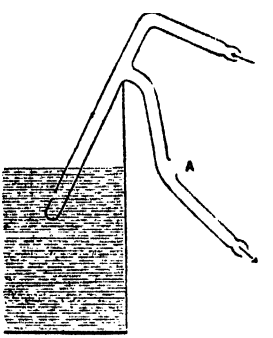
F. H. L.

Composition of Ammonium Magnesium Arsenate. M. Austin. (*Zeits. anorg. Chem.*, 1900, xxiii., 146.)—This precipitate will be obtained of theoretical compo-

sition provided a faintly acid solution of arsenic acid, free from ammonium salts, is treated with 30 c.c. of ammoniacal magnesia mixture more than is necessary to throw down the arsenic, the total volume of liquid not being allowed to exceed 200 c.c. If the precipitate is filtered off and washed with 25 c.c. of ammoniacal water, no arsenic will remain in solution. Ammonium chloride has a slight solvent action upon the double arsenate; and although this effect can be overcome by employing a larger excess of magnesia mixture, the chloride also has a tendency to cause the displacement of part of the magnesium by ammonium in the original precipitate. The author's magnesia mixture contains 110 grammes of crystalline magnesium chloride and 58 grammes of ammonium chloride in 2 litres of water, to which are added 10 c.c. of "ammonia." F. H. L.

Phosphotungstic Acid as a Test for Potassium. **E. Wörner.** (*D. Pharm. Ges. Ber.*, 1900, x., 4; through *Chem. Zeit. Rep.*, 1900, 48.)—A 10 per cent. solution of ordinary crystalline phosphotungstic acid forms a more sensitive reagent for potassium than either platinic chloride or tartaric acid. From acid solutions the potassium salt falls in coarse crystals, from a neutral solution it separates in a very fine state of subdivision, rendering the liquid milky. Barium, strontium, calcium, and magnesium are not thrown down by the reagent; sodium chloride is only precipitated from a saturated solution, and the deposit dissolves immediately on dilution. Ammonium compounds must be previously removed. F. H. L.

Estimation of Iodic Acid in Sodium Nitrate. **R. Auzenat.** (*Monit. Scient.*, 1900, xiv., 72; through *Chem. Zeit. Rep.*, 1900, 48.)—Six similar test-tubes, 18 centimetres tall and 25 millimetres in diameter, each provided with a mark at the 50 c.c. point, are placed side by side in a stand in front of a white background. In the first are put 10 c.c. of a solution of potassium iodate (1 gramme per litre); in the second 30 c.c., in the third 35 c.c. . . . in the sixth 50 c.c. of a solution of the nitrate under examination (33 grammes per litre). The tubes are then filled up to the mark with water, and 2 c.c. of 10 per cent. potassium iodide and 5 drops of glacial acetic acid are quickly added to each. After shaking gently and standing for ten minutes the colours are compared with the standard tube (No. 1); but if none of them is a satisfactory match, the whole test is repeated with a different quantity of potassium iodate. Commercial sodium nitrate generally contains iodic acid equivalent to 1 or 2 per cent. of sodium iodate. F. H. L.



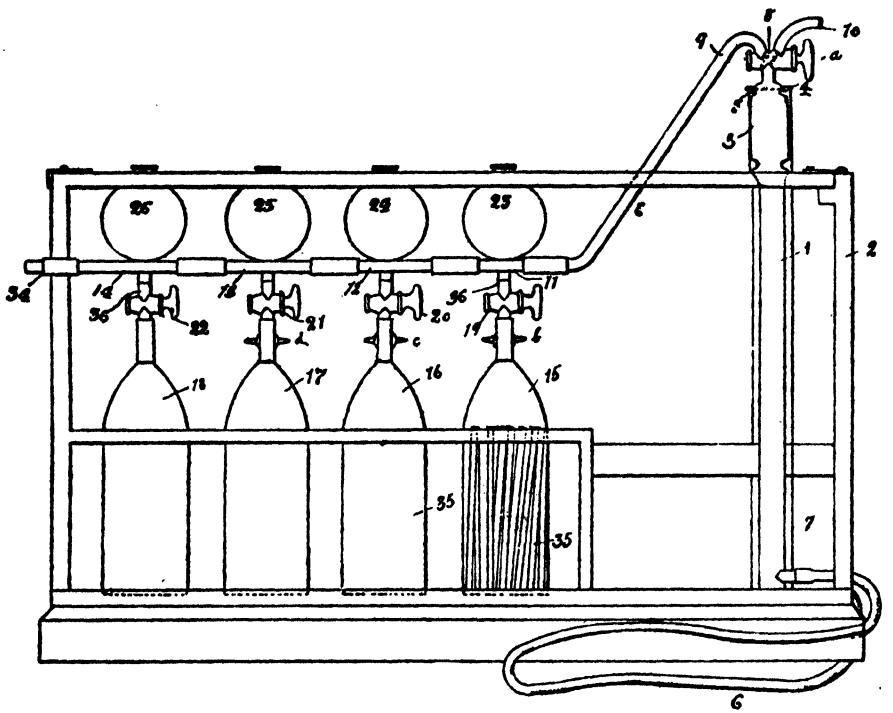
Determination of Phosphoric Acid as Phospho-Molybdic Anhydride. **J. Hanamann.** (*Zeits. landw. Versuchsw. Oesterr.*, 1900, iii., 53; through *Chem. Zeit. Rep.*, 1900, 72.)—The author strongly advocates the direct method of estimating phosphoric acid indicated by the above title. He employs the Wagner-Stutzer reagent: 150 grammes of ammonium molybdate and 400 grammes of ammonium nitrate dissolved in *two litres* of water and poured into 1 litre of 1·19 nitric acid. Twenty-five c.c. of the phosphate solution are mixed with 50 c.c. of the reagent,

warmed very slowly up to 40° C., and stirred for ten minutes; the precipitate is washed with acid ammonium nitrate, then with alcohol, and dried, ignited, and weighed. This ignition must be done uniformly, avoiding too great heat. His factor for the conversion into P_2O_5 is 0·03946. F. H. L.

Erdmann's Reagent [Amidonaphthol-K-Sulphonic Acid] for Nitrites in Water. H. Mennicke. (*Zeits. angew. Chem.*, 1900, 235.)—The present author agrees that Erdmann's new reagent (this vol., p. 81) is most useful. Its indications are perfectly certain. They are not affected by the presence of ferric chloride, nitric acid, or other oxidizing agents; a large excess of the latter bodies only causes the colour to be more wine-red. The limit of sensitiveness for a sharp eye in daylight is 1 part of sodium nitrite per 300 million—*i.e.*, it is about 300 times more delicate than starch and potassium iodide. The colour attains its maximum intensity in half an hour. Mennicke quotes analyses of several town and waste waters which fully bear out his statements. F. H. L.

APPARATUS.

New Form of Water-bath Regulator. H. S. Hatfield. (*Chemical News*, vol. lxxxi., p. 65.)—To obviate the stoppage of the supply by accumulations of air in the ordinary syphon-tube regulator, the author employs the form illustrated in the drawing. The supply-tube is bifurcated, one limb dipping under the liquid of the bath, and the other being open to the air at A. The water in the bath will rise only slightly above the level of A, the excess being due to the force necessary to divert the stream. All the tubes must be full of water; any air-bubbles formed are swept away by the current, which must be strong enough for this purpose. The water must leave the sides of the glass at A.



C. S.

Apparatus for the Analysis of Illuminating and Fuel Gases. G. E. Thomas. (*Journ. Amer. Chem. Soc.*, vol. xxi. [12], pp. 1108-1112.)—The apparatus measures 16 inches long by 15 inches high. The burette, 1, is graduated to 100 c.c., 40 of which (the bulb, 3) are in whole divisions, and the rest in 0·2 c.c. It is fitted with platinum terminals, 4, 5, and filled with water acidified with sulphuric acid to decrease the solubility of the carbon dioxide. The absorption bottles, 15, 16, 17, and the storage bottle, 18, are connected with the burette by a capillary tube, *e*, and the T tubes shown, these latter being provided with rubber connections. Nos. 15 to 17 are fitted with stop-cocks, *b*, *c*, *d*. Bottle 15 is filled with caustic potash solution, the surface being increased by the use of glass tubes; No. 16 contains bromine water, and No. 17 (protected from light) phosphorus under water.

The burette and capillary tube, 10, being filled with water by raising the levelling

tube, 7, the tap, *a* is closed, 10 is connected with the gas supply, and 100 c.c. of gas are drawn into the burette by lowering 7 and reopening *a*. The gas is then forced into bottle 15, the operation being thrice repeated, and the loss (carbon dioxide) in volume measured after draining. The illuminants and oxygen are then measured by absorption in bottles 16 and 17 respectively, care being taken to absorb the bromine vapours in the gas by bottle 15 before measuring the residual gas. The unabsorbed remainder is collected in 18 for explosion tests. For these latter about 80 c.c. of air are drawn into the burette through 10, followed by about 15 c.c. of gas from 18, water being drawn through the capillary as far as *a* from bottle 17. The mixed volume having

been carefully measured, mixing is completed by passing the air and gas into 15 and back again. The tap, *a*, is closed and the pressure reduced by lowering 7; and a water-seal is formed by bending the rubber tube and securing it in a slit in the frame. The spark is then passed, the explosion being very mild owing to the peculiar construction of the burette; and, when cooled down, the contraction in the volume, the amount of carbon dioxide, and the excess of oxygen are determined successively, the water from the burette being finally forced through the capillary system into 17, to insure complete absorption. The final volume contains only the nitrogen in the air plus that in the gas.

For fuel-gas analysis 17 and 18 are charged with cuprous chloride solution, air being excluded by a seal of petroleum in the funnels. A lubricant is necessary to insure success, vaseline being suitable for the bromine bottle. C. S.

THE ANALYST.

JULY, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, June 6, in the Chemical Society's Rooms, Burlington House. The President (Mr. W. W. Fisher, M.A.) occupied the chair.

The minutes of the previous meeting were read and confirmed.

A certificate of proposal for election to membership in favour of Mr. John Stewart Remington, analytical and consulting chemist, Corporation Street, Lancaster, was read for the first time.

Messrs. J. R. Brooke, T. H. Lloyd, and G. H. Morris, Ph.D., were elected members of the Society.

The following papers were read: "The Determination of Oxygen in Copper by Ignition in Hydrogen," by L. Archbutt; "Uniformity in the Conduct of Soil Analysis," by A. D. Hall, M.A.; "The Adulteration of Wheaten Flour with Maize," by G. Embrey; and "A New Colour Reaction for Distinguishing between certain Isomeric Allyl and Propenyl Phenols," by Alfred C. Chapman.

THE INFLUENCE OF TEMPERATURE AND CONCENTRATION ON THE SALINE CONSTITUENTS OF BOILER WATER.

BY CECIL H. CRIBB, B.Sc., F.I.C.

(*Read at the Meeting, April* 4, 1900.)

THE behaviour of the saline constituents of water when used in high-pressure boilers has, as far as I am aware, never formed the subject of a paper before this society. The matter has only a remote connection with analytical work, but to all who are likely to be consulted on questions relating to boiler waters it should be of interest.

Personally, I have not unfrequently been asked by engineers what would happen to a water when heated in a boiler working at a certain pressure, or what proportion of its dissolved salts it would deposit. On looking through the literature of the subject, I was surprised to find how little really definite information was to be had.

The common use of high-pressure feed-water heaters shows that the effect of pressure, *i.e.*, temperature, on the solubility of the salts is fully recognised and taken

advantage of; but I know of no systematic investigation such as would enable one to predict with even approximate certainty the changes in composition that would be brought about when a water is heated above 100° C., or the further changes due to the concentration which necessarily occurs in a boiler working under the ordinary conditions. Again, as analysts, we are frequently called upon to say whether, judging from analysis, a water will, or will not, have any action on the boiler or its fittings. In most cases the problem is a fairly simple one, but in some instances a little knowledge as to what a water is likely to become after concentration to from five to twenty times its original strength might be of considerable use. Even with the best of boiler waters a certain amount of corrosion takes place, and it is not unreasonable to suppose that, in this connection, the concentration is not without influence. In any case, the high temperatures have a marked effect on the chemical activity of those constituents to which corrosion is usually attributed.

The problems to be dealt with are somewhat complicated, because it is impossible, with steam-boilers working under ordinary conditions, to separate the influence of pressure from that of temperature, and these, again, from that of the concentration of the more soluble constituents. The effects of all three are, moreover, obscured by the constant addition of fresh feed water, diluting the boiler contents, and at the same time bringing with it fresh supplies of saline matters, some of which add to the concentration, while others are speedily deposited because of the sudden increase of temperature to which they are exposed, or because of the superabundance of certain salts in the surrounding medium.

The various analyses under the heading "Water from Boiler" (Tables I., III., IV., V., VI. and VIII.) show the sort of samples that are obtained from boilers which have been running for various periods up to six or seven weeks. Of course, in the rare instances in which pure sea-water is used in high-pressure boilers, the degrees of salinity here shown are enormously exceeded, but I have not been able hitherto to obtain any specimens of this sort for examination.

In Table I. is given the composition of a very bad feed water, and of a sample taken from a water-tube boiler in which it had been used for some weeks. The analyses are far from complete, but a brief glance at them will serve as an introduction to the more complicated series of analyses that follow. In this and all the other analyses of waters the results are expressed in parts per 100,000:

TABLE I.

	Feed Water.	Water from Boiler.	Concentration Factor.
	301·5	1,601·2	5·31
	145·5	670·0	4·64
Total hardness:	95·2	183·1	1·91
Permanent hardness:	54·4	183·1	3·34
Temporary hardness:	40·8		

It will be seen at once that all the constituents have become concentrated to a different extent. The numbers under the heading "Concentration Factor" were obtained by dividing the proportion of each constituent of the boiler water by that of the same constituent in the feed water, and they really represent the number of

volumes of the feed water that would contain the same amount of that particular constituent as one volume of the boiler water. If owing to the evaporation taking place in the boiler all the constituents had been concentrated to a like extent, all the concentration factors should be the same. They all, as would be expected, differ, and the question at once arises, Which of them, if any, indicates the real degree of concentration? Or, to put it in another way, have any of the constituents merely gone on accumulating in the boiler? or have they all suffered a certain amount of deposition in the solid form, or have they been decomposed? Obviously, the extent to which any particular salt has gone out of solution, owing either to deposition or decomposition, can only be ascertained if the real degree of concentration is known.

This can plainly only be got at indirectly, but some means of doing it is absolutely essential, so I propose to devote a short time to the discussion of the most suitable plan before proceeding further. In a laboratory experiment the actual solid deposit could be collected, weighed and analysed, or the total amount of water actually used could be measured and compared with the volume of the residual water, but obviously such methods are out of the question in the case of boilers working under ordinary conditions. If, however, one constituent can be found which never goes out of solution, or leaves the water in the boiler owing to decomposition of any sort, then that will serve as a direct measure of the concentration, making it possible, if the capacity of the boiler is known, to calculate the actual volume of water evaporated, and consequently the amounts of each of the other constituents which should remain in the concentrated water had they, too, suffered no loss.

The chlorides, the nitrates and the alkalies are on the whole the most likely to answer the purpose. The nitrates are, however, likely to become reduced, either by organic matter or the metal of the boiler, and the estimation of the alkalies is troublesome and not too accurate, so that one naturally turns to the chlorides. All the chlorides are so soluble in water that they are never likely to come out of solution from mere concentration alone except under the most extraordinary circumstances. Hence it is rare to find scales and deposits from land boilers containing any considerable proportion of chlorine, and, as a rule, that element is present only in minute traces. According to Vivian Lewes ("Service Chemistry," p. 119), even sea-water when evaporated does not begin to deposit salt until about 24 per cent. of the latter is present in solution; and the same author found an incrustation from sea-water to contain only 2·79 per cent. of sodium chloride. In my own experience I have found this figure to be very much exceeded. Thus, a scale from a naval water-tube boiler of recent construction, in which, owing to an accident, much sea-water had to be used, had the following composition, showing that it consisted almost entirely of sodium chloride:

TABLE II.

	Per Cent.
Fe_2O_3	0·28
CaO	0·19
MgO	1·40
SO_3	1·72
Cl	58·49
OH_2...	0·81

No ordinary water is ever allowed to concentrate in a boiler to such an extent as to even approach sea-water in salinity, so that the chances of the salt crystallizing out can be safely neglected. On the other hand, the presence of magnesium chloride has to be reckoned with. There seems to be a good deal of doubt, judging from text-books, as to the behaviour of this substance when heated.

Some, *e.g.*, Bloxam, state definitely that solutions of magnesium chloride decompose on evaporation, giving off hydrochloric acid. Comey's "Dictionary of Solubilities," Watts' "Dictionary of Chemistry" (Morley and Muir), and Blount and Bloxam's "Engineering Chemistry" say practically the same, while most of the other English text-books refer only to the behaviour of the solid substance. There is, in any case, a widespread impression amongst chemists that the solution is decomposed on heating at ordinary pressures.

Those text-books that mention the decomposition of the solution plainly do not refer to evaporation under pressure, and the original fountain-head of their information seems to be a paper by Casaseca (*Comptes Rendus*, 1853, xxxvii., 350), who found that a solution of magnesium chloride, when heated, begins to decompose when it contains only six molecules of water to one of the chloride. From the way he conducted his experiment, he was obviously *igniting* the ordinary crystalline form of the salt ($MgCl_2,6OH_2$).

When a solution of magnesium chloride is evaporated on a water-bath, I find that this salt, with six molecules of water, always remains behind, and the evaporation may be repeated any number of times without any decomposition occurring, the total solid residue remaining quite constant, and always dissolving without difficulty to a clear solution. The proportions of chlorine and of magnesium also show no variation.

If the salt be melted in its own water of crystallization, but little visible decomposition takes place until a temperature of about 150° C. is reached, and the thermometer rises slowly to about 180° C. There can be no doubt that the general impression as to the instability of solutions of magnesium chloride when heated is due to the misleading employment of the term "evaporation" in the text-books.

I find, further, that a solution of magnesium chloride, so strong that it deposited crystals of the hydrated salt in the cold, may be distilled to further concentration without giving off a trace of acid. The same experiment repeated, with the addition of a large quantity of iron filings to the solution, gave a like result, which seems to show that the metal of the boiler would be without influence in this connection. Vivian Lewes ("Service Chemistry" p. 121), states that "when sea-water is evaporated in contact with a large surface of metallic iron, no chloride can be detected in the distillate until four-fifths of the solution has distilled over." Such a concentration of sea-water would not contain more than $2\frac{1}{2}$ per cent. of $MgCl_2$, while the solution I employed was nearer 50 per cent., so that further investigation of the matter is required. The behaviour of magnesium chloride solutions when heated under pressure still remains to be considered. That the salt, if present in the feed water, is almost entirely decomposed in the boiler is plain from the fact that all the analyses in the tables (IV., V., VI. and VIII.) show a remarkable disappearance of the MgO from the water after it has entered the boiler. Magnesium hydroxide is one of the commonest constituents of boiler incrustations, while chlorine in

any quantity is rare. This holds good even when there is much Mg and Cl in the feed water, and is very strikingly shown by the analyses in Table III., in which the feed water contains very large proportions of both MgO and Cl, while the scale is practically free from chlorine, but contains nearly one-third of its weight of magnesia :

TABLE III.

	Feed Water.	Scale from Boiler.
Total solids	938·5	
Chlorine (Cl)	460·0	Moisture trace
Carbonic acid (CO_2) ...	13·38	0 per cent.
Sulphuric acid (SO_3) ...	45·76	39·87 ,,
Lime (CaO)	117·88	28·00 ,,
Magnesia (MgO) ...	129·84	30·14 ,,
Nitric acid (N_2O_5) ...	9·55	Insoluble 3·19 ,,

The magnesium has therefore plainly left the water under the influence of the high temperature to which it has been exposed. What has happened to the chlorine? Unfortunately, in this particular case, I have no analysis of the water after it had been in the boiler, but it by no means follows that because magnesium chloride is decomposed and its base deposited that the chlorine leaves the water at all. The process may be the result of a double decomposition with some other salts; but even if free hydrochloric acid is formed, it is far from certain that it would be evolved as gas and pass away with the steam. That it does not do so in the case of waters reasonably suited for steam-raising is clearly shown by Table IV., which gives the composition of the contents of a boiler using a London water after running for about six or seven weeks, and that of the condensed water collected after the steam had passed through a superheater :

TABLE IV.

Lancashire Boiler : 40 lb. pressure.

	Water from Boiler.	Condensed Steam.
Total solids	503·2	2·60
Chlorine	94·0	0·21
Nitric acid (N_2O_5)	2·65	0·016
Carbonic acid (CO_2)	5·98	0·14
Sulphuric acid (SO_3)	127·68	0·49
Silica (SiO_2)	1·92	0·20
Oxide of iron (Fe_2O_3)	0·72	0·16
Lime (CaO)	18·24	0·65
Magnesia (MgO)	0·33	0·15

In view of the concentration, a good deal of magnesium must have been deposited in the form of sediment or scale, and yet the condensed water shows no excess of chlorine, but rather the reverse. It is, in fact, obvious in the case of ordinary waters that no hydrochloric acid passes away in the steam, as otherwise the engines would *always* be attacked. Further, it has been recently shown by Bailey and Johnston (*J. S. C. I.*, 1899, p. 455) that an aqueous solution of hydrochloric acid does not give off any acid when distilled until the proportion of the latter reaches nearly 1 per cent.

Of course, under a high pressure something entirely different may happen. Table V. which relates to a water which contained a fair proportion of MgO and much chlorine, and acted powerfully on the boiler, and its fittings* affords an indirect proof that no appreciable amount of chlorine leaves the boiler:

TABLE V.

Pressure: 140 *lb.*

	Feed Water.	Water from Boiler.	Concentration Factor.
Total solids	99·2	411·0	
Nitric acid (N_2O_5)	Trace	Trace	
Chlorine (Cl)	18·15	93·5	5·15
Sulphuric acid (SO_3)	16·76	84·8	5·06
Carbonic acid (CO_2)	15·21	38·94	
Silica (SiO_2)	1·30	7·0	
Oxide of iron, etc.	0·40		
Lime (CaO)	7·77		
Magnesia (MgO)	3·33		
Na_2O, and K_2O	44·89	209·9	4·68

The water was strongly alkaline owing to the presence of sodium carbonate, and it is not unreasonable to suppose that the lime and magnesia, which are completely absent from the water after heating, were deposited in the form of carbonates. In the absence of lime and magnesia, there is no more reason for the SO_3 leaving the water in the boiler than for the mixed alkalies or the chlorine, consequently the concentration factors for these three should be identical within the limits of experimental error. This is the case with two of them, and the third is not far out. In any case, the figure for the Cl is the *highest*, as, indeed, it almost invariably is throughout the tables. In this particular analysis, at all events, the amount of chlorine is almost certainly a true measure of the concentration; in the others it is, if not the true one, at any rate the best available.

In the present connection, as well as from a theoretical standpoint, the behaviour of magnesium chloride when its solutions are heated under pressure is of such great interest that I have commenced its investigation, and hope to publish the results elsewhere. I may say briefly that under a pressure of one atmosphere (temperature about 125° C.) practically nothing happens to a solution containing 2·25 per cent. of $MgCl_2$, but at five atmospheres a solution of the same strength is partially decomposed, with deposition of MgO and evolution of HCl, the extent of the decomposition being determined by the duration of the experiment and the freedom with which the steam is allowed to escape. Working with the pure salt, however, the conditions are entirely different to those which obtain in a boiler in which a water containing a mixture of many salts is being evaporated, and the large surface of iron exposed to the liquid may profoundly affect the result.

In any case, I propose to assume, in the absence of satisfactory evidence to the contrary, that in the case of the waters referred to in Tables IV., V., VI. and VIII. the chlorine is a sufficiently exact measure of the concentration to render it possible

* This boiler worked at 140 pounds pressure; other boilers with the same water, working at 80 pounds, gave no trouble.

to calculate the original volume of feed water used. The use I propose to make of the concentration factor obtained in this way will appear later.

Table X. (p. 181) shows the composition, apart from the alkalies, oxide of iron, and silica, etc., of four waters: (1) New River water; (2) water from a boiler for which it was used, after working 82 hours at from 70 to 80 pounds pressure; (3) after working 468 hours at the same pressure; and the same water evaporated at a pressure of only 6 ounces per square inch till the chlorine contents reached that in No. 3.

Table VI. deals with a still more extended series of samples, for which I am indebted to Messrs. W. H. Allen, Son, and Co., of Bedford. The details as to the samples are stated in the tables; the intervals at which the samples were taken are complete days, whereas in Table X. they are hours of actual working.

To get some idea of the effect of concentration alone, Table VI. may be studied in more detail.

TABLE VI.

Bedford water, 180 pounds pressure; boiler evaporates 3,000 gallons in 10 hours; samples collected at intervals of 1, 8, and 24 days from date of lighting up.

	From Hot Well.	After 1 Day.	After 7 Days.	After 24 Days.
Total solid matter ...	33·0	106·12	171·0	341·7
Chlorine (Cl) ...	2·85	14·95	41·15	90·0
Carbonic acid (CO_2)	1·27	0·97	1·22	3·50
Sulphuric acid (SO_3)	11·36	41·02	49·58	82·52
Lime (CaO)	7·35	8·00	5·34	9·20
Magnesia (MgO) ...	1·35	2·77	0·47	0

As would of course be expected, the water at the end of twenty-four days has become highly concentrated, but the results differ for each constituent. Thus, while the total solids in twenty-four days has reached ten times its initial amount, the concentration of the carbonic anhydride is only 3 times, that of the chlorine 30 times, the sulphuric acid 7 times, the lime 1·2, and the magnesia has disappeared altogether. Of course, any comparison between the feed-water and any of the other samples necessarily takes into account the influence of the high pressure and temperature to which the latter have been exposed. But if any one constituent is taken, and the effect of time alone is studied, the figures still require a good deal of interpretation. Thus, the chlorine is 5 times as great after working one day as it was before entering the boiler, but six further days' work only produce 3 times the effect of the one day, and twenty-three days' more only 6 times. The SO_3, again, is 3 times as great after one day, 4·3 times after seven days, and only 7 times after twenty-four days. In fact, of all the constituents estimated not two behave alike.

A very little reflection will, however, be enough to explain some of these seeming contradictions. Thus, the apparent effect of the initial day of working will always be greater than that of any subsequent one (as far, at all events, as the CO_2, SO_3, lime, and magnesia are concerned), because the boiler is started with its contents undiluted with condensed water from the engine.

That the changes produced in a unit of time should decrease as the concentration increases is what would naturally be expected, in view of the fact that the solid matter entering the boiler with the feed water must bear a steadily decreasing ratio

to the ever-growing amount of dissolved matter already there. The ratio will, of course, be partly dependent on the proportion existing between the evaporative power and the capacity, at working level, of the boiler—a proportion which varies very widely in the different types of boiler.

That the individual constituents differ from one another in the extent to which they have become concentrated is, of course, owing to the greater insolubility of some of them at high temperatures, or to their insolubility in strong solutions of the other saline constituents, of which by far the most important in this, as in the majority of waters, is the sodium chloride. Further changes may also be produced by double decompositions, giving rise to less soluble compounds.

A very cursory inspection is sufficient to show that there is a continual falling out of solution of the majority of the salts, but the full extent of this is marked by the mere accumulation of what remains. To get any idea of how much has gone out of solution, it is necessary to consider the amount of feed water that the contents of the boiler at any time represent, *i.e.*, to know the true concentration factor. I have already given reasons for assuming that the chlorine is the best guide to this.

On this assumption it is only necessary to divide the chlorine in the boiler water at any period by the chlorine in the feed water to find out how many volumes of the latter one volume of the water in the boiler represents, this figure being, of course, the true concentration factor.

If this figure in turn be divided into the amount of any constituent, it will give the proportion of that constituent still remaining dissolved in the boiler water expressed in parts per 100,000 of the *feed water*.

Thus, taking the chlorine in Table VI., the amount after one day, viz., 14·95, divided by 2·85 (the amount in the feed water), gives 5·2; this is the concentration factor, and indicates that the water after one day in the boiler contains Cl belonging to 5·2 times its volume of feed water, and, if the assumption already referred to be correct, not only the chlorine, but each of the other constituents as well, unless the actual amount has been reduced by the particular consituent leaving the water owing to deposition as scale or sludge, or by evolution in the gaseous form. If 5·2 be now divided into 14·95, the amount of Cl belonging to one volume of feed water is obtained, *i.e.*, 2·85, the same as in the feed water, because, according to the initial assumption, no chlorine is lost. If 5·2 be divided into the other figures for the same period of working, the results differ from the proportions of the same constituent in the feed water, because all the constituents, other than the chlorine, have suffered loss either by deposition as sediment or scale or by evolution as gas.

TABLE VII.

After compensating for Water evaporated.

	From Hot Well.	After 1 Day.	After 7 Days.	After 24 Days.
Total solid matter ...	33·0	20·23	11·84	10·56
Chlorine	2·85	2·85	2·85	2·85
Carbonic acid	1·27	0·184	0·085	0·108
Sulphuric acid	11·36	7·82	3·43	2·55
Lime	7·35	1·525	0·396	0·285
Magnesia	1·35	0·528	0·032	0

Table VII. is obtained in this way, viz., by dividing the respective concentration factors for each sample, calculated from the chlorine, into all the other figures for the same sample. The effect is practically to restore the water that has been evaporated, thus doing away with the merely cumulative effect of the concentration, and laying bare the combined effect of the high pressure and temperature and of the increasing salinity on the solubility of the various salts.

The total solid matter obviously suffers from any changes that affect its constituents. In Table VI. it has increased to about ten times its original amount, but Table VII. shows that as long as the experiment lasted solid matters continued to leave the water, and at the end of the twenty-four days $33{\cdot}0 - 10{\cdot}56 = 22{\cdot}44$ parts of solid matter per 100,000 of feed water used had actually disappeared.

The carbonic acid, owing to the use of a hot well and of condensed water, is very small in the feed water, and the subsequent differences in Table V. hardly exceed the ordinary error of experiment, except in the case of the last. This sudden increase I am not prepared to explain. It may mean that calcium carbonate is more soluble in the presence of much sodium chloride, or it may be the result of some double decomposition between the already deposited carbonate and the salts in solution. In any case, the difference is not very great.

The sulphuric acid in Table VI. steadily increases, but with no apparent relation to the time. Table VII. shows that there has been a steady and continuous loss of SO_3 from the solution.

The lime, to which, with the magnesia, the greatest interest attaches, is apparently slightly more after one day in the boiler than in the feed water; but when allowance is made for the concentration, it is apparent (Table VII.) that that constituent has suffered more heavily than all the others, only one-fifth of the total amount present in the feed water remaining at the end of one day. The temptation to speculate as to its fate is very great, and I much regret that the analyses are not complete. They were made some time ago, when I did not realize the importance that might attach to the alkalies. The amounts of lime that have vanished, calculated from Table VII., seem to bear no regular relation to the CO_2 and SO_3 which have disappeared, and it seems probable that double decompositions between the scale and sediment and the dissolved salts are constantly occurring. In any case, it would be unjustifiable to base any theories on such a small number of analyses.

As there is always far more than an equivalent amount of SO_3, it is fair to regard the lime left at the end of twenty-four days as being all present as sulphate; the amount found, viz., 9·20, is equivalent to 22·34 parts of calcium sulphate.

Tilden and Shenstone (*Phil. Trans.*, part 1, 1884, p. 23) found that 100,000 of pure water at a temperature which gave a pressure of 132 pounds per square inch held in solution 27·0 parts of calcium sulphate, and at 513·5 pounds only 18·0 parts, and, calculating from these figures, I find that at 180 pounds 26 parts per 100,000 should remain in solution, so that it seems probable that the point of saturation for calcium sulphate at this temperature had been reached. Tilden and Shenstone's figures were obtained with pure water, so that it is plain that the concentration of the salts in the boiler water has not materially affected the solubility of the calcium sulphate. In Table X., column 3, however, although the concentration has not been

carried nearly as far, the sulphate of lime, calculated from the CaO, cannot exceed and is almost certainly less than 42·6 parts per 100,000, whereas Tilden and Shenstone found 56 parts to be soluble at that pressure. Here, therefore, it is quite plain that the saturation-point for 80 pounds pressure is not nearly reached, and yet it is obvious from Table XI. that SO_3 in some form has been continuously deposited since the boiler commenced to work. So, too, in Table IV. the lime is equivalent to 44·29 parts of calcium sulphate, while, according to Tilden, about 53 parts should be soluble.

To return to Tables VI. and VII. The magnesium exhibits similar peculiarities of behaviour to the lime, but it is very interesting to note that at the end of twenty-four days it has absolutely disappeared.

Although in Table VI. the quantity shows an increase at the end of one day, Table VII. makes it plain that a continual deposition of MgO in some form went on throughout the whole period dealt with.

In Table IV., which deals with a longer period, the MgO also nearly, but not quite, vanishes; and also in Table X.

In Table V. the disappearance is absolute, owing no doubt to the large proportion of alkaline carbonates present.

So far the tables have dealt with cases in which the pressure remained constant while evaporation went on. Through the kindness of Messrs. Marshall and Co., of Gainsborough, I was enabled to obtain samples from a boiler in which the reverse conditions obtained—*i.e.*, the pressure varied, and loss by evaporation was as far as possible avoided, thus affording an opportunity of studying the effect of pressure and the resulting high temperature, comparatively free from the disturbing influence of the concentration.

It is, of course, impossible in the case of steam boilers to separate the effect of pressure from that of temperature, as the one is the necessary concomitant of the other. But though water is commonly regarded as incompressible, the effects of pressure upon its volume are quite enough to produce important and far-reaching consequences by depressing the level of the ocean (Tait, *Challenger* Reports, "Physics and Chemistry," vii.). The pressures referred to here are, however, infinitely greater than anything occurring in boilers.

It is, I believe, generally admitted that hydraulic engineers are not troubled in any way by chemical changes in the water constituents brought about by the highest pressures they employ. Nevertheless, the possibility of the pressure itself playing some part in the changes taking place in the boiler contents must not be entirely disregarded, although everything seems to show that it can only be slight.

From a purely scientific point of view, the effect of pressure has been studied by Bunsen (*Ann. d. Chem. u. Pharm.*, 1848, 76-85), who obtained entirely negative results.

Sorby (*Proc. Roy. Soc.*, xii., 54) pointed out that Bunsen had failed to allow enough time for the effects to manifest themselves, and showed, by sealing up various substances in tubes which were completely filled with the cooled solution and warming them, that chemical changes followed by increase of volume are resisted, and those resulting in a decrease of volume are promoted, by pressure. Similarly

with solution: substances which expanded on entering into solution became less soluble under pressure, and substances which contracted became more soluble. The vast majority of substances contract, and therefore pressure increases their solubility.

The pressures he employed were, however, from 100 to 200 atmospheres, but even then the effects were extremely minute; for instance, the solubility of sodium chloride was only increased to the extent of 0·419 per cent. by a pressure of 100 atmospheres, that of potassium sulphate to the extent of 2·914 per cent.

The experiments of Tilden and Shenstone have already been referred to. Spring, of Liège (*Zeit. für Physik. u. Chem.*, 1889), found that when a diminution of volume accompanies solution, the presence of water facilitates the solidification of powders by pressure; and it seems extremely probable that in this direction, if at all, the pressure, apart from the temperature, affects the behaviour of the salts in boiler waters.

There is one important difference between the conditions which obtain in a boiler and those under which all the above investigations were made—namely, that in the former case steam in large quantity is continuously leaving the boiler, and is free to carry with it any gaseous products that may be formed.

TABLE VIII.

Gainsborough Water, heated up and kept for ten minutes at pressure of 50 lb., 100 lb., 150 lb., 200 lb., and 250 lb. per square inch. Steam kept as far as possible from escaping.

Magnesia	6·29	4·31	3·80	2·99	2·03	1·11

The samples dealt with in Table VIII. were drawn from a new boiler under the conditions stated in the table. The water was kept for ten minutes at the pressure

stated, and at the end of that time a sample was taken. The steam was kept as far as possible from evaporating, but it is quite evident that before 50 pounds' pressure was reached a considerable amount of concentration had taken place.

After that there are curious differences in the chlorine figures, for which I am quite at a loss to account, except on the supposition that some fresh feed water was allowed to get into the boiler. The time during which each of the stated pressures was maintained was unfortunately so short that the full effect could not be produced, and could the period have been twenty times as long it would have been much better. This, however, would have necessitated extending the whole experiment beyond one day, and could not conveniently be arranged for. The mistake, however, carried with it a certain compensation, for it disclosed a phenomenon which under other circumstances would probably not have been revealed. As a rule, water drawn from a boiler is, of course, very turbid, but the particles are large and settle down very quickly, leaving the supernatant liquid quite clear. In the case of those samples the water was turbid, or it would be better described as opalescent, but the particles were so fine that they were invisible when examined under the microscope with a one-sixth objective. It was absolutely impossible to filter the liquids clear, and I had to make the analysis with the turbid fluid. At the end of several months, however, the particles seemed to have got larger and heavier, and eventually sank to the bottom. When shaken up after this the liquid settled down clear almost immediately.

Dealing first with Table VIII., the total solids appear to be almost unaffected by 50 pounds pressure; but when allowance is made for the small amount of concentration that has taken place (Table VIII.), it is seen that there has been a considerable reduction, amounting in all to 22 parts per 100,000, of feed water, which appear to be made up, roughly speaking, of 5·7 SO_3, 5·4 CO_2, 7 of CaO, 2 of MgO, and 1 of SiO_2, while the Fe_2O_3 has increased, owing no doubt to action on the metal of the boiler.

At all the higher pressures the total solids undergo further diminution, with the exception of the figure in the fifth column, where there is a slight, but unmistakable, increase, which is more conspicuous when calculated on the feed water as in Table VIII. Between the time when a pressure of 150 pounds was reached and that when 200 pounds was registered, something seems to have happened which I cannot at present satisfactorily explain. The result is such as might be produced by a sudden inrush of feed water. In any case, I cannot attribute it to errors in the analytical determinations, as most of the results relating to these two samples were done in duplicate.

Between 200 and 250 pounds there is a sudden and very marked fall in the total solids, which may be fairly put down to the action of the increasing pressure and temperature on the solubility of calcium and magnesium sulphates, as it is plain from Table VIII. that the great bulk of the loss in total solids in the sixth column is accounted for by reductions in the SO_3, CaO, and MgO.

The lime is equivalent to 24·2 parts per 100,000 of calcium sulphate. Tilden and Shenstone's curve for the solubility of calcium sulphate in pure water indicates that from 25 to 26 parts per 100,000 should be soluble at the temperature attained under

the 250 pounds pressure, which is a sufficiently good agreement. At 200 pounds pressure, Tilden and Shenstone's curve gives the solubility as about 29 parts per 100,000, while the lime in the boiler water at that pressure is equivalent to 33 parts per 100,000 of calcium sulphate.

At the lower pressure, given in Table VIII., the point of saturation for calcium sulphate is never reached, and so the SO_3 remains practically the same or increases slightly; the lime decreases at first until most of the carbonate has been deposited—*i.e.*, till 100 pounds pressure is reached—after which it increases very slowly, until at 200 pounds a saturated solution remains.

The magnesium behaves in a somewhat unexpected manner. A considerable proportion of it remains in solution throughout the whole series of samples. In Table VIII., at 50 pounds pressure, there is actually more in solution than in the feed water, and, even when allowance is made for the concentration, the loss only amounts to one-third of the whole. It seems, therefore, fairly obvious that the carbonic acid which has gone out of solution is mainly combined with lime, unless, indeed, magnesium carbonate is deposited only to part with its carbonic acid immediately afterwards; but even then it is not easy to see how the latter could get once more into combination with any of the bases still left in the water.

From the time 100 pounds pressure is reached, practically no combined carbonic acid leaves the water, and yet the MgO goes on disappearing in regularly increasing amounts for every 50 pounds rise of pressure.

That the MgO should not be deposited as long as any CaO remains in solution is quite in accordance with the observations of C. H. Bothamley (*Chem. Soc. Journ.*, 1893, 698), who found that when solid calcium carbonate is left in contact with a solution of magnesium sulphate, or solid magnesium carbonate with a solution of calcium sulphate, magnesium sulphate is always eventually found in solution, and calcium carbonate is deposited.

TABLE X.

Lancashire Boiler, working pressure, 70 to 80 lbs.

	Feed Water.	Water in Boiler after working 82 hours.	Water in Boiler after working 468 hours.	The same Water evaporated at about 6 oz. per square inch.
Nitric acid (N_2O_5) ...	1·315	3·587	6·48	16·29
Chlorine (Cl)	1·70	15·75	37·0	37·00

Table IX. contains the analytical results of two samples taken from a boiler, using New River water, at the expiration of the periods stated, together with those of the feed water. In order to get some idea of the difference of composition produced by evaporating at the ordinary pressure and at high pressure, a quantity of New River water was evaporated in the laboratory until it had the same *chlorine* figure as

the sample taken from the boiler after it had worked 468 hours. This was then analysed, and the results are placed side by side with those for the boiler sample of the same concentration.

The value of the figures is somewhat lessened by the fact that an organic boiler fluid was used in the boiler. Only 2½ gallons, however, was employed during the whole period, and it is probable that only the nitrates were in any way affected by it.

Of course, in the water evaporated in the laboratory, which was distilled from a 5-gallon tin can, which was replenished until the residue had the desired concentration, no boiler fluid was used.

Table X. gives the figures for the same samples after allowance has been made for evaporation in the usual way.

TABLE XI.

	Feed Water.	After 82 Hours.	After 468 Hours.	Evaporated at Ordinary Pressure.		Incrustation from Boiler. Parts per cent.
Nitric acid (N_2O_5) ...	1·32	0·39	0·30	0·75	moisture and organic matter	4·26
Chlorine (Cl)	1·70	1·70	1·70	1·70		
Carbonic acid (CO_2) ..	8·68	4·84	2·80	0·09		32·65
Sulphuric acid (SO_3) ...	3·57	1·98	1·38	2·75		4·42
Silica (SiO_2)	—	0·55	0·38	0·13		7·24
Oxide of iron, etc. ...	—	0·04	0·01	0·03		0·39
Lime (CaO)	11·8	2·91	0·62	2·19		44·84
Magnesia (MgO)	0·81	0·05	0·008	0·15		6·20
Total solids	33·7	12·41	8·36	10·8		—

The differences between the analytical results obtained from the samples of the same concentration evaporated at different pressure are much greater than would be expected. The N_2O_5 is between two and three times as great in the water evaporated at ordinary pressures, but this is no doubt partly accounted for by the presence of the boiler fluid; but, of course, it is quite possible, and indeed probable, that nitrates are more readily reduced by the metal of the boiler at high than at low temperatures. The tin can in which the *laboratory* sample distilled had lost most of the tin from its inner surface, so it is not surprising to find in Table X. that even here the nitric acid has been considerably reduced in amount.

The most surprising difference is found in the carbonic acid. The figures for it in this and in all the tables are really the *alkalinity expressed as* CO_2. (In the incrustations the CO_2 figures are the result of *direct* estimation.) There is actually less in the water evaporated at the ordinary temperature than in the sample taken from the boiler. As the estimations were done in duplicate, I am not disposed to attribute the discrepancy to error of analysis. A number of possible causes at once suggest themselves, but it would be unwise to speculate without further investigation.

The SO_3 is exactly double in the fourth column of what it is in the third. The difference here may fairly be put down to the high pressure and temperature combined affecting the solubility of the calcium sulphate.

The behaviour of the lime is almost as puzzling as that of the carbonic acid. In spite of the latter having almost entirely disappeared when the water was concen-

trated at ordinary pressure, three times as much lime remains in this sample as in that taken from the boiler. A glance at Table X., however, shows that the loss of lime when concentration takes place at ordinary pressure is mainly due to the deposition of calcium carbonate, the amount of sulphate of lime leaving the water being very small. At higher pressures it has already been seen that the latter salt becomes much less soluble.

Finally, the magnesia has diminished considerably less at the low than at the high pressure, which is quite in keeping with what happened in some of the other series of analyses.

The temptation to theorize and to draw conclusions even in the complicated phenomena under discussion is very great, but the series of analyses are not sufficiently extended and do not deal with waters of sufficiently varied types to justify it. They do, however, suggest many points of theoretical interest which require investigation, and may perhaps eventually pave the way to a clearer knowledge of the behaviour of salts in solution when heated under pressure.

I have to express my indebtedness to Mr. Charles E. Franck, my late assistant, and to Mr. F. W. Arnaud, for valuable assistance in carrying out the somewhat monotonous series of analyses.

Discussion.

Dr. Rideal said that an investigation of this kind ought to throw some light on the mineral constituents of natural water. The composition of natural water must depend upon the temperature and pressure at which the saline constituents came into contact with the water.

Mr. Jenkins desired especially to thank the author for the figures which the paper contained, which would be of great interest to many chemists. He would like to hear whether the author had any experience of an alkaline water, such as that referred to in Table V., showing, after evaporation, any evidence of caustic alkali. Dr. Paul had some considerable time ago recorded results indicative of the presence of caustic soda, as well as of carbonate of soda, in boiler water. It was within his own knowledge that water softened with a small quantity of soda (introduced as caustic soda, but fully carbonated before the water was put into the boiler) contained, after concentration in the boiler, small quantities of caustic alkali, as shown by titration with phenolphthalein and methyl orange. He had himself met with a case of salt scale from a land boiler which had to use water containing a considerable quantity of common salt. This scale contained about 80 per cent. of sodium chloride, most of the remainder being magnesium sulphate.

Mr. Allen said that a good deal of the effect of magnesium chloride was mitigated in the presence of an excess of sodium chloride, whereby it might be converted into a fairly stable double chloride of magnesium and sodium which did not decompose on evaporation. A similar reaction was to be observed in the case of magnesium chloride and ammonium chloride, a double chloride of magnesium and ammonium being formed which would stand evaporation. In fact, this was the explanation of the fact that sea water could be used in a boiler without serious corrosion taking place. Any calcium sulphate present in a boiler water (at any rate from a

high-pressure boiler) must be looked upon as absolutely insoluble, it being a well-established fact that calcium sulphate was insoluble in water under a pressure of, say, two additional atmospheres. Having regard to the conditions under which water could be softened by means of sodium carbonate, mixed perhaps with lime, he was driven to the conclusion that calcium carbonate was not insoluble in water under all conditions, as was supposed to be practically the case, and that it might often exist permanently in solution to a considerable extent, perhaps in a colloid condition, in which it was not readily precipitated by boiling. In instances within his recent knowledge, at least two or three times as much sodium carbonate had been added to water as was theoretically sufficient to precipitate all the calcium carbonate, and yet the water contained calcium carbonate representing a hardness of 7° or 8°, not capable of precipitation by an excess of sodium carbonate.

Mr. W. T. BURGESS inquired what was the source of the alkaline water referred to in Table V.

Mr. BEVAN said that he would like to hear how the carbonic acid had been estimated.

Mr. CHAPMAN said it was interesting to note how completely the magnesia seemed to have disappeared in two of the cases referred to. He would like to hear whether the author was of opinion that the whole of the magnesia had become converted by double decomposition into magnesium hydroxide.

The PRESIDENT (Mr. Fisher) said that he also had noted the alkaline water referred to in Table V., and had a certain amount of curiosity to know from what geological formation it came. It was a common experience to find alkaline water whenever a bed of clay was pierced at some distance from the outcrop of the porous beds. It seemed as though the magnesia disappeared as the carbonic acid disappeared from the water. Where the carbonic acid remained, as was indicated in Table V., it was bound by the potash and soda, and so the magnesia had not any control over it. It was interesting to notice how well the chlorine served as an index of concentration in connection with questions as to the formation of scale. The concentration which took place in the chlorine, where it was originally present in small quantities, afforded a valuable index of the ratio of feed water to evaporated water; but where the chlorine was higher originally than in most of the cases now referred to, there might not be quite so much certainty in applying that comparison.

Mr. CRIBB, in reply, said he saw no reason for supposing that caustic soda might not be present in boiler water as the result of some double decomposition, though he had not looked for it in the course of the present investigation. With regard to the question of the insolubility of calcium sulphate, all his analyses showed that, at any pressure at which he had experimented, a considerable quantity of calcium sulphate remained in solution. Had calcium sulphate been quite insoluble, all the lime should have disappeared, seeing that there was always more sulphuric acid present than was required by the lime; but in no case had this happened. The water referred to in Table V. came from the chalk under the London clay. The figures given under the heading "Carbonic Acid" were really the alkalinities of the waters expressed as CO_2, and were obtained by adding excess of standard acid and titrating back with alkali, using methyl orange as indicator. The end reaction was always considerably

obscured in the case of the very concentrated waters. He therefore could not claim any very great accuracy for the carbonic acid determinations in these cases. He was of opinion that the magnesia in the scale referred to in Table II. was in the form of oxide, and not of hydroxide, although in all the published analyses of scales he had seen the magnesia was put down as hydrate. It was pretty generally accepted that calcium sulphate was deposited as a hydrated sulphate, and afterwards underwent conversion into anhydrous sulphate, and in view of the high temperature to which one side of a thick incrustation would be exposed there was no reason why magnesia should not also become dehydrated.

Mr. JENKINS said that he had often found considerable quantities of calcium sulphate present in blow-off waters; and his experience was also that, in the case of such waters, the magnesia had nearly entirely disappeared. If one considered the magnesia as present in the form of carbonate rather than of chloride, the method of its precipitation became clear.

Mr. ARCHBUTT, who was unable to be present at the reading of the paper, has forwarded the following remarks:

One of the most interesting facts brought out by the paper was the very complete manner in which magnesia becomes precipitated in the boiler. This he was able to confirm from some analyses of his own. It seems probable that this is brought about by the calcium carbonate reacting with the magnesium salts, as shown by the following equation: $CaCO_3 + MgSO_4 + H_2O = CaSO_4 + Mg(OH)_2 + CO_2$; for Bohlig has shown that when calcium carbonate is boiled with a solution of magnesium sulphate, CO_2 is evolved, calcium sulphate is found in solution, and basic magnesium carbonate is precipitated. If the temperature be high enough, the precipitate consists of magnesium hydroxide (*Zeits. Anal. Chem.*, 1879, 195). The boiler scale in Table III. consists mainly of $CaSO_4$ and MgO; and as the original water contained a fair amount of carbonate, the whole of the precipitated calcium carbonate appears to have been used up in decomposing magnesium salts. It would be interesting to know what would happen in the case of a water entirely free from carbonates.

Another important fact confirmed by Mr. Cribb's experiments is that calcium sulphate does not, as commonly stated, become insoluble in water at 302° F., corresponding to a boiler pressure of 55 pounds per square inch. As Tilden and Shenstone's experiments related only to solutions of calcium sulphate in pure water and in water containing chlorides, it is satisfactory to find their results practically confirmed under conditions of actual boiler practice. It is a pity that in the interesting experiments contained in Table VIII. the heating at each temperature could not have been maintained for a longer period, but the results, confirmed by other analyses in the paper, seem quite to dispose of the contention that by merely heating hard water to 350° F. in closed heaters, without chemicals, the hardness can be reduced uniformly to 5 or 6 degrees, as has been stated. This statement can only be true of waters the hardness of which is mainly temporary. Nevertheless, it seems that after the removal of the temporary hardness a water containing a moderate amount of calcium sulphate might be prevented from forming scale by the judicious use of the blow-off cock and sufficiently frequent washing out of the boiler, so as to prevent the calcium sulphate from reaching the saturation point. Practical experience in many places seems to confirm this supposition.

The author's experiments and observations on the behaviour of magnesium chloride solutions when evaporated and distilled afford valuable information, and his promised further experiments on the behaviour of such solutions when distilled under pressure will be awaited with interest, as beyond the fact that waters containing much chloride and magnesia are found to be corrosive to boilers our knowledge is not as definite as it might be.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Determination of Chloral Alcoholate in Chloral Hydrate. F. Schmidinger. (*Monatsh. Chem.*, 1900, xxi., 36.)—Meyer and Haffter (*Ber.*, vi., 600) have recommended a method which is quoted in the Commentary to the Austrian Pharmacopœia, depending on a titration of the chloral hydrate with normal sodium hydroxide. According to the equation

$$CCl_3CH(OH)_2 + NaOH = CHCl_3 + HCO_2Na + H_2O$$

100 parts of the pure hydrate should react with 24·17 parts of soda, whereas 100 parts of chloral alcoholate only require 20·67 parts of alkali. The process is useful to ascertain whether a particular sample is pure; but it can only indicate the presence of alcoholate provided other impurities not capable of reacting with sodium hydroxide are absent. The author finds that Zeisel's methoxyl method (*Monatsh. Chem.*, 1885, vi., 992) is better adapted for the examination of chloral hydrate, and that it gives satisfactory results. About 1 or 2 grammes should be operated upon.

This process is carried out by boiling the substance with 10 c.c. of hydriodic acid of specific gravity 1·68 in a current of carbon dioxide, the flask being attached to an inverted condenser which is supplied with water at 40° or 50° C. The vapours pass through bulbs charged with water and amorphous phosphorus maintained at 50° or 60° C., and are then absorbed in two flasks filled with an alcoholic solution of silver nitrate. After about two hours the whole of the iodine resulting from the methylic iodide which is produced by the action of the hydriodic acid upon the methoxyl compound is converted into silver iodide; the alcoholic solution is diluted with water, and the precipitate is weighed as usual. F. H. L.

Detection of Antifebrin [Acetanilide], Phenacetin, Exalgin, and *P*-amidophenol in Antipyrine or Quinine. P. N. Raikow and P. Schtarbanow. (*Oesterr. Chem. Zeit.*, 1900, iii., 125.)—Two processes are recommended: Distillation with phosphoric acid for the detection of the acid radicle and observation of certain changes in colour, and distillation with potassium hydroxide for the detection of the basic constituent. One gramme of the substance is cautiously warmed with 3 c.c. of

phosphoric acid, specific gravity 1·7, to a temperature short of that which decomposes the aniline phosphate, when antifebrin, phenacetin, and exalgin yield distillates of acetic acid. Antipyrine, antifebrin, and exalgin become more or less yellow or brownish yellow; phenacetin gives very characteristic colours: at first the mixture is pink, then wine-red, red-violet, violet, bluish green, and finally dirty green. If the liquid is cooled at the red-violet stage, it retains its colour unaltered for a long time, and this colour is not affected by the presence of antipyrine or antifebrin. The violet tint appears immediately antifebrin containing only 2 per cent. of phenacetin is boiled with phosphoric acid.

To detect the base, a few decigrammes of the sample are heated with 2 to 4 c.c. of strong aqueous potash, allowing the distillate to drop on to a little chloride of lime solution in a test-tube, which is changed (if necessary) after each single drop has fallen. Antifebrin gives the violet colour characteristic of aniline with its first or second drop, and the tint steadily becomes stronger. With phenacetin, the first drops remain colourless, subsequent ones yielding a brick red, due to the phenetidine, while on further heating the chloride of lime becomes turbid, and an amorphous red substance collects on the surface of the liquid, which finally turns yellow and clear again. Mixtures of phenacetin with 2 per cent. of antifebrin may be recognised by the different boiling-points of their basic constituent, changing the receivers so as to collect the pure aniline in one, and the phenetidine in the second, third, or fourth. When pure antipyrine is boiled with caustic potash, the chloride of lime remains colourless; but afterwards a substance distills which renders the solution milky, eventually forms white scales, and, combining with aniline and phenetidine, may prevent them yielding their characteristic colour reactions. This substance, however, which is neither antipyrine itself nor a chlorine derivative, is not produced till after the aniline from a mixture of antipyrine and antifebrin has passed over, so that 2 per cent. of the latter is easily to be found. Mixtures of antipyrine with phenacetin do not exhibit the proper red colour unless the proportion of the phenacetin is relatively high; the chloride of lime becomes yellowish green, then yellowish gray. A material composed of 0·1 gramme of antipyrine, 0·01 gramme of antifebrin, and 0·03 gramme of phenacetin, yielded the violet aniline colour with its first drop of distillate, which was changed to an orange by the next drops, so that both the latter bodies could be identified in the antipyrine. Distilled with potash, exalgin yields oily drops of methylaniline floating on the chloride of lime solution; these quickly turn green, and a dirty-brown precipitate appears. The test succeeds in the presence of antipyrine and antifebrin.

Quinine gives rise to no volatile compound on distillation with potassium hydroxide which is capable of affecting the solution of bleaching powder. Before testing with phosphoric acid the free base must be liberated from its salts; then the alkaloid yields no acid vapours, while the liquid in the retort first becomes yellow, then shows an intense "yellow-bluish-green" fluorescence.

Traces (0·0001 gramme) of *p*-amidophenol in these febrifuges are indicated by a deep violet colour when the sample is shaken with the phosphoric acid in the cold; the solutions ought to be colourless. F. H. L.

ORGANIC ANALYSIS.

Sugar Estimation in Zeiss's Immersion Refractometer. J. A. Grober (*Centralbl. inn. Med.*, 1900, xxi., 201 ; through *Chem. Zeit. Rep.*, 1900, 73.)—In the original article this apparatus is fully described, and its sphere of usefulness outlined. By observing saccharine urine before and after fermentation, the difference in reading divided by 2·9 gives directly the percentage of sugar; and by examining albuminous urine before and after precipitation with acetic acid, the difference divided by 0·3 gives the albumin in parts per 1,000. F. H. L.

The Solubility of Essential Oils in Sodium Salicylate. M. Duyk. (*Bull. de l'Acad. belge royale ;* through *Journ. Pharm. Chim.*, 1899, x., 500-504 ; *cf.* ANALYST, this vol., 72.)

Oil of Peppermint.—This yields to dilute salicylate solution (4 : 1·5) 78 per cent. of soluble products containing menthone and nearly the whole of the menthol. The insoluble portion consists principally of hydrocarbons (? menthene), and other compounds but little known.

The menthol contained in the soluble and insoluble portions may be estimated in the following manner : Several grammes of the substance are boiled for two hours under a reflux condenser with 10 c.c. of acetic anhydride and 2 grammes of sodium acetate, and the acetyl value calculated from the difference between the amount of sodium hydroxide required by the acetic anhydride used and that required after acetylation.

The amount of menthol is obtained by the formula

$$x = \frac{60 \times A}{156},$$

in which A represents the amount of acetyl which has entered into combination, and 60 and 156 the respective molecular equivalents of acetic acid and menthol.

Oil of Black Mustard.—This consists of allyl sulphocyanide, and is insoluble in the salicylate solution.

Oil of Bitter Orange.—The aldehydic compounds (citral, etc.), which are present in very small quantities, dissolve in the salicylate solution. The limonene remains undissolved.

Oil of Rosemary.—An oil of doubtful purity yielded to the salicylate solution 16 per cent. of substances, with a strong odour of camphor. The insoluble portion had a higher rotatory power than the original oil.

Rose Oil.—This is completely soluble in dilute salicylate solution (4 : 1). When adulterated with paraffin compounds it is only partially soluble.

Santal Oil (Indian) contains only traces of compounds soluble in salicylate solutions.

Oil of Turpentine.—When pure, this is insoluble in the salicylate solution; but when oxidized, the aldehydic compounds which have been produced are soluble.

The test is valuable in detecting the presence of turpentine in soluble essences.

Oil of Thyme.—The whole of the thymol and carvacrol are extracted by the salicylate solution, and when separated form a colourless syrupy liquid. The hydrocarbons are left undissolved. C. A. M.

Terpeneless Essential Oils of Lemon and Orange. N. Wender and G. Gregor. (*Chem. Zeit.*, 1900, xxiv., 210.)—The authors have examined samples of these oils which were described as being "terpeneless," obtained from three well-known firms, and they record their results herewith. The opticity was determined in a 100-millimetre tube at 20° C., using sodium light passed through a chromate solution; and owing to the high rotatory power of the oils themselves, they were tested in the form of alcoholic solutions, preliminary experiments having shown that no appreciable errors in the readings are introduced by the dilution. As the terpenes of the essential oils are less soluble in water than the oxidized constituents, experiments were also tried to discover a relationship between the water-solubility of the "terpeneless" oils and their rotatory power, these being carried out by shaking a 10 per cent. alcoholic solution in a tall, graduated cylinder at 15° C. with increasing quantities of water, till a homogeneous, faintly opalescent liquid was produced. The last column in the table indicates the volume of water in c.c. required to dissolve 1 c.c. of the 10 per cent. alcoholic solution.

	Mark.	Strength of Solution, Per Cent.	Opticity of Solution.	Opticity of Pure Oil.	Solubility.
Lemon Oil ...	H. H.	25·61	−1·90°	−7·41°	400
,, ,, ...	Sch. and Co.	25·09	−0·25°	−0·99°	500
,, ,, ...	O. W. and Co.	23·83	+1·75°	+7·34°	1,000
Orange Oil ...	H. H.	25·87	+3·40°	+13·10°	500
,, ,, ...	Sch. and Co.	25·97	+16·60°	+63·91°	1,000
,, ,, ..	O. W. and Co.	20·85	+14·50°	+69·70°	1,200

Especially in the case of terpeneless orange oil, the solubility in water falls as the rotatory power rises; but it is clear that these oils are still of very uncertain composition, even when procured directly from reputable firms. F. H. L.

Estimation of Chromium in Chrome-tanned Leather. P. von Schroeder. (*Deutsche Gerber Zeit.*, 1899, December; through *Zeits. angew. Chem.*, 1900, 142.)—About 3 grammes of the leather are thoroughly ignited for two or three hours in a porcelain crucible. The residue is moistened with 60 per cent. nitric acid (specific gravity, 1·37), and solid potassium chlorate is added. The crucible is heated on the water-bath with fresh additions of acid and chlorate until the solution becomes red, when it is evaporated to dryness two or three times with strong hydrochloric acid. The solid matter is then washed into a porcelain basin by means of water, a few drops of dilute sulphuric acid are introduced, and sodium peroxide is cautiously dropped in until the green liquid changes to pure yellow. The hydrogen peroxide (which would reduce the chromic acid when the solution was acid, but which is inert in presence of alkali) is next removed, either by simple evaporation or by means of a little alcohol; the whole is mixed with 25 c.c. of 10 per cent. solution of potassium iodide and 25 c.c. of 1 : 5 sulphuric acid, and the iodine liberated is titrated with decinormal thiosulphate. Seven samples of chrome-tanned leather gave 0·82, 1·68, 1·43, 3·4, 2·9, 3·22, and 2·25 per cent. of metallic chromium respectively; but it should be noted that there appears to be no connection between the proportion of chromium and the quality of the leather. F. H. L.

INORGANIC ANALYSIS.

The Gas-Volumetric Estimation of Hydrogen. A. Colson. (*Ac. des Sciences*, 1900, cxxx., 330; through *Journ. Pharm. Chim.*, 1900, xi., 335.)—This method is based upon the fact that hydrogen is absorbed by silver hydroxide. The reaction takes place slowly in the cold, but at 100° C. is rapid, and furnishes a means of separating hydrogen from a saturated hydrocarbon or from oxygen.

The mixed gases are introduced into a eudiometer, provided near the top with a horizontal side-tubulure, in which has previously been placed 1 to 2 grammes of silver hydroxide. On heating the side-tubulure the mercury rises in the eudiometer, and the absorption is complete in two and a half to three hours. In calculating the true volume of the residual gas, allowance must be made for the tension of the water-vapour formed during the reaction.

Hydrogen is completely absorbed, even at a very low pressure, whilst, as the author shows in his test estimations, no absorption of ethane, methane or oxygen takes place. C. A. M.

The Estimation and Separation of Copper by means of Hydrazine Sulphate or Hydrazine Hydrochloride. P. Jannasch and K. Biedermann. (*Berichte*, 1900, xxxiii., 631-636.)

Estimation of Copper.—The hot solution of the copper salt is poured, with constant stirring, into a porcelain basin containing a solution of 5 grammes of pure sodium hydroxide in 50 c.c. of water. The resulting precipitate is reduced to cuprous hydroxide by adding 1 to 2 c.c. of a boiling 3 per cent. solution of hydrazine sulphate, and slowly heating the basin on the water-bath while its contents are continually stirred. On the further addition of 3 c.c. of the hydrazine sulphate solution the copper is reduced to the metallic state. After cooling, or diluting the liquid with boiled water, the precipitate is collected on a filter, washed with hot water, dried at 90° C., the paper ignited apart from the copper, and the latter oxidized over a Bunsen flame in a current of oxygen and weighed.

The results thus obtained in test experiments with copper sulphate were satisfactory.

Separation of Copper from Zinc.—In the authors' experiments the solution of the mixed sulphates was introduced drop by drop into a basin containing 50 c.c. of 10 per cent. sodium hydroxide solution. Five c.c. of a 3 per cent. solution of hydrazine sulphate were then added to the cold liquid containing a large excess of sodium hydroxide, and the whole slowly heated on an asbestos board. After about five minutes there was a complete precipitation of the copper, which was collected and oxidized as described above.

The filtrate containing the zinc was treated with hydrochloric acid, until the precipitate, which formed after some time, again dissolved, and the liquid was distinctly acid. The zinc was then precipitated as carbonate, which was ignited and weighed in the usual manner. Sometimes the zinc oxide obtained was not completely soluble in dilute acetic acid owing to the presence of traces of silica.

In this way the following results were obtained :

In Solutions used Per Cent.		Found Per Cent.	
Copper.	Zinc.	Copper.	Zinc.
16·77	7·74	16·73	7·68
15·69	8·68	15·61	8·68

Separation of Copper from Arsenic.—A solution of copper sulphate and arsenic acid was introduced drop by drop into 40 to 50 c.c. of 10 per cent. sodium hydroxide solution, the liquid warmed after the introduction of 4 to 5 c.c. of hydrazine sulphate solution, and the precipitated copper estimated as before.

The solution containing the arsenic was acidified with hydrochloric acid, a little nitric acid being added with it towards the end of the neutralization, and the whole evaporated to about 80 c.c., care being taken to have some nitric acid continually present. The clear liquid when cold was treated with ammonium hydroxide in excess, and the arsenic precipitated with freshly-prepared magnesia mixture, and estimated in the usual way. Results :

Taken Per Cent.		Found Per Cent.	
Copper.	Arsenic.	Copper.	Arsenic.
17·53	23·41	17·46	23·37
13·68	35·29	13·56	35·24

Separation of Copper from Tin.—Mixtures of pure copper and tin were dissolved in *aqua regia*, the solutions diluted with an equal volume of water, and added drop by drop to a hot solution of sodium hydroxide containing fifteen times more alkali than the weight of the dissolved metals. After the addition of 2 to 3 grammes of hydrazine hydrochloride the liquid was heated, and the heating continued for some time, in order to dissolve as sodium stannate any tin carried down with the copper. In the absence of sulphates any tin readily dissolved. The copper was collected on a double filter, washed with boiling water, and if necessary with dilute sodium hydroxide solution and again with water, dried, oxidized and weighed.

The filtrate was rendered slightly acid with strong hydrochloric acid, and the tin precipitated with ammonium hydroxide. The precipitate was dissolved by adding ammonium sulphide, and the liquid heated for a time on the water-bath and then slightly acidified with hydrochloric acid. After being heated for about an hour on the water-bath, the resulting precipitate of tin sulphide subsided and could be easily filtered. It was washed with warm hydrogen sulphide solution, ignited in a current of oxygen and weighed. The following results were obtained :

Taken Per Cent.		Found Per Cent.	
Copper.	Tin.	Copper.	Tin.
25·81	74·18	25·72	74·06
31·28	68·61	31·28	68·48

C. A. M.

The Analysis of Molybdenum Alloys. H. Borntträger. (*Zeit. anal. Chem.*, 1900, xxxix., 91.)—As a supplement to his method of analysing molybdenum glance

(ANALYST, xxiii., 332), the author describes the following process for determining molybdenum in its alloys:

About 1 gramme of the sample is dissolved in 50 c.c. of *aqua regia* on the water-bath, the solution evaporated in a porcelain basin, and the nitric acid expelled by means of hydrochloric acid.

The residue is taken up with 50 per cent. alcohol, and the liquid filtered. The residue left on the filter will now contain the bulk of the molybdic acid.

The filtrate is evaporated to dryness, and the residue once more taken up with alcohol, after which treatment the remainder of the molybdic acid will be left as a residue.

The molybdic acid in the two residues can then be weighed directly, whilst the metal in the solution can be estimated in the usual way as oxide.

From an alloy known to contain 66 per cent. of molybdenum and 44 per cent. of iron, the author obtained by this method 65·6 per cent. of molybdenum. C. A. M.

The Detection of Boric Acid in the Form of Borates. H. Borntträger. (*Zeit. anal. Chem.*, 1900, xxxix., 92.)—When borates are heated with hydrochloric, nitric, or sulphuric acid, a Bunsen flame is not coloured green. On the other hand, when heated with hydrofluoric acid alone, or with ammonium nitrate and ammonium chloride, or with sulphuric acid and hydrochloric acid, or sulphuric acid and nitric acid, or hydrochloric acid and nitric acid, borates impart a bright green colour to the flame; and this coloration is more intense, and appears sooner, than that obtained on heating the salts with alcohol and sulphuric acid. C. A. M.

A New Method of estimating Bromides in the Presence of Chlorides and Iodides. J. v. Weszelszky. (*Zeit. anal. Chem.*, 1900, xxxix., 81-91.)—Bromine can be determined in the presence of chlorine by taking advantage of the fact that in an alkaline solution it is oxidized by chlorine to bromic acid, as in the equations:

$$Br + 6KOH + 5Cl = KBrO_3 + 5KCl + 3H_2O, \text{ and}$$
$$KBr + 6KOH + 3Cl_2 = KBrO_3 + 6KCl + 3H_2O.$$

The excess of chlorine is converted into chloride and chlorate; but as the solution of the latter salt is too weak to act upon iodides in the cold, the amount of bromate formed may be determined by adding a solution of potassium iodide, acidifying, and titrating the liberated iodine.

For the separation of bromine and chlorine from iodine, the author makes use of Winkler's method, which is based upon the fact that chlorine oxidizes iodine or iodides in acid solution to iodic acid, whilst the bromine is only liberated. Thus, on acidifying a solution of the mixed halides, adding an excess of chlorine water, and boiling the liquid, the resulting iodic acid remains behind, while the bromine and excess of chlorine distil over. On adding potassium iodide to the cooled liquid in the flask, and titrating with $\frac{N}{10}$ thiosulphate, a sixth part of the iodine found corresponds to the iodine originally present.

In applying these reactions, if the solution contains no iodine, about 1 gramme

of potassium carbonate is introduced, together with a sufficient quantity of chlorine water, and the liquid cautiously evaporated to dryness over a naked flame. The residue, when cold, is dissolved in 100 to 150 c.c. of water, potassium iodide added, and the liquid acidified and titrated with $\frac{N}{10}$ thiosulphate. The number of c.c. used, multiplied by 0·001333, gives the quantity of bromine.

When iodine is present, the liquid is placed in a distilling flask, similar to that used by Bunsen and Fresenius in the analysis of manganese peroxide (Fresenius, "Quantit. Analyse," 6th edit., i. 382). This is connected with an absorption vessel, containing 0·5 to 1·0 gramme of potassium hydroxide dissolved in water. After the addition of a sufficient quantity of chlorine water, the flask is warmed, and when the greater part of the chlorine and bromine has passed over, a current of carbon dioxide is passed through the apparatus until the end of the distillation.

The bromine in the distillate and the iodine in the flask are determined by titration with thiosulphate, as described above.

When the solution of the halogen contains iron, the latter should be separated by precipitation with potassium carbonate; arsenic and antimony when present must also be removed.

The author gives tables of the results of test analyses of experimental mixtures of bromides, iodides, and chlorides, from which it appears that the method is extremely accurate, even when only minute quantities of the halogens are present.

C. A. M.

The Determination of Clay in Soils. F. Poquillon. (*Bull. Soc. Chim.*, 1900, xxiii., 115, 116.)—The author recommends the following method as being much more rapid than the usual process, requiring at the outside only two or three days.

Ten grammes of the soil are triturated with about 25 c.c. of water added drop by drop, and 100 to 120 c.c. of a solution of ammonium chloride (1 gramme per litre) added to the mixture. The mass is stirred with a glass rod, and after standing for five minutes the supernatant liquid is transferred to a litre flask. The residue is again treated with 100 to 125 c.c. of the ammonium chloride solution, and the liquid again decanted after five minutes, this process being repeated until the washings are clear. About six or eight washings are required in the case of heavy clay soils. The residue is then treated with dilute hydrochloric acid, washed with water, dried, and weighed, the weight giving the amount of total sand.

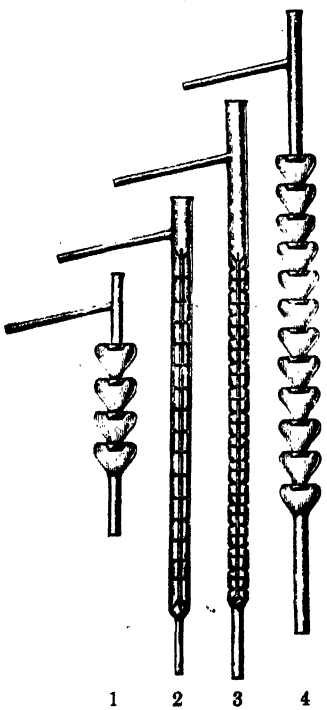
The liquid in the flask is treated with a few drops of hydrochloric acid to dissolve carbonates and to coagulate the clay, after which it is left until the supernatant liquid is clear. This usually takes two or three hours. The deposited clay is then collected on a weighed filter, washed with water, dried, and weighed.

The following results were obtained by this method, and by the ordinary method, which takes from eight to ten days:

Clay in the Soil.—Parts per Thousand.

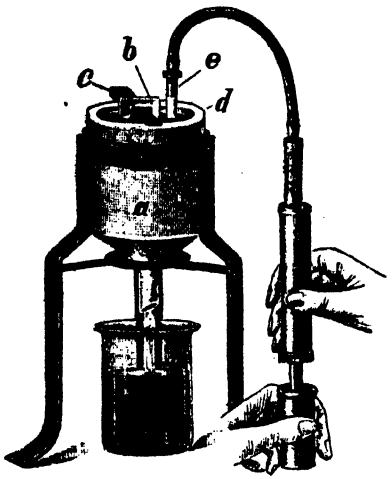
Old method	... 206·0	60·2	198·0	218·0	122·0	129·3
New method	... 205·3	60·5	198·0	217·1	121·9	129·5

C. A. M.



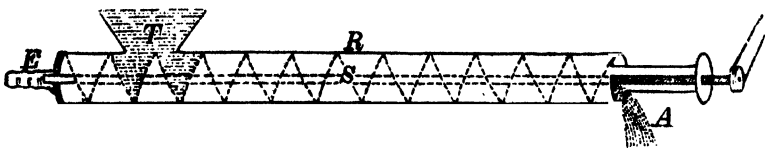
A New Indicator: Alizarin Green B. J. Formánek. (*Zeit. anal. Chem.*, 1900, xxxix., 99-103.)—Alizarin Green B, which is manufactured by Dahl and Co., Barmen, is obtained by the action of β-naphtho-quinone-sulphonic acid on (2)-amido-(1)-naphthol-(4)-sulphonic acid.

It is a greenish-black powder, which dissolves fairly readily in water, forming a dirty-green solution. It is somewhat less soluble in alcohol, the colour of the solution being flesh-red. On adding a dilute acid to the alcoholic solution the colour becomes carmine red, whilst alkalies change it to a pure green. Like litmus, it is sensitive to carbonic acid.



The changes in the colour reactions are exceedingly sharp, and are as perceptible with an artificial light as in daylight. C. A. M.

APPARATUS.



Some Improved Still-heads. S. Young. (*Journ. Chem. Soc.*, 1899, lxxv., 679.)—In this article the author draws attention to the various defects of the popular dephlegmators, and shows that the Glinsky tube (glass balls) is inferior even to the Le Bel Henninger (platinum gauze and lateral reflux tubes). He then describes two new forms of apparatus, which are illustrated herewith. Figs. 1 and 4 represent the "pear" head of different sizes. In this the liquid condensed in any particular bulb drops vertically through the lower ones without travelling over the surface; and thus the quantity of condensed fluid is diminished. Figs. 2 and 3 show the "rod and disc" heads. The discs are flanges of glass constructed on a glass rod by "upsetting" it at the necessary places. In Fig. 2 the main tube is parallel, and the rods-and-discs can be withdrawn; in Fig. 3 the tube is provided with constrictions, which increase the efficiency of the device. To obtain fractionation equivalent to that yielded by a three-bulb Le Bel Henninger tube, the rod-and-disc apparatus, or preferably the "pear" tube is advocated. They are simpler, better suited for the treatment of small volumes of liquid, and at the end of the process return almost all the residue to the still [while, as the makers point out, the "pear" head enables the retort to be recharged without disarranging the whole apparatus, and without danger of breaking the tube]. For an efficiency equal to that of a Young and Thomas dephlegmator of 12 or 18 columns, however, the new heads are too long; and therefore either the former device, modified according to the illustration on p. 700 (*loc. cit.*), should be retained, or preferably an "evaporator" still-head (p. 696) should be adopted. The improved heads are made by J. J. Griffin and Sons. F. H. L.

A Laboratory Filter Press. **W. v. Loeber.** (*Chem. Zeit.*, 1900, xxiv., 193). —This apparatus is specially suitable for the filtration of hot or volatile liquids where the ordinary suction-pump exhibits certain disadvantages. *a* is a cylindrical porcelain vessel carrying a perforated false bottom just above its conical base. At the top it is fitted with a flange, the internal edge of which is elliptical in shape; and the cover, also elliptical, is of larger area than the aperture. The cover has an open handle (*b*), through which a wooden wedge (*c*) is driven, and this arrangement pulls it upwards against the inner surface of the flange, making a tight joint through the agency of a rubber washer. [This part of the device is precisely analogous to the "manhole" of a steam boiler.] The tube *e* is closed at its internal end, but has a lateral opening; a piece of rubber tube is slipped over it to form a non-return valve. Pressure is applied by means of a pneumatic tyre inflator. In using the apparatus a moistened filter-paper is laid on the perforated bottom; and if the liquid is such that the paper does not lie flat, the two halves of a split porcelain ring are placed on it to hold it down. The cover is then brought within the flange at right angles to its proper position, held lightly with the wedge, and the liquid is run in through a funnel; the cover is next rotated to its correct position, tightened up, and the pressure applied. If the precipitate is one of those that fissure before they are fairly dry, thus permitting escape of air, when the bulk of the filtrate has run through, the apparatus is opened, another paper is laid on the top of the precipitate, the cover is wrapped in a thin sheet of rubber, *e.g.*, a piece of a toy air-balloon, and the joint is made as before. On pumping up, the rubber expands till it fills the space of the filter, pressing the top paper downwards on to the precipitate, and thus acting as a press. To release the pressure it is then necessary to puncture the rubber from beneath by means of a needle; but the hole in the sheet can be afterwards mended with tyre solution. A cyclist's pressure-gauge can be added if desired. The machine, made in two sizes, 250 c.c. and 2 litres, is on sale by the Actienges. für pharmaceut. Bedarfsmittel, Cassel, and has been protected as a "Gebrauchsmuster" in Germany. F. H. L.

A Laboratory Apparatus for igniting Large Quantities of Substances. **G. P. Drossbach.** (*Berichte*, 1900, xxxiii., 486.)—By means of the simple device shown

in the figure several kilogrammes of solid matter in the form of powder may be ignited in any gas required.

It consists of a tube (*R*), provided with a funnel (*T*), and a spiral conveyor (*S*), driven by a motor. The solid substance is introduced through *T* into the heated tube, and the gas at *E*, while the ignited product is discharged at *A*.

If the tube is 30 centimetres long and has a transverse section of 1 square c.c., and the spiral revolves once in a second, the substance will remain for a minute in the hot tube. C. A. M.

DIVISION OF SAMPLES UNDER THE SALE OF FOOD AND DRUGS ACT.

QUEEN'S BENCH DIVISION.

(Before Mr. JUSTICE DARLING and Mr. JUSTICE BUCKNILL.)

MASON *v.* COWDARY.

(*From the* PHARMACEUTICAL JOURNAL, *June* 9, 1900.)

THIS was a special case stated by the Justices of Bedford. It stated that, at a Petty Sessions held at Luton, January 8, 1900, an information was preferred by Geo. Mason, under Section 6 of the Sale of Foods and Drugs Act, 1875, against Ellen Cowdary, that she on November 16 did unlawfully sell to the prejudice of the appellant camphorated oil which was not of the nature, substance and quality demanded. The respondent kept a small shop in the village of Leagrave, Beds, and the appellant purchased from her six twopenny bottles of camphorated oil. The oil was exposed for sale in bottles which were not apparently prepared by respondent, but each of them bore a label with the name of a chemist in the neighbouring town of Luton. There was no evidence whether or not the bottles were identical in character or appearance, or whether or not the labels all bore the name of the same chemist, but the six bottles were all purchased at the same time. At the time of the purchase, the appellant intimated to the respondent his intention to have the oil analysed, and he divided the six bottles into three lots of two bottles, each of which he sealed up, handing one lot to the respondent, keeping one lot, and sending the other lot to be analysed. Appellant did not open any one of the bottles of oil, or mix or divide the contents; but the two handed to the respondent were in the same condition as when purchased. The appellant received from the Public Analyst a certificate of the analysis of the contents of the two bottles submitted to him, and the analysis was put in evidence. It showed that the camphorated oil in the bottles analysed contained only 17·5 per cent. of camphor, whereas proper camphorated oil should contain 20 per cent. of camphor. For the part of the appellant, it was contended that the requirements of Section 14 of the Sale of Food and Drugs Act had been complied with by him, inasmuch as he had divided the article into three parts, each of which was marked and sealed; but the justices were of opinion that the appellant had not complied with the requirements of Section 14, and, further, that they were not satisfied that the two bottles analysed by the analyst were identical in nature and substance with the other two sets of bottles in the hands of the seller and the appellant respectively. They accordingly dismissed the summons.

Mr. BONSEY said the appeal had been made because the appellant wished the point decided whether or not it was necessary to divide up each bottle in order to comply with Section 14.

Without calling on the other side, their lordships held this was a purchase of six separate articles, and therefore each required dividing and analysing. The appeal was therefore dismissed with costs.

APPOINTMENT.—Mr. Norman Leonard, B.Sc., F.I.C., has been appointed Public Analyst for the Borough of Northampton, *vice* Mr. Raymond Ross, resigned.

THE ANALYST.

AUGUST, 1900.

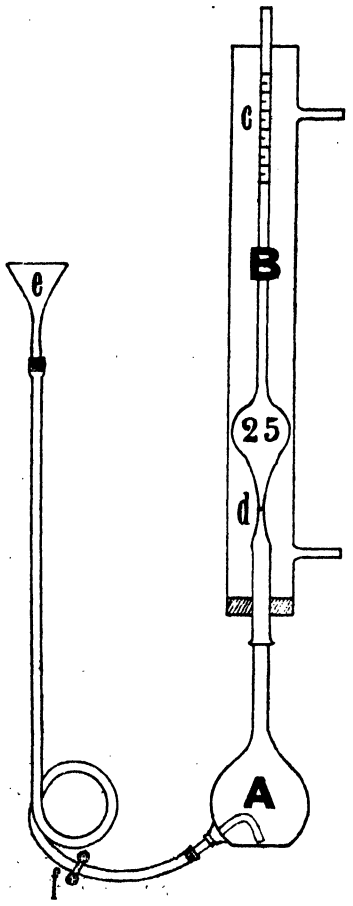
PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

ON AN IMPROVED ABSORPTION APPARATUS FOR USE IN THE ANALYSIS OF ESSENTIAL OILS.

By Alfred C. Chapman, F.I.C., and H. E. Burgess.

(*Read at the Meeting, April* 4, 1900.)

Absorption methods involving the removal of certain active constituents of essential oils by means of appropriate reagents, and the subsequent measurement of that portion which remains unabsorbed, are of very frequent application in laboratories where these oils are examined. As examples, the estimation of citral in lemon and lemongrass oils, cinnamic aldehyde in oil of cassia, and eugenol in oil of cloves, may be mentioned.



The instrument almost invariably used for such determinations is a simple glass flask capable of holding about 200 c.c. Its neck has such a capacity that it will hold 25 c.c. of the oil, and the space between the zero and the 25 c.c. mark is graduated in $\frac{1}{5}$ths, and sometimes $\frac{1}{10}$ths, of a c.c.

This piece of apparatus is known as a Hirschsohn flask, and there are many objections to be urged against its use. In the first place, it is practically impossible to treat the oil under examination with a second quantity of the reagent, or to wash it; it is, moreover, impossible, as a rule, to shake the mixture in the flask with sufficient vigour for fear of obtaining an emulsion, which will not readily separate, and any insoluble matter, such as is frequently formed on shaking the oil with the necessary reagents, accumulates at the junction of the two liquids, thus obscuring the meniscus and reducing the accuracy of the reading, an error which is further increased by the closeness of the graduations, due to the width of the neck.

It was to obviate to some extent these objections that we devised the piece of apparatus represented in the accompanying figure.

It consists essentially of two parts, the flask A of about 250 c.c. capacity, and

the measuring tube B. The latter is accurately ground to fit the flask A, and is arranged so that the volume intervening between the zero mark of the scale C and the mark *d* is exactly 25 c.c. The portion of the tube above the bulb has a considerably smaller diameter (about 5 millimetres) than that below, and is graduated downwards in 0·1 c.c., from 0 to, say, 5. The flask A has a tubulure at the bottom, through which passes a glass tube connected by indiarubber tubing to the funnel *e*. Communication between the two may be closed or established by means of the pinch-cock *f*.

In using the apparatus, 25 c.c. of the oil to be analysed is pipetted at a known temperature into the flask, and is there treated with a sufficient quantity of the necessary reagent, the pinch-cock *f* being closed. When the soluble portion has been dissolved, the aqueous layer may be run off by opening the pinch-cock, and hot or cold water for washing purposes may be run in through the funnel *e*, or a further quantity of the reagent may be introduced if it is thought that the absorption has not been quite complete.

The measuring tube is then fixed in position and the residual washed oil is transferred to it by running cold water through the funnel. The tube is next fitted with a cylindrical glass jacket, water is poured into, or circulated through, it, and the oil brought to the temperature at which it was originally measured out. Then, by raising or lowering the funnel, the meniscus is brought exactly to the lower mark, and the reading on the narrow portion of the tube taken, from which the percentage of the absorbed constituent can be at once determined.

It is obvious that several measuring tubes of different shapes and sizes may be fitted to the same flask, the character of the tube depending in each case on the precise purpose for which it is to be used.

The tube represented in the figure is suitable for the estimation of citral in oil of lemons, or for the examination of any other oil in which the soluble constituent does not occur to the extent of more than about 20 per cent.

This apparatus has now been in constant use for some months, and during that time many determinations have been made, working on artificially-prepared oils containing known percentages of the soluble constituents, with very satisfactory results.

Since our communication was made to the Society, we have seen in a paper by Soldaini and Berté a description of a piece of apparatus intended for the analysis

of lemon oil, which is very similar to ours in principle, but in which only 5 c.c. of the oil are used. So far as we are able to judge from the description, however, we are inclined for several reasons to give the preference to the apparatus described in this paper.

We may add that the complete apparatus may be obtained from Messrs. C. E. Müller and Co., 148, High Holborn, London, W.C.

Mr. CHAPMAN, in reply to a question put by Dr. Lewkowitsch, said that he had had experience of the direct method of determining eugenol, based on the conversion of the eugenol into benzoyl-eugenol, and had found that this method involved errors rather greater than those of estimation by difference.

ON THE COMPOSITION OF DANISH BUTTER.

BY HARALD FABER.

(*Read at the Meeting, April* 4, 1900.)

THE following few remarks on the composition of Danish butter were originally intended only for use in the discussion of a paper by Mr. Estcourt on "Butter from Various Countries Compared."

Very full information of the amount of water in Danish butter is obtained by the numerous analyses made in connection with the State Butter Shows in Copenhagen (Foreign Office Report, 1889, Miscellaneous, No. 151). Table I., showing the amount of water found by the analysis of about 12,000 samples during nine years, calls for very few remarks. The average is about 14 per cent., most samples having from 13 to 15 per cent., and very few less than 12 per cent., or more than 16 per cent.

TABLE I.

AMOUNT OF WATER IN DANISH BUTTER.

According to analyses of samples at the State Butter Shows.

Yearly Averages.

	Number of Samples.	Percentage of Water.
1890-94	4,458	14·32
1895	1,517	13·70
1896	1,992	13·68
1897	2,016	13·79
1898	2,110	13·93

Samples grouped according to Amount of Water.

Percentage of Water.	Number of Samples as Percentage of Total Number.	
	1897.	1898.
10-11	0·8	0·4
11-12	4·9	2·4
12-13	17·1	12·6
13-14	37·4	37·0
14-15	29·7	35·3
15-16	8·5	10·3
16-17	1·2	1·7
17-18	0·4	0·3

The Customs have for some years taken samples of butter on landing. Duplicates of the samples of butter from Denmark have been analysed by Professor Stein at Copenhagen. From his reports I have compiled the following table (Table II.), showing monthly averages for the years 1898 and 1899 of the Reichert-Wollny figure, the refraction and also the number of samples which responded to the Becchi test. The refraction is by Zeiss's refractometer at 45° C.

The chemical composition of the butter-fat as expressed, for instance, by the Reichert-Wollny figure varies with the season, the time since calving, and the treatment generally of the cows. In Denmark cows are generally housed from the middle of October to the middle of May, and the calving takes place in autumn and winter. Correspondingly, we find the Reichert-Wollny figure higher in the winter and spring than in summer, and lowest in the autumn, the maxima (32·6 and 32·5) for the two years occurring in March, the minima (24·3 and 25·6) in October. The effect of moving the cows from cold fields to warm byres in October, additional to the increased number of new-calved cows, finds its expression in a rapid rise in the Reichert-Wollny figure from October to November.

It has at last been recognised, also by the chemists of the Government Laboratory, that the feeding of cotton-cake imparts something to the butter which reacts to the Becchi test, and that, consequently, a cotton-oil reaction does not necessarily imply an addition of margarine. The comparison of the number of samples for the two years which gave the Becchi reaction is interesting. In 1898, which was remarkable for a luxurious growth of grass, the cows were grass-fed all through the summer, and from June to October inclusive not one sample exhibited the reaction, as no cotton-cake was used, while several samples reacted during the time the cows were stall-fed. The year 1899 was quite different; a cold and dry spring and a dry and hot summer affected the growth of grass so unfavourably that the cows had to have some additional food nearly all through the summer, and as cotton was the cheapest cake, and Russian sunflower cake (which is otherwise very much used) difficult to get, large quantities of cotton-cake were used, with the result that every fourth sample gave the Becchi reaction in summer-time, and six out of every seven responded to the test during the months of November and December.

TABLE II.

STATEMENT SHOWING VARIATION IN CHEMICAL COMPOSITION OF DANISH BUTTER.*

The samples analysed are duplicates of those taken by Her Majesty's Customs at port of importation.

THE POLARIMETRIC ESTIMATION OF CAMPHOR IN CAMPHORATED OIL.

By Norman Leonard, B.Sc., F.I.C., and H. Metcalfe Smith, F.I.C.

In a previous note on the examination of liniment of camphor (*Analyst*, 1898, xxiii., 272) we described two methods for the estimation of camphor in camphorated oil, one of which, yielding only approximate results, depended on a determination of the specific gravity of the liquid, whilst in the second and more accurate method the camphor was determined from the loss of weight on heating. Further experiments have shown us that by means of the polariscope the assay of camphorated oil may be effected both accurately and expeditiously.

The rotatory power of camphor in its solutions in alcohol, benzene, and some other organic liquids has been studied by Landolt and others, but, so far as we are aware, no experiments have been made with olive or other oils as solvents. We have therefore examined a number of solutions prepared by digesting known weights of camphor and olive oil together at the ordinary temperature until complete solution had been effected. In the table below are given: (1) The weight of camphor contained in 100 parts of the solution; (2) the specific gravity of the liquid at 60° F., compared with water at the same temperature; (3) the angular rotation for sodium light observed in a 200-millimetre tube with a Schmidt and Haensch half-shadow instrument; (4) the amount by which the specific gravity is raised by each 1 per cent. of camphor; (5) the angular rotation per 200 millimetres for each 1 per cent. of camphor. The olive oil used in the preparation of the solutions had a specific gravity 0·91666, and a rotatory power +0·13° per 200 millimetres. The latter figure was deducted from the observed rotations of the solutions in calculating the numbers in the fifth column of the table. The last solution was a saturated one prepared by gently warming olive oil with excess of camphor, cooling to about 10° C., and filtering; the camphor in it being determined from the loss of weight sustained on heating at 110° to 120° C.:

1. Camphor per cent.	2. Specific Gravity at 60° F.	3. Rotation per 200 Millimetres.	4. Specific Gravity raised per 1 per cent.	5. Rotation per 200 Millimetres per 1 per cent.
5·32	0·91903	+ 5·26°	0·000446	0·964°
11·26	0·92173	+ 11·35°	0·000450	0·996°
20·66	0·92604	+ 20·74°	0·000454	0 998°
26·78	0·92911	+ 26·79°	0·000465	0··996°

It will be seen from these results that the rotation is increased by nearly 1° for each per cent. of camphor present, and that the observed rotation of a sample of camphorated oil in a 200-millimetre tube gives at once, without calculation, the percentage of camphor with sufficient accuracy for most purposes. The rotation appears not to be appreciably influenced by ordinary variations of temperature. According to Bishop (*Journal of the Society of Chemical Industry*, 1887, p. 750), olive oil has a rotatory power +0·13° per 200 millimetres, and several specimens examined by us have given values closely approximating to this, values too small to affect

seriously the optical estimation of camphor dissolved in such oils. In the case of some other oils which are occasionally substituted for olive oil in liniment of camphor the rotatory power is greater. Thus, we have found the rotation of two specimens of rape oil to be $-0{\cdot}16°$ and $-0{\cdot}3°$, and of sesame oil $+1{\cdot}6°$, per 200 millimetres, results which are in accord with those of Bishop, whilst two samples of fluorescent mineral oil gave rotations of $+0{\cdot}12°$ and $+0{\cdot}42°$. Experiments with rape oil and mineral oil have shown us, however, that the increased rotation caused by the solution of camphor in the oils is practically the same as with olive oil, so that if the nature of the oil used in the preparation of the sample is known, the process is still applicable. With regard to the identification of the oil used, we have found that the sample may be examined directly with the refractometer, the refractive index of the oil being apparently almost unaffected by the presence of dissolved camphor.

It is worthy of notice that the specific rotation of camphor in its solutions in olive oil is shown by our experiments to be about $+54°$, a higher result than is given by any of the solvents examined by Landolt, and approximating to the value ($+55{\cdot}4°$) calculated by him for the absolute specific rotation of camphor.

Since writing the above, our attention has been called to an account of some experiments by E. Dowzard (*British Food Journal*, 1900, p. 69), who finds, by comparing the rotatory power of a number of samples of camphorated oil with the amount of camphor "ascertained by the gravimetric process," that the angular rotation per 100 millimetres multiplied by the factor 1·962 gives the percentage of camphor in the sample. This result is in fair agreement with our own experiments.

We are indebted to Dr. Thomas Stevenson for permission to use results obtained in his laboratory.

NOTE.—We are indebted to Mr. A. H. Allen for informing us, in a private communication, that P. Chabot (*Compt. rend.*, cxi., 231, and *Journal of the Chemical Society*, Abstracts, 1890, 1427) had previously determined the rotatory power of camphor when dissolved in various oils. A 20 per cent. solution in olive-oil gave the value $+55° 12'$, and this also agrees fairly with our own results.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Foreign Colouring Matter in Milk. **A. E. Leach.** (*Journ. Amer. Chem. Soc.*, vol. xxii. [4], pp. 207-210.)—To detect foreign colouring matters the author curdles 150 c.c. of the suspected milk by the aid of heat and acetic acid, the curd being collected in a lump by means of a stirring-rod, or else separated by straining through a sieve. The whole of any annatto or aniline-orange and a portion of any caramel colouring matter employed will be retained by the curd, which is next broken up and treated with ether for the extraction of fat and annatto. The residual curd will be

white if the milk has not been artificially coloured, or if only annatto has been used; whereas caramel will leave a brown curd, and aniline-orange a more or less bright orange tinge.

Annatto can be separated from the ethereal extract by evaporating the latter, making the residue alkaline with sodium hydroxide and pouring it on a wet filter, which will absorb annatto and acquire a fairly permanent orange tint, turning to pink in presence of stannous chloride.

Caramel may be regarded as present if the coloured curd from which the fat has been extracted yields a deep blue coloration on agitation with concentrated hydrochloric acid, such as the white fat-free curd of an uncoloured milk would give,* and may then be confirmed by any of the usual tests on a fresh sample of the milk. When aniline-orange has been employed the acid treatment develops a pink coloration immediately. C. S.

Artificial Cooking Fat and its Digestibility in Comparison with Lard. H. Lührig. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 73-87.)—This paper is a further instalment of the author's researches upon the digestibility of various fats (*cf.* ANALYST, 1899, xxiv., 237 and 283). Two preparations of cooking-fat were examined and compared as regards digestibility with lard. Preparation I. consisted of tallow and cotton-seed oil; Preparation II. of tallow, cotton-seed oil and lard, both being productions of a well-known margarine factory. The methods pursued were mainly the same as described in the author's previous communications. The following coefficients of digestibility were obtained: for lard, 96·36; for Preparation I., 96·09; for Preparation II., 96·47. H. H. B. S.

The Detection of "Vinoline" and Bordeaux Red in Wines. A. Casali. (*Staz. Speriment. Ital.*, 1900, xxxiii., 183-189.)—In the author's experience the artificial coloration of Italian wines is at the present time a very general practice, those from the central provinces being chiefly coloured with "vinoline," and those from the south with Bordeaux red.

The name "vinoline" is not applied to a single colouring matter, but usually denotes a mixture of different coal-tar reds. In Italian wines the author has found it to consist to a large extent of salts of rosaniline, such as the hydrochloride, acetate, nitrate, and (more rarely) the sulphate. In order to detect these, 100 c.c. of the wine are rendered strongly alkaline with ammonium hydroxide, and after the addition of a few drops of a solution of sodium hydroxide, shaken for a long time with 30 c.c. of chloroform. The solution of the colouring matter in chloroform becomes red on acidification, and when allowed to spontaneously evaporate leaves a scarlet residue.

Wines coloured with Bordeaux red (azo-naphthyl-naphtol-sulphonic acid) differ from those coloured with "vinoline" in giving a turbidity on the addition of hydrochloric acid. To detect this, 50 to 100 c.c. of the suspected wine are treated with 10 to 20 c.c. of a 10 per cent. solution of barium chloride, and sufficient potassium bisulphate

* In order to obtain this reaction, which is hastened by gentle heat, it is necessarythat the curd should be thoroughly freed from fat.

solution to precipitate the barium salt. When the precipitate has subsided, the supernatant liquid is decanted, and after the addition of 3 to 6 c.c. of hydrochloric acid and sufficient water to bring it to its original volume, it is boiled for 5 to 10 minutes with a few fibres of fat-free wool.

In the presence of Bordeaux red the wool is dyed a bright-red colour, which does not alter on adding ammonium hydroxide. In certain cases the colour appears to be carried down with the precipitate, and the wool, when boiled with the deposit and washed, assumes, on treatment with alkali, a green tint, which changes to red on again washing with water.

"Vinoline" colours which are not in the form of salts do not behave like the dyes mentioned above, but can be readily extracted from the wine by means of hot amyl alcohol. This extraction can be made even when 9 to 11 per cent. of alcohol are present and in the presence of acetic or hydrochloric acid. The wool dyed red in the amyl alcohol solution becomes green on treatment with ammonium hydroxide, and again red when washed with water. When dried and digested with dilute hydrochloric acid it colours the liquid violet-red—a property which distinguishes it from wool dyed with Bordeaux red. C. A. M.

Cider Vinegar; its Solids and Ash. R. E. Doolittle and W. H. Hess. (*Journ. Amer. Chem. Soc.*, vol. xx., [4], pp. 218-220.)—Two samples of imitation cider vinegar containing the statutory percentages of solids and ash were found on examination to furnish an evaporation residue resembling molasses, and of sharp acid odour, whereas the solids from the genuine vinegar are light and foamy in appearance, with an aroma of baked apples. The following results were obtained on analysis:

	Pure Cider Vinegar.	Apple Pomace Vinegar.	Suspected Vinegar. 1	Suspected Vinegar. 2	Boiled Cider.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Solids:					
Reducing sugar, before inversion	0-14	0	42·88	56·82	61·12
Reducing sugar, after inversion	0-10	0	33·36	57·04	66·45
Polarization, before inversion	0°	0°	+ 40·7°	- 31·14°	- 17·9°
Polarization, after inversion	0°	0°	+ 38·8°	- 34·25°	- 25·0°
Ash constituents:	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
CaO	3·4-8·21	4·73	4·70	37·95	
MgO	1·88-3·44	4·12	2·00	2·22	
K_2O	46·33-65·64	37·00	nil	7·84	
Na_2O	trace	trace	49·71	trace	
SO_3	4·66-16·29	34·78	27·04	12·74	
P_2O_5	3·29-6·66	9·66	0·005	1·82	
Fe_2O_3	trace	trace	trace	1·60	
CO_2, loss, etc.	40·44-0	9·64	16·54	35·83	

The suspected sample No. 1 was therefore compounded of dilute acetic acid, glucose and soda ash; No. 2 of acetic acid, boiled cider, and lime. C. S.

The Detection of Foreign Colouring Matters in Preserved Tomatoes. G. Halphen. (*Journ. Pharm. Chim.*, 1900, xi., 169-172.)

1. *Coal-tar Colours.*—The usual method of testing for these consists in mixing the tomato-pulp with dilute ammonium hydroxide, extracting it with amylic alcohol, and evaporating the extract in the presence of undyed silk. In the author's experience this has not proved satisfactory, partly on account of the readiness with which certain colouring matters become attached to the vegetable fibres, and partly because the particles of tomato prevent the solvent from coming into contact with the colour.

He has obtained better results by extracting the desiccated pulp with ordinary alcohol from an acid medium. An addition of an equal volume of sand or precipitated silica is advantageous during the drying, which in certain cases should take place at the ordinary temperature in order to prevent the possible decomposition of unstable azo-compounds. In very many cases, however, the mass may be dried on the water-bath.

The dried substance is pulverized, transferred to a flask, and covered with glacial acetic acid. The mass is well stirred and the flask closed, and left for ten minutes. The liquid is then mixed with twice its volume of alcohol (90 per cent.), and again allowed to stand. After ten minutes it is transferred to a filter, and the filtrate collected in a 250 to 300 c.c. flask. After the addition of ten times its volume of water, a small knot of flossy silk is introduced, and the liquid boiled for at least fifteen minutes. In the absence of coal-tar colours the silk becomes slightly yellow or brown, without any trace of red or rose; but in the presence of these dyes it assumes a rose-red or salmon colour.

2. *Cochineal.*—According to the author, this is always used in the form of a lake, and as these lakes are often not attacked by glacial acetic acid, it is frequently possible to detect the dyes in the residue left on the filter in testing for coal-tar colours. It is preferable, however, to use a fresh portion of the tomato, which is mixed with silica and dried on the water-bath.

The dried residue is thoroughly mixed with pure hydrochloric acid (specific gravity 1·16 to 1·17), and after being left for ten minutes the paste is shaken with twice its volume of 90 per cent. alcohol, allowed to stand for ten minutes, and filtered.

The filtrate is mixed with at least ten times its volume of water, and is shaken with sufficient amylic alcohol to form a layer of not less than 5 c.c. when the liquids separate. The lower aqueous layer is withdrawn, leaving the carminic acid and part of the natural colouring matter of the tomato in the amylic alcohol.

In order to separate these, from 1 to 1·5 times the volume of carbon bisulphide and 4 to 5 times the volume of water are added to the amylic alcohol, and the mixture shaken with a circular motion. After standing, the lower layer is removed and the upper aqueous layer filtered. When cochineal has been used the filtrate will have a rose colour, with more or less of a yellow shade, and on shaking with 2 or 3 c.c. of amylic alcohol the colouring matter can be extracted, forming a yellowish-red solution. The amylic alcohol solution is tested with a drop of a concentrated solution of uranium acetate, and on shaking gives a characteristic green coloration.

C. A. M.

The Occurrence and Estimation of Tin in Preserved Meat. F. Wirthle. (*Chem. Zeit.*, 1900, xxiv., 263.)—The author has recently had the opportunity of investigating some samples of tinned meat, one, two, three, and four years old, which had been preserved in vessels of tin-plate with folded seams, solder not being used. He found that the proportion of tin in the food slightly increased during the time of keeping after the second year, but between the first and second year there was a minute falling off in metallic contamination. He also corroborated Günther's statement that the amount of tin in the meat itself is about two or three times as much as in the liquor. His maximum figures were obtained on a sample four years old, where the meat gave 0·0094 per cent., while another specimen of beef of the same age gave 0·0082 per cent. in the meat and 0·0028 per cent. in the juice. A sample of beef five years old, on the other hand, contained 0·0325 per cent. of tin, and the liquor 0·014 per cent., the inner surface of the vessel being completely destroyed. Corrosion of the can occurs mainly where it comes in contact with the fat; and the white deposit noticed in bad cases consists of basic stannous chloride.

For the determination, 120 grammes of meat (or liquor and fat) are heated in a porcelain basin over an asbestos plate with 5 c.c. of strong sulphuric acid; the mixture is stirred at intervals, and more acid (altogether 15 or 20 c.c.) is dropped in gradually, until a porous carbonaceous mass is obtained. This is powdered and rinsed with dry sodium carbonate into a porcelain crucible, more sodium carbonate and some nitrate are added, and the whole is fused. The melt is extracted with water and a current of carbon dioxide is passed through the liquid. When clear, the precipitate is collected, washed, dried, and ignited, then heated in the covered crucible with potassium cyanide to a dull-red heat. The mass is treated with water, the metallic iron and tin filtered off, and dissolved in warm hydrochloric acid. The tin is precipitated with sulphuretted hydrogen, collected, washed with sulphuretted hydrogen-water containing some ammonium nitrate solution, dried and ignited with the paper to constant weight. F. H. L.

ORGANIC ANALYSIS.

The Detection of Benzene in Alcohol. G. Halphen. (*Journ. Pharm. Chim.*, 1900, xi., 373-375.)—As it has been proposed in France to denature alcohol for commercial purposes by the addition of benzene oils, the question has arisen as to whether it is possible to detect the presence of benzene in the alcohol recovered from such denatured products.

The author finds that the following method is extremely sensitive and gives good results. It consists in isolating the hydrocarbons and converting them into diazo-compounds, which combine with naphthols to form coloured compounds.

From 10 to 20 c.c. of the spirit under examination are shaken with 5 to 10 c.c. of carbon bisulphide in a separating funnel, and after the addition of ten times the volume of sodium chloride solution (about 20 per cent.), the funnel is inverted several times and allowed to stand. The lower layer of carbon bisulphide is withdrawn, and the hydrocarbons nitrated by the addition of 0·5 to 1 c.c. of a mixture of 10 c.c. of Nordhausen sulphuric acid and 1 c.c. of fuming nitric acid, the liquids being stirred

together for two or three minutes. The supernatant carbon bisulphide is then decanted, 5 c.c. of water added, the rise in temperature produced accelerating the separation of the last portions.

The acid layer is diluted with 15 to 20 c.c. of water and shaken with 4 or 5 c.c. of sulphuric ether, in order to remove the nitro-compounds, which are nearly insoluble in water.

The residue left on evaporating this extract is treated with 20 c.c. of water acidulated with hydrochloric acid (5 to 10 per cent.), then with one drop of a solution of platinic chloride, and 0·2 to 0·3 gramme of zinc dust, and the evolution of hydrogen continued for at least ten minutes.

The liquid, which should still be acid, is filtered, and when cold is treated with 4 or 5 drops of a 10 per cent. solution of sodium nitrite, and after ten seconds the excess of acid neutralized by a slight excess of sodium carbonate.

The solution with the zinc carbonate in suspension is then tested with a few drops of an alkaline solution of α-naphthol, which, in the presence of nitrobenzene, produces an orange-red coloration.

Similar colorations are also obtained with the nitro-compounds of the higher homologues of benzene. C. A. M.

A Comparison of some Formaldehyde Tests. B. M. Pilhashy. (*Journ. Amer. Chem. Soc.*, vol. xxii. [3], pp. 132-134.)—The author finds that the following reagents recommended for the detection of formaldehyde, viz., Schiff's (fuchsine and sulphurous acid), phenol and sulphuric acid, diazobenzene-sulphonic acid, and Nessler's solution, also give reactions with other aldehydes, whilst the coloration produced by dimethylaniline and sulphuric acid (Trillat) is due to the dimethylaniline alone. Lebbin's test he finds unreliable below the limit of 1 : 200,000, whilst the limit of delicacy of the morphine hydrochloride test is 1 : 1000. On the other hand, phenylhydrazine hydrochloride forms the best test, a decided green coloration being developed in half a minute in a 1 : 100,000 solution, and in ten minutes with a 1 : 250,000 solution. For the same reagent in conjunction with sodium nitrocyanide and concentrated sodium hydroxide the limit of sensitiveness seems to be about 1 : 1,000,000. C. S.

Two Deceptive Reactions. C. Amthor. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 233-235.)—*Detection of Formaldehyde.*—The author has studied the colour reaction with hydrochloric acid, which Leonard and Smith supposed to be indicative of milk containing formalin, but which Fisher pointed out was also obtained with milk containing boric acid (ANALYST, xxiv., 86). He finds that the reaction is neither characteristic of formaldehyde nor of boric acid, but is equally well produced when both bodies are absent. He ascribes it to the presence of albuminous bodies in conjunction with sugar (cane-sugar, milk-sugar, dextrose, etc.). With sour milk, owing to the small quantity of sugar remaining therein, the reaction is weak, but it becomes immediately stronger on the addition of a little milk-sugar.

The reaction can also be produced with meat or egg-albumin, but here also the addition of a little sugar is necessary to produce a strong reaction.

Detection of Sesame Oil.—The author found that the reaction above referred to was frequently obtained with butter, owing to the presence of small quantities of casein and milk-sugar, and that when only slight it could be intensified by the addition of milk-sugar. Further, that the same effect was produced when furfurol was substituted for sugar. The fact is of importance in connection with the detection of sesame oil in butter by means of furfurol, since unless the casein be previously completely removed by filtration or other means, the reaction may be obtained in the complete absence of sesame oil. H. H. B. S.

Note on the Estimation of Formic Acid in the Presence of Acetic Acid. F. Sparre. (*Zeit. anal. Chem.*, 1900, xxxix., 105, 106.)—The method given by Leys (*Zeit. anal. Chem.*, xxxviii., 677), which consists in heating the liquid with mercuric oxide, suffers from the drawbacks that the flask must be allowed to stand overnight, and that the precipitate must be filtered, washed, dissolved in nitric acid, precipitated with sodium chloride, and estimated gravimetrically.

In the author's experience, the method of Portes and Ruyssen is less tedious and equally accurate. In this 5 grammes of sodium acetate, 25 c.c. of a 1 per cent. solution of the liquid under examination, and 200 c.c. of a 4·5 per cent. solution of mercuric chloride are heated in a flask for one to one and a half hours on the water-bath, and then diluted to 500 c.c. and filtered. The amount of formic acid is then calculated from the number of c.c. of the liquid required to produce a red coloration with 1 gramme of potassium iodide. C. A. M.

A New Reagent for Phenolic Bodies. G. Candussio. (*Chem. Zeit.*, 1900, xxiv., 299.)—This reagent consists of a 1 per cent. solution of potassium ferricyanide, containing 10 to 20 per cent. of ammonia; and its effect on various phenols, etc., is shown in the paper, side by side with that of a 10 per cent. solution of ferric chloride. The tests are carried out in three ways: by adding the reagent drop by drop to the phenol; by dropping the phenol into an excess of the reagent; and by making the phenolic solution alkaline with sodium hydroxide, and then adding the reagent. Potassium ferricyanide exhibits several advantages over ferric chloride; and in particular it can be used on an alkaline or faintly acid liquid without previous neutralization, so that in the examination of essential oils, or in physiological and pathological work, it is distinctly preferable. Reducing bodies, such as sodium phosphite and hypophosphite, formaldehyde, and especially sodium sulphite, destroy the reactions, precisely as happens with ferric chloride. F. H. L.

The Theory of Saponification. J. Lewkowitsch. (*Berichte*, 1900, xxxiii., 89-99.)—Geitel came to the conclusion that during the saponification of fats and oils mono- and di-glycerides are produced as intermediate products, but Henriques (ANALYST, 1898, 290) was unable to obtain any confirmatory evidence of this. The author has therefore made a large number of experiments in order to settle the

question. In these, several pounds of tallow and of cotton-seed oil were saponified with sodium or calcium hydroxides in the same way as in the ordinary manufacturing process. From time to time samples were withdrawn, treated with hydrochloric acid, and washed and dried. The acetyl value and the Hehner and saponification values of the acetylated product were determined, whilst the amount of free acid calculated from the acid value showed to what extent the saponification had progressed.

The line of reasoning followed was, that if the saponification only produced glycerin and fatty acids, the acetyl value of the partially saponified fat should not exceed that of the original fat; but if, on the other hand, lower glycerides were formed as intermediate products, these having a definite acetyl value would cause an increase in the acetyl value of the samples (*cf.* ANALYST, xxiv., 326).

Confirmatory evidence would also be obtained from the Hehner and saponification value of the acetylated product, which would show great variations in the presence of mono- or di-glycerides.

The experiments proved that the acetyl values rose and fell with the progress of the saponification, whilst at the same time the Hehner and saponification values of the acetylated products showed a corresponding variation. The author, therefore, has arrived at the conclusion that there can be no doubt that the saponification process takes place in stages, and that it must be regarded, not as a tetramolecular change, but as a bimolecular reaction in agreement with the views of Geitel.

As a typical example, the following results of one of the experiments may be quoted:

SAPONIFICATION OF COTTON-SEED OIL WITH CALCIUM HYDROXIDE.

		ACETYLATED PRODUCT.		
	Acid Value.	Acetyl Value by Filtration Process.	Hehner Value.	Saponification Value.
Original oil acetylated ...	0·0	11·7	93·5	—
Partially saponified oil:				
1.	0·5	14·9	94·5	206·3
2.	0·6	20·0	92·84	209·2
3.	16·0	43·15	92·0	230·1
4.	17·6	59·2	89·1	240·0
5.	19·9	28·3	92·35	215·3
6.	53·4	24·9	93·8	214·8
7.	73·2	32·4	93·6	223·4
Fatty acids obtained by saponification with alcoholic KOH, acetylated	199·45	13·8	99·4	216·4

Of this experiment the author remarks that the fairly rapid rise of the acetyl value, with at the same time the slower rise of the acid value, indicates the predominance of the first or first two steps in the saponification, whilst the subsequent rapid decrease in the acetyl value points to the decomposition of the monoglycerides predominating.

It is pointed out that in such experiments as these only the mean values of the concurring phases of the saponification are determined, since simultaneously a molecule of diglyceride may be converted into monoglyceride and fatty acids, or a molecule of monoglyceride into fatty acids and glycerin, while a molecule of triglyceride is only passing through the first stage.

In one of the experiments the saponification proceeded with such rapidity, that but for the fact that a higher acetyl value was obtained with one of the first samples, the results might have appeared to support the older view of saponification.

C. A. M.

Volumetric Estimation of Fatty Acids. J. Swoboda. (*Chem. Zeit.*, 1900, xxiv., 285.)—Standard alcoholic solutions of alkali hydroxides have the disadvantage of not retaining their strength for long; whereas in the titration of fatty acids aqueous alkalis are inconvenient, because of the precipitation of the fatty matter. The author suggests that fatty acids should be dissolved for titration in a mixture of 1 part of absolute ethylic alcohol and 2 parts of amylic alcohol, to which liquid an aqueous alkali may be added without causing separation, and in which the colour of the indicator is perfectly distinct. F. H. L.

Mixtures of Maize Oil with Cotton Oil. G. Morpurgo and A. Götzl. (*Oesterr. Chem. Zeit.*, 1900, iii., 53.)—Inasmuch as cotton oils with a low solidifying point are greatly sought after and fetch a high price, an addition of maize oil is quite possible, although its price is higher than ordinary cotton oil. The authors give a table of the constants of both oils as obtained from the examination in duplicate of four separate brands of American cotton and two brands of maize oil, the figures "agreeing fairly well" (*sic; cf.*, however, ANALYST, 1899, xxiv., 16) with those already quoted by De Negri and others. The most prominent differences between the oils are found in their iodine values and the melting-point of their fatty acids, and the following table represents these constants in the case of the genuine oils and in various mixtures thereof:

	Iodine Value.	Melting-point of Fatty Acids.
Cotton oil, mean figures*	106·47	36-37°
4 parts cotton oil + 1 part maize oil ...	107·40	36-37°
3 ,, ,, + 1 ,, ,, ...	110·80	35-36°
2 ,, ,, + 1 ,, ,, ...	112·05	34-34·5°
1 part ,, + 1 ,, ,, ...	115·70	31-32°
1 ,, ,, + 2 parts ,, ...	118·30	29-30°
Maize oil, sample No. 1	147·60	18-20°
,, ,, No. 2	124·50	18-20°

Maize oil does not give the Becchi reaction, so that additions of cotton oil can be detected in this manner. Taste and smell cannot be relied upon: hot-pressed cotton oil is much like roasted maize oil; sometimes, however, the latter is practically odourless. The acid value of pure commercial cotton oil is generally under 1, and it does not increase much when the oil becomes rancid; maize oil oxidises more readily, so that an excess of free acid points to the presence of maize oil in cotton oil.

F. H. L.

* Extreme figures, 104·45 and 107·61.

The Detection of Cotton-seed Oil by the Pentosan Reaction. B. A. van Kettel. (*Monit. Scientif.*, 1900, xiv., 154-156.)—In a former communication (*Ber. Nederl. Maatschap. Pharm.*, October, 1897) the author described a test based upon the fact that vegetable oils, and notably cotton-seed oil, contain traces of pentosans, whilst animal oils are free from such substances. Ten grammes of the oil are heated with a few c.c. of hydrochloric acid (specific gravity 1·06) until permeated with the acid vapours. The tube is then left for 10 minutes for the liquids to separate, and on now adding a solution of phloroglucinol hydrochloride, a red ring is formed at the juncture of the layers, in the presence of pentosans.

Among the oils which do not give the pentosan reaction are cacao oil, earthnut oil, croton oil, rape-seed oil, and linseed oil. Two specimens of pure olive oil examined by the author also gave negative results.

In the present paper the results of this test are compared with those of Halphen's and Cavalli's reactions. The latter test consists in shaking the oil with a mixture of 2 grammes of resorcin, 20 c.c. of water, and 15 c.c. of sulphuric acid, a red coloration changing to blue being given by cotton-seed oil.

Six specimens of cotton-seed oil of different origin and a specimen of cotton "stearin" were tested. With Halphen's reagent all gave a red coloration with the exception of a crude yellow Egyptian oil. With Cavalli's reagent only two of the oils gave a pronounced reaction, and one a faint coloration. With the author's pentosan reagent five of the samples, including the Egyptian oil, gave a marked coloration, and the other two a faint reaction.

The crude Egyptian oil was treated with animal charcoal and the filtrate tested with Halphen's reagent, but as the red coloration was still not obtained, the conclusion was arrived at that this oil did not contain the substance producing the reaction.

In view of the results of these experiments, Cavalli's test was regarded as unreliable.

The author found that his own reagent was capable of detecting 10 per cent., and sometimes 5 per cent. of cotton-seed oil in earthnut oil.

Holde and Pelgry have shown (ANALYST, xxiv., 214) that cotton-seed oil, after being heated at 220-225° C., no longer reacts with Halphen's reagent. The author has tested his pentosan reagent on the six oils mentioned above, after heating them for 30 to 40 minutes at about 250° C. Only two gave a coloration with Halphen's reagent, whilst with the author's reagent two gave negative results, four faint reactions, and one a pronounced coloration. C. A. M.

Separation of the Constituents of Rancid Fats and Oils. J. Nagel. (*Amer. Chem. Journ.*, 1900, xxiii., 173-176.)—The following classes of compounds were identified by the author in his investigation on the rancidity of fats and oils: (1) Free fatty acids (saturated and unsaturated). (2) Hydroxy-fatty acids. (3) Lactones and anhydrides of fatty acids. (4) Alcohols, such as butylic, amylic, and caprylic alcohol. (5) Esters of saturated, unsaturated, and hydroxy-fatty acids, with higher and sometimes also polybasic alcohols. (6) Aldehydes (saturated and unsaturated). (7) Acetals and (8) Terpenes.

I. *Separation of Saturated, Unsaturated, and Hydroxy Acids.*—These were neutralized with a solution of soluble glass instead of with alkalies, with the result that emulsions were avoided, the silicic acid liberated in the reaction drawing the alkali salts mechanically to the bottom.

II. *Separation of Lactones.*—Those lactones which were volatile with steam were removed simultaneously with terpenes by distillation, as in VI. Non-volatile lactones were converted into salts of hydroxy-fatty acids by boiling the oil, from which the free fatty acids had been removed, with a concentrated solution of an alkali. The resulting insoluble salts were separated by filtration.

III. *Alcohols and Esters*, when volatile with steam, were removed as described under VI.

IV. *Separation of Aldehydes.*—When volatile, these were removed by distillation. To separate the non-volatile aldehydes 4 volumes of the oil were heated for an hour with 1 volume of a concentrated solution of sodium bisulphite, and the aqueous layer separated on cooling. The compounds of the aldehydes with sodium bisulphite being slightly soluble in the solution of bisulphite, were removed together with the solution.

V. *Separation of Acetals.*—Where these were not volatile with steam, it was found best to decompose them into alcohols and aldehydes by heating the fat with dilute sulphuric acid. The resulting compounds were removed, as in IV. or VI.

VI. *Separation of Terpenes.*—These were removed by distillation, being all volatile with water-vapour. In order to prevent further changes in the oil by the prolonged action of steam at 100° C. and of atmospheric oxygen, the steam was either passed through the oil together with a neutral gas, or was gradually superheated (100° to 170° C.) and accompanied by an inert gas. In fractionating with superheated steam, the most volatile substances passed over before the more highly-heated steam, which would have decomposed them, was introduced. The oil was subsequently cooled *in vacuo* or in an atmosphere of an inert gas, such as hydrogen or carbon dioxide.

In conclusion, the author describes a method of practically applying the results of his investigation to the purification of rancid fats and oils on a large scale.

C. A. M.

Macassar Oil. **J. J. A. Wijs.** (*Chem. Rev. Fett. u. Harz-Ind.*, vol. vii. [3], pp. 46, 47.)—A sample of the butter-like fat obtained from the seeds of *Schleichera trijuga Willd.*, by extraction with benzene, furnished the following constants: Melting-point (Le Sueur and Crossley's method) of the fat, 22° C.; of the fatty acids, 52° to 54° C.; Hehner value, 91·55; saponification value (Henriques' cold method), 215·3; iodine value (Wijs' method) of the fat, 55·0; of the fatty acids, 58·9; Reichert-Meissl value, 9; acid value of the fat, 19·2; of the fatty acids, 191·2 to 192; percentage of unsaponifiable matter, 3·12 per cent.

The seeds yielded 40 per cent. of kernel, containing 70·5 per cent. of fat, 3·5 per cent. water, and 12 per cent. protein. The volatile acids, examined by the Duclaux method, were found to consist of acetic acid with a small quantity of a higher acid: probably butyric, by the odour of the ester furnished on treating the

distillate with alcohol and sulphuric acid. Of the non-volatile acids, 45 per cent. consisted of solid fatty acids and 55 per cent. of liquid acids, having the iodine value 103·2. C. S.

The Composition of Japan Wax. A. C. Geitel and G. van der Want. (*Journ. prak. Chem.*, 1900, lxi., 151-156.)—Considerable variations were found in the constants of four specimens of the commercial wax examined by the authors. The acid value fluctuated between 21·7 and 32·6; the saponification value between 217·5 and 237·5; the iodine value between 8·3 and 8·5; and the amount of unsaponifiable matter between 1·48 and 1·63 per cent. In two different samples 90·62 and 90·66 per cent. of insoluble fatty acids, and 4·66 and 5·96 per cent. of soluble fatty acids, were respectively found.

The soluble fatty acids had the consistency of lard; their acid value was 345·2, and their mean molecular weight 162. In the authors' opinion they consisted of a mixture of fatty acids, produced by the action of the oxidizing agents employed to bleach the wax.

The insoluble fatty acids had an acid value of 212·2 to 215·7, and an iodine value of 10·6. By fractional precipitation with magnesium acetate they were separated into palmitic acid, oleic acid contaminated with unsaponifiable matter, and a fatty acid melting at 117° C., to which the authors gave the name of *Japanic acid.*

This acid, when purified by recrystallization from alcohol or chloroform, melted at 117·7° to 117·9° C. It was found to be saturated, and to contain no hydroxyl groups. It could be dried without loss at 115° to 120° C. Its molecular equivalent, as found by titration, was 186·2, but by the boiling-point method its molecular weight was found to be 365. The conclusion finally arrived at was that it belonged to the succinic acid series, and had the formula $C_{20}H_{40}(COOH)_2$.

By recrystallizing the wax from hot benzene a hard, wax-like substance, melting at 43° to 45° C., and with an ester value of 252·6, was eventually obtained. As a glyceride containing one molecule of *Japanic acid* and one molecule of palmitic acid would have an ester value of 253·4, the authors considered it highly probable that this acid is present in Japan wax in the form of a mixed glyceride. A reference is made to the abnormal behaviour of the fatty acids of Japan wax when dissolved in a saturated alcoholic solution of stearic acid (ANALYST, xxi., 330). C. A. M.

Notes on Commercial Glycerin. H. Struve. (*Zeit. anal. Chem.*, 1900, xxxix., 95-99.)—The author gives a detailed account of a number of experiments, from which he has arrived at the following conclusions:

1. The purest glycerin in the market contains from 6·02 to 8 per cent. of water.

2. Commercial glycerin does not lose the whole of its water when dried *in vacuo*, but retains 1·52 per cent.

3. The most anhydrous glycerin is hygroscopic, and absorbs moisture from the atmosphere up to 17·46 per cent.

4. Traces of glycerin are volatile in a current of steam. In one experiment the loss on distillation amounted to 0·379 per cent. C. A. M.

Some Properties of Rosin. **A. Smetham and F. R. Dodd.** (*Jour. Soc. Chem. Ind.*, 1900, xix., 101.)—The authors call attention to the fact that the constants of colophony acids are not the same as those of the rosins from which they have been derived; therefore, in the analysis of soaps, especially those containing much rosin, it is not possible to calculate accurately the proportion of colophony used by the manufacturer by comparing the analytical data with the figures published for ordinary rosin. The annexed table gives, firstly, some constants of various brands of commercial rosin, and secondly the similar constants of the same materials after saponification, decomposition of the soaps, and removal of the resinous matters by means of ether.* The iodine values were obtained with the Hübl solution at eighteen hours, employing an excess of 300 per cent. of iodine.

	Brands.				
	"Wite."	"Nemo."	"W. W. Zante."	"N. Xeres."	"W. G. Wax."
Original rosin:					
Acid value	160·8	162·0	154·5	157·3	160·1
Saponification value ...	177·6	176·4	174·3	174·3	177·3
Iodine value	184·7	181·0	158·5	168·4	165·9
Recovered resin:					
Acid value	163·9	163·9	159·1	159·1	161·0
Saponification value ...	176·4	175·3	167·5	165·5	169·5
Iodine value	175·5	166·8	154·9	149·9	153·6

The authors agree with Lewkowitsch that the effect of the Wijs and Hübl iodine solutions on fats and oils is fairly concordant; but on rosin or resin acids it is very different. One sample of rosin gave a Hübl value of 156·7, and a Wijs value of 250·6 at eighteen hours. The widely different results obtained by the two methods would suggest that chlorine compounds are formed, and this seems to be borne out by the immediate change in the colour of the Wijs solution on coming into contact with the rosin, whereas in the case of tallow acids no such change occurs. The authors therefore conclude that the iodine process as at present worked is of doubtful utility in determining the nature of the fatty matters in a mixture of these with resin acids.

F. H. L.

Essential Oil of Chrysanthemum. **G. Perrier.** (*Bull. Soc. Chim.*, 1900, xxiii., 216, 217.)—The green leaves of *Chrysanthemum japonicum*, or autumn chrysanthemum, furnish, on distillation with water, a green essential oil. The yield (about 16 per cent.) varies with the different species of the plant, the maximum amount being obtained just before the flowers begin to fall.

The essential oil is a liquid of an oily consistency, with an odour recalling that of peppermint and that of chamomile. It begins to boil at 160° C., and has a specific gravity of 0·932 at 15° C., and a refractive index of 1·4931 at 18° C. It is soluble in 10 volumes of 95 per cent. alcohol, but is nearly insoluble in 70 per cent. alcohol.

* These latter figures, however, can scarcely be considered to represent the constants of colophony acids, for the unsaponifiable matter of the rosin, except that "removed in [aqueous] solution or by volatilization in the process of drying," was not extracted. The abstractor has usually found the proportion of unsaponifiable matter in the low-grade rosin "B.C." to be about 7 per cent.—F. H. L.

When cooled to −15° C., it deposits a small quantity of a solid amorphous substance, probably a paraffin; at −24° C. it becomes viscid, and solidifies when cooled in a mixture of ether and solid carbon dioxide. It combines partially with sodium bisulphite, is acid to litmus, and has a saponification value of 8·61. The alkaline salt formed in the saponification yields, when treated with hydrochloric acid, a solid substance with an odour of angelic acid.

From a preliminary examination the author considers that chrysanthemum oil resembles the oil of Roman chamomile in composition. C. A. M.

Properties of some Essential Oils. Schimmel and Co.'s April Report. (*Chem. Zeit.*, 1900, xxiv., 304.)—*Oil of Basil.*—Two descriptions of this substance are now recognised. From the large-leaved variety of *Ocymum basilicum*, known locally as Selasih Mekah, between 0·18 and 0·32 per cent. of oil can be obtained by distillation, which has a specific gravity of 0·90 at 26° C., and a rotatory power of −30·5° to −36° in a 200-millimetre tube. The oil contains from 30 to 40 per cent. by volume of eugenol. From its neutral constituents a body of agreeable odour, boiling at 190° C., has been recovered, and is now under investigation. The other variety of *O. basilicum* yields about 0·2 per cent. of oil, smelling like fennel, with a specific gravity of 0·948 at 25° C. It boils mostly between 214° and 218° C., and consists largely of methyl-chavicol. On treatment with alcoholic potash, it gives anethol; and on oxidation, anisic acid.

Oil of Iris.—J. C. Stead has succeeded in obtaining from 5 parts of the usual solid or buttery material 1 part of a golden-yellow oil, with a fine odour of violets when highly diluted. It is soluble in all proportions in ether, alcohol, chloroform, petroleum spirit and benzene, and yields a clear mixture with 8 volumes of 70 per cent. alcohol. It is acid to litmus. Its optical values are $d_{15·5} = 0·9489$; $[\alpha]_D = -28·25°$. It solidifies at −5° C. It decomposes on distillation at atmospheric pressure, and contains no constituent separable by bisulphite; but by treatment with alkali before and after acetylation is shown to contain free acids and some alcoholic bodies.

Oil of Rosemary.—Recent investigations by Guerbet of pure santalol recovered from its phthalic acid compound throw doubt on the correctness of the hitherto accepted formula, $C_{15}H_{26}O$. On hydrolysing acetylated santalol, figures were obtained corresponding to a content of 103·5 per cent. of santalyl acetate, whence santalol must either have a smaller molecule (perhaps $C_{15}H_{22}O$), or it must be a mixture of two differently composed alcohols.

Oil of Wartara.—This is a new product, prepared by Schimmel from Bombay Wartara seeds, which closely resemble the fruit of *Xanthoxylum piperitum D. C.*, and probably also belong to the *Rutaceæ*. On distillation, about 2 per cent. of an oil smelling like coriander was obtained: specific gravity, 0·8714; rotatory power, $[\alpha]_D = +6° 31'$; saponification value, 27·1; solubility, 1 vol. in 1 vol. of 80 per cent. alcohol. By distillation at a pressure of 14 millimetres it was separated into six fractions, of which the first boiled at 175° to 176° at atmospheric pressure, and gave a large yield of a tetrabromide melting at 125°, showing it to be almost pure pentene. The fractions 3 to 5 were rectified, and finally an oil was recovered which exhibited the properties of *d*-linalol: specific gravity, 0·868; rotatory power, +14° 20′; boiling-

point, 78° at 14 millimetres. The identity of this oil with *d*-linalol, which has hitherto been found only in oil of coriander, was proved by its conversion into citral and into *l*-terpineol, etc. F. H. L.

On Certain Methods for the Determination of Cellulose. C. Beck. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 158-164.)—The methods studied by the author were Lebbin's (*Arc. Hyg.*, 1897, xxviii., 212), König's (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1898, i., 3-16; ANALYST, 1898, xxiii., 47), and Henneberg's. Lebbin's method is briefly as follows: 3 to 5 grammes of the substance are first boiled with 100 c.c. of water for half an hour; 50 c.c. of 20 per cent. hydrogen peroxide are then added and the boiling continued for twenty minutes, during which 15 c.c. of a 5 per cent. ammonia solution are added in small quantities at a time. This is followed by another boiling for twenty minutes, after which the raw fibre is filtered off, washed with hot water, dried and weighed. König's method has already been published in this journal (*vide* abstract cited above). The old method of Henneberg (boiling successively with dilute sulphuric acid and potash solution) was studied in conjunction with the two newer processes for the sake of comparison. In all cases the amount of cellulose was arrived at by deducting the sum of the pentosans (determined by Tollens and Councler's method), the nuclein (N by Kjeldahl × 6·25), and the ash from the raw fibre. The most concordant results were obtained with Henneberg's method, and the author considers that for establishing a comparison between the finer sorts of flour, this method furnishes the most reliable data. Lebbin's method yielded the least concordant results. In connection with this method, the author tried the effect of removing, as far as possible, the starch and the albuminous bodies before boiling with the hydrogen peroxide. The results, however, were still unsatisfactory, and are only interesting in so far as they show the unsuitability of hydrogen peroxide for the purpose, even under conditions more favourable than obtain in the original method. The author does not consider Lebbin's method of any value at all, either scientific or practical. The results obtained by König's method were also very discordant, owing apparently to variations in the boiling-point of the liquid. It also seemed that some other substance must be left in the raw fibre in König's method, since the cellulose found in bran and flour by this method by deducting the nitrogenous substances, pentosans and ash from the raw fibre was greater than that obtained by Henneberg's method, notwithstanding that the cellulose is less attacked in Henneberg's method than it is in König's.

Remarks on the Foregoing Paper by J. König.—König remarks that the discordant nature of the results obtained by Beck with his method was probably due to his instructions regarding temperature not having been accurately followed. The temperature should be maintained within the limits of 131° and 133° C. This can easily be done by using glycerin of 1·229-1·230 specific gravity, working upon air-dried substances containing not more than 12 per cent. of water, and reducing the flame of the burner as soon as the fluid commences to boil. The use of a digester, however, is preferable to open boiling, and in this case the temperature should be maintained at 137° C. for one hour. Beck's opinion as regards the suitability of Henneberg's method for discriminating between fine flours is directly contrary to König's experience. He considers that Henneberg's method is less reliable with fine

flour, and rarely gives concordant results, on account of the difficulty of filtration. König remarks further, that his object, as stated in his paper, was to devise a method for separating as completely as possible the pentosans from the hexosans, and that no method yet proposed furnishes pure cellulose of the formula $n(C_6H_{10}O_5)$.

H. H. B. S.

Notes on the Estimation of Cellulose. C. Councler. (*Chem. Zeit.*, 1900, xxiv., 368.)—The author discusses four methods which have been proposed for this determination: (1) The Schulze-Henneberg process, (2) H. Müller's process, and (3) that recommended by G. Lange (ANALYST, 1895, xx., 283). Müller's process is carried out by extracting the material with a mixture of alcohol and benzene, and next with hot water; then removing from the residue certain "incrusting substances" by repeated alternate treatments with 0·4 per cent. bromine-water and 0·4 per cent. hot ammonia, filtering and washing the mass between each stage of the operation. Müller claims that four such treatments with bromine and ammonia are sufficient to yield pure cellulose; but Councler always finds more, sometimes twenty, alternations to be necessary. The method thus becomes exceedingly laborious, and Councler has endeavoured to shorten it by (4) previously heating the sample with calcium bisulphite solution (8° Beaumé) for four or eight hours at a temperature of 110° to 140° C. in a sealed tube, and then proceeding as before.

All these four processes show different results, (3) and (4) giving the lowest, but not identical figures; (3) is untrustworthy because, no true solvent for cellulose having yet been discovered, the substance dissolved by Lange's alkali and precipitated by his strength of acid is not cellulose; (4) is incorrect because cellulose appears to be attacked by bisulphite at temperatures of 100° C. and upwards; (1) and (2) seem to give better results, but are too complicated and tedious. An exact and simple method of estimating cellulose has therefore yet to be elaborated.

F. H. L.

On the Determination of Carbon and Hydrogen by Combustion in Oxygen, using Copper Oxide. C. F. Mabery and W. R. Clymer. (*Journ. Amer. Chem. Soc.*, vol. xxii., [4], pp. 213-218.)—In investigating the conditions necessary to insure accuracy in the combustion analysis of hydrocarbon oils the authors find that copper oxide is reliable when brought into a constant condition by blank trials. For the drying apparatus they recommend combustion-tubes 175 centimetres long, bent at an angle of about 105° at 30 centimetres from one end, one set being filled with broken glass and concentrated sulphuric acid, the other with glass and 40 per cent. potassium hydroxide solution.

Sulphuric acid forms the best absorbent for the water produced during combustion, and when used in small quantity (2 to 3 c.c.) retains but a very slight proportion of carbon dioxide. The tube employed has a bulb for collecting the greater part of the condensed water; the front limb of the U-tube is 10 centimetres high, and a lateral tube is attached for connection to the potash bulb. This drying-tube may be used for ten to twelve combustions before recharging with acid.

For carbonic acid absorption the Geissler bulb is the most convenient apparatus,

and no loss occurs, provided the 33⅓ per cent. potassium hydroxide be used for not more than four or five analyses. With the ordinary calcium chloride tube air may be safely passed at the rate of 500 c.c. per minute, and the freshly-fused, fine granular chloride may be used in a large number of analyses.

The combustion-tubes require a long time to bring them and the connections into good working order—expulsion of volatile impurities from the copper oxide, moisture from the tube, oxide, and rubber stoppers, etc. If the tube be filled with oxygen before inserting the substance, and the rate of volatilization be carefully controlled, any hydrocarbon may be burned in a 20-burner furnace. No advantage is gained by weighing the absorption-bulbs full of oxygen instead of air. C. S.

The Elementary Analysis of Organic Substances containing Nitrogen. F. G. Benedict. (*Amer. Chem. Journ.*, vol. xxiii., [4], pp. 334-352.)—To secure the reduction of the copper without adding unknown amounts of carbon dioxide and water to the materials to be weighed, the author recommends that such nitro-compounds as contain a deficiency of carbon and hydrogen in the molecule should be burned in admixture with a carbonaceous substance of known composition, the resulting products being then in a position to react upon and reduce the oxides of nitrogen present. Naphthalene, benzoic acid, and sucrose are highly suitable, but the first-named is difficult to obtain pure, whereas pure, dry sucrose can be readily obtained.

It is generally desirable, in charging the boat, to leave a free space of about 1 centimetre at the front end, which space is filled with the reducing agent (*e.g.*, sucrose), the rest being sprinkled over the substance. A space of 1 centimetre is left between the front end of the boat and the asbestos plug in the combustion-tube. The spiral in the front end of the tube is heated first, and then the copper oxide, before the reducing material in the boat is reached. The gases evolved by the sucrose reduce part of the adjacent copper oxide; and the final charring of the sucrose leaves an excess of carbon to aid in reducing the nitro-group. The conditions are different with benzoic acid, there being little or no carbon left, though the copper oxide is reduced for a distance of several centimetres. In calculating the results, allowance is made for the known weight of water and carbon dioxide formed by the reducing agents employed.

An admixture of three or four volumes of finely-powdered, dry silica increases the regularity of combustion, and appears to have a direct influence on the reduction of the oxides of nitrogen, which under these circumstances are found in much smaller quantities in the products of combustion. C. S.

A Colour Reaction given by the Products of the Digestion of Fibrin and Albumin with Papayotin. V. Harlay. (*Journ. Pharm. Chem.*, 1900, xi., 172-178.)—The products of the digestion of proteids with the juice of *Carica hastifolia* were found by the author to give with tyrosinase the same coloration as that given by the products of peptic digestion (ANALYST, xxiv., 272), but in a greater degree of purity. The green colour in the case of pepsin resembled that of chlorophyll, whilst the

papayotin green had more of a blue shade. This was shown to be due to the presence of other colouring matters which accompanied the pepsin green, and which on reduction with zinc and hydrochloric acid were destroyed first. In both digestions the main colours had the same spectrum and reactions, and were considered by the author to be identical. C. A. M.

A Method of distinguishing Indigo from other Blue Dyes in Woven Fabrics. F. H. van Leent. (*Zeit. anal. Chem.*, 1900, xxxix., 92-95.)—The threads of the fabric under examination are disintegrated into a loose wool, and a portion covered with pure melted phenol in a test-tube, which is then kept for an hour in a boiling water-bath, with occasional agitation. The blue solution which is obtained when indigo is present is poured off from the fibres, and the treatment with phenol repeated if required. The fibres are then washed two or three times with strong alcohol, and, after pressing and drying, a pure white wool is left.

Indigo red and another red colouring matter, possibly originating from the indigo, are simultaneously dissolved by the phenol. When the phenol solution is mixed with a large quantity of strong alcohol, the greater part of the indigo blue is precipitated, and the liquid shows the colour of the indigo red.

If the fibres be boiled with the phenol, they are strongly attacked by it, which, however, is not the case at the temperature of boiling water. Aniline and nitrobenzene extract but little indigo from dyed wool at 100° C., and are therefore unsuitable solvents for the test.

In experiments with wool dyed with other colouring matters, the author has so far found that, with the exception of indophenol, indigo is the only dye dissolved by phenol under the above conditions.

The results of his experiments are shown in the following table :

Pure indigo	Colour completely extracted; fibres white.
Indigo with sandal-wood	Indigo removed; red colouring matter left on the fibres.
Indigo and alizarin blue with chrome mordant	Indigo removed; fibres blue.
Indigo over alizarin	Indigo removed; fibres red.
Indigo and indophenol in mixed bath	Much colour removed; fibres still blue.
Indigo sulphonic acid	Only a little colour removed; fibres blue.
Brilliant sulphonazurine	Nothing removed; fibres unchanged.
Indulin	A little removed; fibres blue.
Alizarin indigo blue	Nothing removed; fibres unchanged.
Alizarin cyanin	Liquid coloured red; fibres remain blue.
Anthracene blue	Some red extracted; fibres unchanged.
Logwood with mordant of alum, chromium, and antimony ...	Unchanged.

Other dyes, such as palatine scarlet, cochineal, and anthracite black, also remained undissolved by the phenol. On testing a mixture of fibres dyed with pure indigo, with anthracene blue, and with indigo and sandal-wood, only the indigo dissolved, and, under the microscope, the different colourless, blue, and reddish brown fibres could be identified.

The test is not so suitable for cotton as for woollen fabrics, since indoïn is dissolved from cotton by the phenol as readily as indigo.

The author has not succeeded in quantitatively estimating the indigo by this method, chiefly on account of the difficulty of separating the fibres from the phenol solution without loss. C. A. M.

Notes on the Valuation of Tanning Materials. Paessler. (*Zeits. angew. Chem.*, 1900, 318.)—The author holds that if the directions laid down in the "Report of the First Congress of Leather-Trades Chemists" (H. Proctor and J. P. Parker) are followed exactly, the results obtained on analysing samples of tanning materials will become quite satisfactorily uniform and accurate. He also calls attention to the following points: It is necessary to take great care in selecting a small sample for analysis, even when the material has already been sampled from bulk. Many tanning materials contain a large number of foreign substances of different specific gravities, and so tend to separate into layers of different composition during agitation or transport. Especially with materials which are but imperfectly soluble in water, the particular grade of filter-paper employed is of considerable influence on the results. Schleicher and Schull's No. 602 "Extra Hard" is the best; in all cases the filtrate must be perfectly clear, for even the trace of suspended matter that passes a softer paper and renders the liquid only opalescent is taken up by the hide-powder and affects the figures of the analysis. The use of a hide-powder containing a certain proportion of filter-paper is distinctly advantageous; the cellulose prevents the liquid from rising up the walls of the filtering vessel, and also assists in the washing of the tanned hide-powder. Mehner and Stransky of Freiberg-i.-S., are now making a powder with 15 to 18 per cent. of filter-paper (instead of the 35 per cent. advised by Cerych), which behaves admirably. The hide-powder is best packed so that the filtrate passes at about 10 drops per minute; excessive tightness causes loss of tannins by dissolution of the soluble matters of the powder, but the errors are not serious. It is advisable, and in special cases important, that the temperature of the extract when being diluted to the desired volume, and of the liquid during filtration, should be maintained at the normal point, 17·5° C.; for the degree of solubility of some of the almost insoluble tanning constituents depends largely upon that temperature. F. H. L.

The Detection and Estimation of certain Vegetable Substances commonly used to adulterate Sumach. G. Scarlata. (*Staz. Speriment. Agrar.*, 1900, xxxiii., 168-171.)—Sicilian sumach should consist of the dried and powdered leaves of *Rhus coriaria*; but from the author's experience it appears to be widely adulterated with the leaves of other plants containing tannin, and notably with those of the *Tamarix africana* and of the lentiscus (*Pistacia lentiscus*).

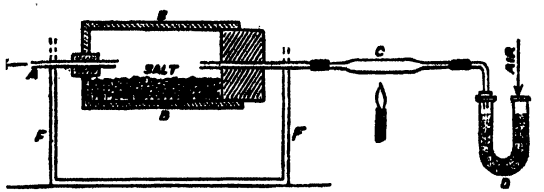
Of the methods proposed to detect these adulterants, a microscopical examination of the powder, as recommended by Brizi, requires long experience, and is, hence, practically unused, whilst that of Spica (*Gazzetta*, 1897, 354) does not solve the problem.

The author's method is based on the fact that when finely-powdered sumach is

allowed to fall upon glycerin (specific gravity 1·26), which is then brought to the boiling-point and left for an hour, the sumach subsides completely, and the supernatant glycerin assumes a greenish-yellow tint.

If, however, the test be tried with finely-powdered lentiscus leaves, the powder is left on the surface of the glycerin, to which it imparts a wine-red colour; whilst in the case of the tamarix leaves the powder remains in suspension, and only falls after twenty-four hours. Here, too, the glycerin is coloured wine-red.

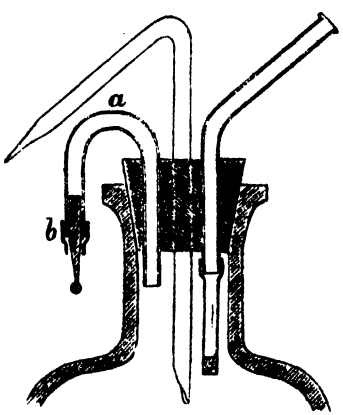
In his experiments on the quantitative determination of lentiscus in sumach, the author prepared a mixture containing 20 per cent. of the former. Five grammes of this mixture, previously passed through a fine-meshed sieve, were introduced into a large test-tube containing 110 c.c. of glycerin (specific gravity 1·26); the liquid was heated to the boiling-point, without shaking, and boiled for a few moments until there was a complete emulsion. It was then left for twenty-four hours, after which the supernatant glycerin, together with the powder on its surface, was removed by means of a pipette. The powder was collected on a weighed filter, washed with water until free from glycerin, dried in the water-oven, and weighed. The results thus obtained varied from 0·65 to 0·70 gramme. The loss, through solubility of the powder in the glycerin, amounted, in the mean of several determinations on 1 gramme of pure lentiscus, to 30 per cent., and on adding this to the amount actually found, the results agreed well with the quantity taken.



It was not found possible to quantitatively estimate tamarix leaves in this way, but they could be identified. For this purpose 5 grammes of the sieved sample were introduced into the tube of glycerin, which was then boiled as described above, and allowed to stand for two hours. If the supernatant glycerin was then clear and of a yellowish-green colour, the sumach was regarded as pure. If, however, after twenty-four hours part of the powder remained on the surface, while the glycerin was clear and of a wine-red colour, the presence of lentiscus leaves was, in the author's experience, certain. Finally, when tamarix leaves were the adulterant, part of the powder remained after two hours in suspension in the glycerin, which had the same wine-red colour as in the case of lentiscus. After twenty-four hours the suspended powder completely subsided. C. A. M.

INORGANIC ANALYSIS.

Direct Determination of Carbon in Metallic Alloys. H. Brearley. (*Chem. News*, vol. lxxxi., pp. 91, 92.)—Samples of various alloys were heated for one hour in a Bunsen furnace, the porcelain tubes being supported in asbestos arches, thus enabling a higher temperature to be maintained than usual with combustion tubes. The results showed the method to be applicable to metallic tungsten, ferro-tungsten, ferro-silicon, 12 per cent. silicon-spiegel, ferro-silico-molybdenum, and 20 per cent. spiegel, though the last-named could not be completely oxidized. On the other hand, metallic molybdenum volatilizes, leaving only impurities like SiO_2, WO_3, etc.; tungsten-nickel alloy is imperfectly oxidized, and ferro-manganese, ferro-chromium, chromium nickel and metallic chromium cannot be oxidized without some other oxidizing reagent. Ferromanganese is oxidized completely in presence of oxides inert towards chromium alloys, *e.g.*, zinc oxide. C. S.



APPARATUS.

New Device for drying Crystallized Salts. F. H. Getman. (*Chem. News.*, vol. lxxxi., p. 91.)—The apparatus consists of a large porous cup, B B, to contain the salt to be dried, with a hole in the bottom to take a good-sized cork, the mouth being also closed with a cork. Glass tubing is fitted centrally through both corks, and, the whole being placed in a frame or box F F, the tube A is connected with an aspirator, whilst the other tube is connected with the drying tube D, with or without the intermediate tube C, which can be heated to any desired temperature when hot air is required. The cup may be slowly rotated from time to time to expose a fresh surface of the salt to the air current.

C. S.

An Improved Wash-Bottle with Bunsen Valve. O. Gamber. (*Chem. Zeit.*, 1900, xxiv., 395.)—When an ordinary wash-bottle is fitted with a Bunsen valve, it is impossible to arrest the stream of water suddenly without loosening the cork of the flask, unless the exit tube is provided with a length of rubber which can be pinched with a clip or with the fingers. The annexed sketch represents an improvement that brings the current of liquid under more immediate control. *a* is a bent piece of glass tube, carrying at its outside end a short length of rubber, *b*, the normal diameter of which is about one-half that of the glass. Within the glass tube slides easily a conical piece of rod (shaded in the diagram), which has a maximum diameter less than that of the glass, but greater than that of the rubber. When there is an excess of pressure in the wash-bottle, the rod is forced outwards till it makes a joint against the rubber tube; but if the finger give a slight lifting movement to the ball at the end, the rod slips upwards, the joint is broken, the pressure relieved, and the stream of water stops.

F. H. L.

Aluminium Plates for Laboratory Purposes. Fritsch and Venator. (*Chem. Zeit.*, 1900, xxiv., 286.)—The authors recommend sheets of aluminium 3 or 4 millimetres thick as substitutes for the ordinary wire gauze or sand bath. They have employed such a plate for five years in a fume cupboard, and it is still in perfect condition. The efficiency of the gas-burner is much greater than with a sand bath, while dust and breakage of the gauze are avoided. When evaporating liquids to dryness, a thin sheet of asbestos should be laid over the metal.

F. H. L.

INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND.

THE following is a list of the names of the candidates who passed the examination of the Institute of Chemistry held in July, 1900:

INTERMEDIATE EXAMINATION.—Brown, J. A., University College, Nottingham. Chapman, E. M., Pharmaceutical Society's Laboratories, and King's College, London. Cunliffe, F., Owens College, Manchester. Dewhirst, J. A., Yorkshire College, Leeds, and Pharmaceutical Society's Laboratories. Dick, W. D., King's College, London. Ellis, A. W., Mason University College, Birmingham. Gray, A., Glasgow and West of Scotland Technical College. Jenkins, J. E., King's College, London. Lowson, W., Yorkshire College, Leeds. Lumsden, W. W., Glasgow and West of Scotland Technical College. McLellan, B. G., Glasgow and West of Scotland Technical College. Nuttall, W. H., University College, Nottingham. Partridge, W., Finsbury Technical College, London. Richmond, S. O., Finsbury Technical College, London. Robertson, A. J., University College, Dundee, and under R. R. Tatlock, Esq., F.I.C. Tainsh, P. W., Glasgow and West of Scotland Technical College. Tebb, W. S., M.A., M.D. (Cantab.), Cambridge University and King's College, London. Thorburn, J., Glasgow and West of Scotland Technical College. Watson, F. W., Glasgow and West of Scotland Technical College.

GENERAL PRACTICAL EXAMINATION.—Scott, A.,* Glasgow University, Glasgow and West of Scotland Technical College, and under R. R. Tatlock, Esq., F.I.C.

FINAL A.I.C. EXAMINATION.—*In Mineral Chemistry:* Baguley, A., B.Sc. (Wales), University College, Bangor. Davidson, A., Glasgow and West of Scotland Technical College. Hartley, T.,* Yorkshire College, Leeds. Kinnersley, H. W., Merchant Venturers' Technical College, Bristol, King's College, London, and under E. H. Cook, Esq., D.Sc. (Lond.), F.I.C. Reinherz, O., B.A. (Cantab.), Trinity College, Cambridge. *In Metallurgical Chemistry:* Levy, A. G., Finsbury Technical College, London. Morgan, J. J.,* of Wednesbury. *In Physical Chemistry:* Pope, T. H., A.C.G.I., City and Guilds of London Institute, Central Institution, and Finsbury Technical College, London. *In Organic Chemistry:* Billows, F. G. H., A.C.G.I., City and Guilds of London Institute, Central Institution, and Finsbury Technical College, London. *In the Analysis of Food and Drugs, including an Examination in Therapeutics, Pharmacology and Microscopy:* Aston, S., University College, London. Booth, N. P., Mason University College, Birmingham. Glass, T. W.,* B.Sc. (Lond.), Pharmaceutical Society's Laboratories, and under Messrs. T. H. Redwood and A. J. de Hailes, FF.I.C. Jollyman, W. H., Finsbury Technical College. Platt, W. N.,* B.Sc. (Lond.), A.R.C.Sc. (Lond.), Royal College of Science, London. Woodhead, S. A.,* B.Sc. (Dun.), Durham College of Science, Newcastle-on-Tyne.

The examiners in chemistry were Dr. Bernard Dyer, D.Sc. (Lond.), F.I.C., and Dr. W. Palmer Wynne, D.Sc. (Lond.), F.R.S., F.I.C. The examiner in therapeutics, pharmacology and microscopy was Dr. Thomas Stevenson, M.D. (Lond.), F.R.C.P., V.-P.I.C.

* For the Fellowship (F.I.C.).

THE ANALYST.

SEPTEMBER, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE COMPOSITION OF MILK AND MILK-PRODUCTS.

By H. Droop Richmond.

(*Read at the Meeting, May* 2, 1900.)

Of the 34,943 samples analysed in the Aylesbury Dairy Company's Laboratory during 1899, 29,256 were analyses of milk.

The composition of 14,133 samples taken on arrival of the milk from the farms at the chief and branch depôt is given in Table I. The composition of the morning and evening milk is kept separate.

Table I.

Average Composition of Milk during 1899.

Month.	Morning Milk.				Evening Milk.				Average.

Average	1·0324	12·51	3·57	8·94	1·0321	12·83	3·90	8·93	1·0322	12·67	3·74	8·93

As has been noticed in former years, the lowest fat occurs in June and the highest in October. During the months of July and August the solids-not-fat are

below the average, as has been recorded in every previous year. Last year, owing to the drought, the depression in solids-not-fat extended into September, while this year the September solids-not-fat show a marked increase over those of August. As the September of 1899 was a comparatively wet month, this is further evidence that drought has a tendency to cause low solids-not-fat.

Three samples representative of the mixed bulk of milk from a whole farm fell below 3·0 per cent. of fat, the lowest figure recorded being 2·94, and many samples, especially during July and August, fell below 8·5 per cent. solids-not-fat.

Three samples especially may be mentioned. Of these the first is from a single cow with a suspicious udder, whose calf died and was found to be in an advanced stage of tuberculosis; this sample was not obtained from the herds supplying the company, but was obtained from a private source. The other two are from milk taken under the personal supervision of the lady to whom the herd belonged.

	I.	II.	III.
Specific gravity	1·0302	1·0288	1·0290
Total solids	10·66	11·39	11·50
Fat	2·60	3·37	3·40
Sugar	3·23	4·03	4·08
Proteids	3·98	3·24	3·27
Ash	0·85	0·75	0·75
Solids-not-fat	8·06	8·02	8·10

These samples confirm the view previously expressed, that when genuine samples are low in solids-not-fat, the proteids and ash are normal, and the milk-sugar is the constituent on which the deficiency falls.

I have in a previous paper (ANALYST, xxiii., 169) drawn attention to the fact that the expression G + F is approximately a constant; this does not hold in abnormal samples. I would here mention that all milks, abnormal or otherwise, conform to the following two rules, which are practically different modes of expression of the same fact.

A. The solids-not-fat, less the milk-sugar, calculated on the milk devoid of fat, amount to at least 4·0 per cent. This, expressed as a formula, is:

$$(S - L)\frac{100}{100 - F} \text{ exceeds } 4{\cdot}0.$$

(S = solids-not-fat, L = milk-sugar, F = fat.)

B. The sum of the specific gravity degrees and the fat, less four times the milk-sugar, exceeds 16·0; this, expressed as a formula, is:

$$G + F - 4L \text{ exceeds } 16{\cdot}0.$$

The following Table II. gives analyses which support this view. The bulk of the analyses have been previously published, and the references are given for verification.

H. Timpe (*Chem. Zeit.*, 1899, 1040) has lately drawn attention to the fact that there is a constant relation between the proteids and fat in genuine milk, expressed by the formula $P = 2 + 0{\cdot}35\ F$; and he proposes to detect adulteration in milk by a divergence between the proteids found and calculated.

If the difference (found *minus* calculated) is positive, and exceeds in mixed milk +0·06, he concludes skimming; if negative, and exceeding −0·06, he concludes dilution either by excess of fat or by water, and decides between these two causes by the sugar and ash determinations.

He deduces his formula from twenty-one analyses of "normal" milks, in which the differences vary from +0·12 to −0·11. He gives analyses in his paper of forty abnormal milks, the first nine of which are classed as abnormal because the cows were either stall fed or experimentally fed, the next fifteen samples because the cow was diseased (and these are rightly classed as abnormal); the last sixteen samples were derived from a cow which had recovered from gastric catarrh.

He also quotes feeding experiments by Langbeck on three cows: one cow remained of the same weight, and gave milk of fairly constant composition throughout the series, and he points out that the milk of this cow agreed with his formula except when the food was changed; the other two cows altered in body-weight, and their milk constantly disagreed with his formula, and was therefore classed as abnormal.

He concludes that normal milk—*i.e.*, milk produced from grass-fed cows, whose food is not changed, and who are not suffering from disease—will, when the mixed product of several cows is considered, agree with his formula within ±0·06 per cent. (though one-third of his normal milks exceed this). This conclusion involves the assumptions that stall-feeding, change of ration, etc., are practically unknown, and that the methods of analysis involve an experimental error of less than 0·06 per cent. These assumptions appear to be unwarranted. Certainly in English dairy practice

stall-feeding and change of diet are largely practised; and if we admit his results with stall- and experimentally-fed cows as "normal"—and there appears no reason to suppose them otherwise—the percentage of disagreement with his formula jumps up to over 50.

If we take the results obtained in the estimation of the fat and proteids, an experimental error of 0·1 per cent. is by no means an over-estimate of possible variations; an error of 0·1 per cent. in each might mean a variation of 0·135 per cent. in the difference, a figure which is more than double his allowable variation.

When his series is extended—and I have done this by applying his formula to over fifty milks—the agreement practically disappears. The following table expresses my results in a condensed form:

Percentage of Fat.	Percentage of Proteids. Extremes.	Mean.	Calculated.	Difference.
3·0 -3·25	3·11–3·48	3·35	3·08	+0·27
3·25–3·50	3·22–3·60	3·38	3·19	+0·19
3·50–3·75	3·27–3·76	3·46	3·27	+0·19
3·75–4·00	3·30–3·63	3·40	3·36	+0·04
4·00–4·25	3·27–3·68	3·49	3·44	+0·05
4·25–4·50	3·45–3·55	3·50	3·60	−0·10
Above 4·50	3·42–3·66	3·52	3·77	−0·25

The maximum individual differences varied from +0·46 to −0·44, or nearly 0·5 per cent.

It is seen from the above table that there is a very slight tendency for the proteids to be higher when the fat is high, but the tendency is very much less than that indicated by Timpe's formula.

In my opinion, the conclusions arrived at in the paper are entirely unwarranted by the facts, because—

(*a*) The number of samples of "normal" milk is too small to admit of a general conclusion being drawn.

(*b*) The limitations within which the formula is applicable are so narrow as to destroy its usefulness in commercial work, and the "abnormal" samples are classed as such on insufficient grounds.

(*c*) The agreement expected is greater than the accuracy with which commercial analysis can be done.

(*d*) On applying the formula to results obtained under other conditions it fails utterly.

The bulk of the fat estimations of the milks referred to in Table I. were made by the Gerber method; though the accuracy of this is generally admitted, I have thought that some figures, showing the differences between this and gravimetric methods during 1899 would show the extent to which the figures are reliable.

In all 65 experiments where comparisons were made are available; the fat varied from 1·98 per cent. to 4·60 per cent. The maximum differences were +0·15 and −0·20, with a mean difference of −0·016.

Of the 65 samples 39 had an error of 0·05 or less = 60·0 per cent.; 15 an error of 0·06 to 0·10 = 23·1 per cent.; 9 an error of 0·11 to 0·15 = 13·9 per cent.; and 2 an error of 0·16 to 0·20 = 3·1 per cent.

The two samples with differences of more than 0·15 were a human milk and a somewhat clotted sterilized milk, and excluding these, and including only the 68 ordinary milks, the maximum differences were +0·15 and −0·14, and the mean was −0·01 per cent.

Storch holds that the fat globules in milk are surrounded by a "mucoid" membrane; I have already expressed myself as unable to accept this view (ANALYST, xxii., 207). If Storch's view were correct, it would be expected that the membrane would bear such a proportion to the smallest fat globules that their density would be equal to that of the milk serum, and the last traces of fat could not be removed by centrifugal force. By means of the Crown Hand Separator, which is very efficient, I have succeeded, on running milk twice, in obtaining samples of separated milk in which the percentage of fat is so small that it does not reach the second place of decimals per cent.; this fact, while not definitely disproving Storch's view, is further evidence against it.

A sample of separated milk was run for fifteen hours in a centrifugal machine at the rate of 1,000 revolutions per minute. Cultivations on gelatine were made from the top portion, the middle, and the bottom. The results were, after eight days of at 22°:

	Colonies per $\frac{1}{1000}$ c.c.	Remarks.
Top	197 ...	Growth rapid, about 20 per cent. liquefied.
Middle ...	5	
Bottom ...	194 ...	Growth slow, none liquefied.

This appears to show that while some micro-organisms have a density greater than 1·036, others have a less density. The top cultivation was made from the portion immediately underneath the thin layer of cream, so that it is not probable that they were carried up by the cream.

The composition of clotted cream during 1899 was found to be:

Constituent.	Maximum.	Minimum.	Average.
Total solids	71·58 ...	60·75 ...	65·74
Fat	64·70 ...	50·27 ...	58·24
Ash	0·83 ...	0·46 ...	0·60
Solids-not-fat	10·48 ...	5·67 ...	7·50

The composition agrees with that found in previous years.

The following percentages of water in butter have been found:

	Maximum.	Minimum.	Average.
French, fresh	15·10 ...	13·08 ...	14·32
Irish, fresh	14·09 ...	11·79 ...	12·87
Irish, salt	13·29 ...	11·33 ...	12·31
Danish, salt	13·17 ...	10·63 ...	11·93

Two samples of butter prepared by a "butter extractor" which was claimed to increase the yield of butter was examined. The analyses were:

	I.	II.
Fat	77·86 ...	—
Water	20·42 ...	23·16
Curd	1·49 ...	—
Salt	0·23 ...	—

It is not difficult to see how the increased yield is obtained.

The following average figures were determined on the fat with a Zeiss butyro-refractometer:

	Refraction Number at 35°.	KOH absorption.
French butter	46·4°	22·88 per cent.
Irish ,, ...	46·4°	
Danish ,, ...	46·2°	

A sample of butter prepared from the milk found last year to be low in solids-not-fat was found to have a refraction number of 47·2° at 35°, and a KOH absorption of 22·12 per cent.

Some experiments were carried out, chiefly by Mr. C. H. Rosier, on the reaction described by Dupouy (ANALYST, xxii., 211) with paraphenylene-diamine for distinguishing between fresh and boiled milk; none of the usual preservatives added to milk were found to interfere with this reaction, though in the presence of formaldehyde the colour had a somewhat grayish tint. It was found that metaphenylene-diamine also gave a blue colour less strongly developed than when the para-compound was used. On adding amyl alcohol, shaking, and allowing to separate, the colour was in each case taken up by the amyl alcohol, but while the colour turned brown with the para-compound, it remained blue with the meta-compound. Alkalies turned the colours red. We found that the amyl alcohol solution of the colour from the para-compound turned brown very rapidly when exposed in thin layers to the air, while the solution with the meta-compound remained blue, and the amyl alcohol could be evaporated without much change. Oxidizing agents, such as potassium permanganate, produced a blue compound with both para- and meta-phenylene-diamine.

It appears probable than an oxydase which is destroyed by heat, exists in milk and this produces an unstable blue compound with para-phenylene-diamine, and a stable one with meta-phenylene-diamine; the addition of amyl alcohol increases the delicacy of the test with the latter; we recommend meta-phenylene-diamine, together with amyl alcohol, as the best reagent.

A sample of separated milk was met with which did not give this reaction, either with para- or meta-phenylene-diamine, although it had not been heated above the temperature necessary for separation; it also curdled with difficulty with rennet, and contained abundance of soluble albumin. The colour tests for heated milk should not be implicitly relied upon, and Faber's albumin test (ANALYST, xiv., 141) should always be applied before concluding that milk has been heated.

Before concluding I would mention that the bulk of the work has been performed by Messrs. F. R. O'Shaughnessy, J. B. P. Harrison, and C. H. Rosier.

DISCUSSION.

The PRESIDENT having invited discussion,

Dr. DYER desired to ask if the author knew what was the breed of the cows that yielded the samples of abnormal milk referred to. He (Dr. Dyer) was inclined to think that the use of some of the formulæ mentioned was in the direction of unnecessary elaboration. In the case of the first formula, for instance, it seemed much simpler to say that, in the fat-free milk, the percentage of proteids and ash was usually above 4, which seemed really to be all that the formula conveyed. Criticism

of this kind, however, did not detract from the appreciation to which the work involved in this series of papers was entitled.

Mr. T. H. POPE desired to point out that in the second formula the limits given for the abnormal milk were inside those in the normal milk, whereas in the case of the first formula they were very close. He understood the author to say that these formulæ would be of use in doubtful cases; but, having regard to these numbers, he hardly thought that that would hold.

Mr. JOHN WHITE said that he too had found that butter containing an excessive quantity of water—*i.e.*, over 16 per cent.—was becoming of less frequent occurrence than formerly. Out of a large number of samples of butter of colonial, Irish, Danish, German and French origin, which had been submitted to him under the Sale of Food and Drugs Act within the last two years, he had only met with two in which the proportion of water was as much as 17 per cent. He also had examined samples of butter made by a process which was supposed not only to yield more butter than ordinary processes, but to yield it in a much shorter time; and one of those samples contained 28 per cent. of water, being in this respect somewhat similar to the samples referred to in the paper.

The PRESIDENT (Mr. FISHER) said that, having had occasion to refer to the former papers of this series for the purposes of the evidence which he had recently laid before the Milk Standards Committee, he felt personally indebted to the author for the large quantity of information which they contained. In reference to the formula $p = 2 + 0{\cdot}35\ f$, it seemed that while, in the case of milk containing about 4 per cent. of fat, the average percentage of proteids was indicated fairly correctly, a larger percentage would be indicated as the fat increased, and a smaller percentage as the fat diminished. But this would not afford any clue to the original composition of a sample of milk from which, for instance, a portion of the fat had been artificially removed. The difference between morning and evening milk was a point of great practical importance as affecting the question of standards and limits, having regard to the small proportions of fat sometimes found in milks which were mixed milks, and yet which must be accepted as genuine.

Mr. RICHMOND, in reply, said that he had no information as to the breed of the cows which yielded samples No. 2 and No. 3. No. 1 was the milk of a Jersey cow. The formula referred to by Dr. Dyer had been introduced because the figure calculated from it might to a certain extent be substituted for the percentage of proteids obtained by direct determination. In the case of formula No. 2, any experimental error in the milk-sugar estimation was multiplied four times, whereas in formula No. 1 it was not multiplied at all, which accounted for the fact that the two formulæ did not give strictly comparative results. Furthermore, any variation in the percentage of fat would affect formula No. 2 and not No. 1, seeing that in No. 1 the milk-sugar was expressed in terms of the fat-free milk, while in No. 2 the milk-sugar was taken as it stood. As, however, the constancy of the results of both formulæ was only approximate, he had not thought it necessary to put them in exactly the same form. He would like to make it quite clear that the samples of butter containing 20·4 and 23·2 per cent. of water were obtained by means of a machine in which the operation of churning was practically instantaneous, whole

placed in the machine, and skim milk running out at one side and butter at the other. He agreed with the President's criticism of the formula $p = 2 + 0{\cdot}35\ f$. As the fat increased, however, there was a slight tendency for the proteids to increase also, though not to anything like so great an extent as the formula represented.

He felt that the fact should be referred to that this series of papers had been commenced by Dr. Vieth, to whom was due in the first instance the system that was now being followed.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Estimation of Total Extract in Wine. **A. Hubert.** (*Rev. gén. Chim. pure et appliq.*, 1900, ii., 374; through *Chem. Zeit. Rep.*, 1900, 168.)—The author obtains constant results by absorbing 5 c.c. of the sample in porous filter-paper, and keeping it for four or five hours over sulphuric acid under diminished pressure at a temperature of 50° C. He has devised a convenient arrangement evacuated by means of a water-pump, fitted with thermostat and pressure-gauge, and capable of being placed as a whole inside a vessel full of warm water. Aqueous glycerol can also be evaporated in a similar manner with moderate accuracy. F. H. L.

Vanillin in Wine Vinegar. **A. Stocky.** (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 235.)—The presence of vanillin being suspected in a sample of wine vinegar, the following procedure was adopted for its detection: A large quantity was evaporated with calcium carbonate, the residue extracted with ether, and the extract evaporated to dryness on the water-bath. The residue was repeatedly re-crystallized from alcohol and identified by the following tests:

(*a*) The production of a metallic mirror with ammoniacal silver solution.

(*b*) The production of phloroglucinvanillin by the addition of phloroglucinol to a moderately strong hydrochloric acid solution of the crystals. H. H. B. S.

Influence of Saccharin upon Peptic and Pancreatic Digestion. **F. Berlioz.** (*Chem. Zeit.*, 1900, xxiv., 416.)—The author's experiments confirm the statement of Nencki (*Farmazeft*, 1899, vii., 1130) that saccharin, at least in small amounts, does not interfere with gastric or pancreatic digestion. F. H. L.

TOXICOLOGICAL ANALYSIS.

Notes on the Detection of Conine in Cases of Poisoning. **D. Vitali and C Stroppa.** (*Boll. Chim. Farm.*, 1900, xxix., 221; through *Chem. Zeit. Rep.*, 1900, 170.)—The authors have recently been engaged in a legal case of the above description, and record the following observations: A one per cent. solution of conine acetate

or tartrate can be distilled without any alkaloid passing over with the When the Stas-Otto method of working is adopted, ether dissolves an appreciable quantity of conine before the liquid is made alkaline, *i.e.*, dissolves alkaloid from an acid solution. Conine can be separated from any colouring matter or ptomaines which may be present, by shaking the ethereal extracts (either from the acid or the alkaline liquors) with water faintly acidified with acetic acid, then making the liquid alkaline with barium hydroxide, and extracting with petroleum spirit boiling between 40° and 60° C. To avoid as much as possible the discoloration of the conine salt on evaporation, it should be treated with lead acetate and sulphuretted hydrogen; the lead sulphide carries down the colouring matter. The characteristic smell of mice is so distinct that it is noticeable on warming a 1 : 100,000 solution. When a few drops of the green solution prepared by dissolving 1 gramme of potassium permanganate in 200 c.c. of strong sulphuric acid are added to a little conine, the colour changes to a violet, and is unaffected by further additions of strong sulphuric acid. Conine gives a white precipitate with Nessler's reagent. With trichloracetic acid in fairly strong solution, it yields a turbidity soluble in excess of acid; on evaporation at a moderate temperature, a residue of microscopic needles (in bunches) is left. Guinea-pigs and frogs die half an hour after the injection of a small dose, exhibiting paralysis, which appears first at the hind quarters. As Rossbach has stated, one drop of a very weak solution of conine is rapidly fatal to the infusoria that develop in water in which oats have been soaked for a few days. F. H. L.

ORGANIC ANALYSIS.

Oil of Mandarin. **G. Fabris.** (*Annali del Laboratorio delle Gabelle*, 1900, iv., 140, 141.)—This oil is rarely obtained pure in commerce, owing to its production being limited and its price high. It is obtained from the peel by hand in the same manner as oil of orange or oil of lemon.

It is a golden-yellow liquid, with a slight bluish fluorescence, which becomes more pronounced on diluting the oil with alcohol. Its specific gravity varies from 0·854 to 0·858 at 15° C., and its rotatory power at 20° C. from +65° to 75°. It begins to boil at 175° C., and distils over almost completely at 179° C. The fraction distilling between 175° and 177° C. has a rotation of 76° to 77°. It consists for the most part of limonene, and also contains small quantities of aldehydes (citral and citronellal).

C. A. M.

Oil of Sweet Orange **G. Fabris.** (*Annali del Laboratorio delle Gabelle*, 1900, iv., 136-139.)—This oil, commonly known as *Essenza di Portogallo*, is principally extracted in Calabria, and in the provinces of Messina, Catania and Syracusa, in Sicily, the peel being squeezed by hand, and the expressed juice caught in a sponge.

It has a more or less pronounced orange colour and an aromatic taste. It consists for the most part (about 90 per cent.) of limonene, and contains citral and possibly another aldehyde, but no pinene. The most characteristic properties of the oil are its specific gravity, rotatory power, and boiling point, which, from the observa-

tion of different authorities, vary within the following limits: Specific gravity at 15° C., 0·848 to 0·852; rotation at 20° C., +96° to +98°; boiling point, 175° to 180° C. The distillate is colourless, and has a slightly lower specific gravity and a slightly higher rotation than the original oil.

Owing to the fact that oil of orange is much more constant in its physical properties than oil of lemon or oil of bergamot, adulteration is more easily detected. Oil of turpentine and oil of lemon, which are the principal adulterants, raise the specific gravity and lower the rotation. In doubtful cases a fractional distillation is useful, since in the case of a pure oil the first distillate has a slightly higher rotatory power than the original oil, whereas in the case of mixtures the rotatory power of the distillate is lower than that of the original mixed oils. C. A. M.

The Aldehydic and Ketonic Constituents of Verbena Oil: "Verbenon." M. Kerschbaum. (*Berichte*, 1900, xxxiii., 885-893.)

I. *Verbena Oil extracted from Chiris Grass.*—When distilled in a current of steam, this is a dark-coloured oil with an odour resembling that of lemon-grass oil. Its specific gravity at 17° C. is 0·903, and its specific rotation = $(\alpha)_D - 12° 30'$. The author found a specimen to contain 26 per cent. of citral and 74 per cent. of terpenes and alcohols. The citral, isolated by Tiemann's method (*Berichte*, xxxi., 3336), contained, in addition to citral *a*, from 17 to 20 per cent. of citral *b*.

II. *Verbena Oil distilled from Spanish plants.*—This oil, which differs somewhat in odour from the preceding oil, has a specific gravity of 0·926 at 17° C., and $(\alpha)_D + 2° 45'$. A specimen examined by the author was found to contain 13 per cent. of citral, 86 per cent. of alcohols and terpenes, and about 1 per cent. of a new optically active ketone to which the name of "verbenon" was given.

This new ketone was obtained as a semicarbazone ($C_{11}H_{17}N_3O$ or $C_{11}H_{19}N_3O$) from the verbena oil, after complete removal of the citral. The semicarbazone (melting point 208-209° C.) yielded, on treatment with phthalic anhydride and steam, "verbenon" as a colourless oil. It had a characteristic odour recalling that of camphor and of peppermint. It was completely insoluble in water, but miscible in all proportions with the ordinary organic solvents.

On oxidation with potassium permanganate it yielded a ketonic acid ($C_9H_{14}O_3$), from which Baeyer's norpic acid, $C_8H_{12}O_4$ (*Berichte*, xxix., 1911) was obtained by treating it with sodium hydroxide and bromine.

It was not definitely determined whether verbenon was a saturated or unsaturated substance, or whether its formula was $C_{10}H_{16}O$ or $C_{10}H_{14}O$. C. A. M.

Examination of Rubber Goods. O. Chéneau. (*Zeits. Unters. Nahrungs. u. Genussm.*, 1900, iii., 312.)

Preliminary Tests.—The homogeneity of any specimen of rubber may be conveniently judged by determining the specific gravity and the ash of various small portions of the sample. As the density of caoutchouc lies between 0·919 and 0·956, a higher gravity points to the presence of mineral matter. The ash should be deter-

mined at the lowest possible temperature; if it be high in amount, a complete analysis is advisable. Some of the material should then be gently ignited and the product examined qualitatively; while in the original substance the mineral matter soluble in acetic acid, the carbon dioxide, and the mercury should be estimated separately, as described below. A sample should be extracted with hot or cold alcohol; if it loses more than 2 per cent. by weight, it may be considered to contain foreign organic matter, or to be of inferior quality. The total sulphur should be determined by Henriques' process (ANALYST, 1899, xxiv., 297), but if the rubber yields only a little ash, Mahler's bomb may be employed to save time. About 50 c.c. of water are placed in the bomb, 1 or 2 grammes of rubber in the crucible; oxygen is admitted to a pressure of 5 or 10 atmospheres, and the material is ignited electrically. The water is then collected, the bomb rinsed out, and the sulphuric acid precipitated with barium chloride.

Systematic Analysis.—(1) A weighed quantity of rubber is treated with warm dilute acetic acid, to which some sugar has been added in order to dissolve red lead. The liquid is decanted through a tared filter, the insoluble matter boiled two or three times with water, brought on to the paper, washed till neutral, dried at 105° C., and weighed. In the filtrate calcium, lead, magnesium, zinc and alkalis may be determined. The proportion of substances really soluble in acetic acid which escape dissolution in this process is so small as to be negligible. If the sample was coloured with ultramarine, part of the sulphur thereof is evolved as sulphuretted hydrogen, part remains suspended in the liquid and passes through the filter. If the odour of H_2S is noticed, the amount of sulphur in a portion of the residue should be determined; deducting this from the total sulphur, the sulphur of the ultramarine and that combined with the substances decomposed by the acetic acid is given. (2) The residue from the acetic acid is boiled for two or three hours with normal alcoholic soda under an inverted condenser, driving off the spirit, adding water, and passing the liquid through a tared filter-paper; this operation is repeated, the insoluble matter is washed with boiling water and with water acidulated with acetic acid, then brought on to the filter, dried at 105° and weighed. The loss in weight represents the rubber substitutes, the sulphur combined therewith, the free sulphur, the natural resins the caoutchouc, added resins, pitch, etc. (3) The residue from the caustic soda is extracted with acetone as long as the solvent is coloured; the acetone is distilled off, the solid dissolved in ether, filtered, evaporated, dried at 100° and weighed. This process yields the unsaponifiable oils (mineral and rosin) and part of any asphaltum in the sample. (4) The residue from the acetone is treated with cold nitrobenzene (30 c.c. per 1 gramme), according to Henriques' method of dissolving "asphaltum" (*Chem. Zeit.*, 1894, xviii., 411, ANALYST, xix., 111); all the latter passes into solution, whether it be natural asphaltum or a product derived from tar. In this process unvulcanized rubber loses 1 or 2 per cent., vulcanized rubber on an average 3 per cent., hard rubber somewhat less. (5) The residue from (4) is extracted with petroleum spirit or chloroform, which dissolves paraffin and the unvulcanized rubber that was not removed by the nitrobenzene. In a part of the residue from (5) sulphur is determined; deducting the yield from the difference calculated in (1), the free sulphur and sulphur combined with rubber substitutes and

with asphaltum is given. According to Helm, the asphaltum contains 8 to 11 per cent. of sulphur combined in an organic form, and 0·36 to 0·4 per cent. combined with bases. (6) The rest of the residue from (5), or the original material simply exhausted with acetic acid and sugar, is boiled for an hour, according to Weber's process, under a condenser with 3 c.c. of chloroform and 50 c.c. of nitrobenzene (per 3 grammes of rubber); after cooling, 100 c.c. of ether are added, the insoluble matter is filtered off, washed with petroleum spirit and ether, dried and weighed. If the rubber is hard or heavily loaded, the liquid may filter badly; in this event the operation should be conducted on a number of small portions, decanting the solutions after subsidence, and employing the residues as below. (7) The residue from (6) will contain the mineral substances insoluble in acetic acid, *e.g.*, talc, kaolin, ochre, barium sulphate, stannic sulphide ("mosaic gold"), cinnabar, lead sulphide and sulphate; sometimes also graphite, ground leather, cork, and vegetable fibres. It should be examined microscopically, submitted to a nitrogen estimation, etc., according to circumstances. In another portion sulphur is determined, and by calculation from that obtained in (5), the sulphur combined with the caoutchouc is given.

Carbon dioxide from the carbonates may be determined by treating the sample with dilute acid, passing the vapours through a tube of pumice and copper sulphate, and absorbing the gas in soda-lime. Or the material can be first attacked with hot chloroform and nitrobenzene, and the CO_2 in the product estimated. If the colour of the goods suggests the presence of cinnabar, the mercury should be estimated by a dry process in the cold nitrobenzene residue. F. H. L.

Influence of Dextrose on the Estimation of Urea by means of Hypobromite. L. Garnier and L. Michel. (*Journ. Pharm. Chim.*, 1900, xii., 53; through *Chem. Zeit. Rep.*, 1900, 208.)—The authors find that the irregularities in the estimation of urea by means of hypobromite may be explained by the presence of dextrose. Hypobromite acts energetically upon dextrose, evolving so much heat that the volume of nitrogen cannot be read off till after half an hour's standing. It is also possible that carbon dioxide may be liberated, which will mix with the nitrogen unless a large excess of alkali is employed. Moreover, the nitrogen is always below its proper quantity, for hitherto no method of liberating all the gas from urea has been discovered.* The Kopp-Yvon process of decomposing urea is very convenient, and although it does not give absolutely correct results, it is fairly accurate, especially if the analysis of a urine be conducted side by side with that of a specimen of pure urea in 3 per cent. solution. Taking 2 c.c. of urine, and calling the volume of nitrogen liberated V', with 2 c.c. of standard 3 per cent. urea solution yielding V c.c. of nitrogen, the weight of urea (p) in 1 litre of urine is

$$p = 0{\cdot}06 \times \frac{V'}{V} \times \frac{1000}{2} = 30\frac{V'}{V}.$$

F. H. L.

* A. H. Allen has shown that by adding sodium cyanate all the nitrogen is evolved.—EDITOR.

Estimation of Oxalic Acid in Urine. Existence of Oxaluric Acid therein. E. Salkowski. (*Zeits. physiol. Chem.*, 1900, xxix., 437; through *Chem. Zeit. Rep.*, 1900, 208.)—In the usual methods of determining oxalic acid in urine, the presence of phosphoric acid is apt to cause inaccuracies; the author therefore employs an immiscible solvent which extracts all the former with only traces of the latter. Five hundred c.c. of unfiltered normal human urine are concentrated to one-third the bulk, cooled, acidified with 20 c.c. of 1·12 hydrochloric acid, and agitated three times with 200 c.c. of a mixture of 9 or 10 volumes of ether with 1 volume of alcohol. The extracts are separated, filtered through a dry paper, and distilled. The residue is treated with 10 or 15 c.c. of water, and cautiously heated on the water-bath in a deep basin until the liquid is clear and resinous matter deposits. The whole is filtered, the insoluble portion washed once or twice with a minimum of water, and the filtrate made faintly alkaline with ammonia; then 1 or 2 c.c. of 10 per cent. calcium chloride solution are added, and finally an excess of acetic acid. After at least twenty-four hours' standing, the calcium oxalate is brought on to an ashless filter-paper, washed, etc., and weighed as CaO. A similar process is available for the examination of fabrics in which oxalic acid is suspected, 250 to 800 grammes being taken for analysis.

When urine is evaporated for a long time, the oxalic acid changes into a form which is no longer capable of extraction by means of ether, but which is reconverted into its original condition on boiling with hydrochloric acid. This substance must be oxaluric acid. Whether the latter actually exists in the urine is still unknown; therefore in estimating oxalic acid, the urine should be acidified during concentration (*ut supra*), and the total yield should be considered to include any oxaluric acid.

F. H. L.

Estimation of Chlorine in the Gastric Juice. G. Meillère. (*Bull. Soc. Chim.*, 1900, [3], xxiii., 404; through *Chem. Zeit. Rep.*, 1900, 176.)—The juice is first filtered or treated in a centrifugal machine, in order that the insoluble matter may be available for further examination. In 10 or 20 c.c. of the clear liquid, the acidity is determined by titration with barium hydroxide and phenolphthalein, calculating the result as HCl. To find the total chlorine, 10 grammes of juice are mixed with a small excess of calcium carbonate and 0·2 or 0·25 gramme of calcium nitrate, then evaporated to dryness, and ignited gently till the carbon is oxidized. The residue is taken up with water containing a little acetic acid, neutralized with chalk, and the liquid titrated with silver nitrate and potassium chromate. To estimate the chlorine in the dry residue of the juice, the sample is evaporated *in vacuo* rather than on the water-bath, and treated as above. The chlorine of the ash is determined by evaporating and igniting 10 c.c., next adding calcium nitrate and burning off the carbon, and finally titrating with silver.

F. H. L.

Detection of Salicylic Acid in Presence of Citric Acid. O. Langkopf. (*Pharm. C.H.*, 1900, xli., 335; through *Chem. Zeit. Rep.*, 1900, 176.)—Citric acid or a citrate prevents the ferric chloride reaction for salicylic acid appearing. A fruit

syrup in which the presence of the latter is suspected should therefore be extracted with equal parts of ether and petroleum spirit, and the preservative sought for after the solvents have been driven off. F. H. L.

Detection of Salicylic Acid in Presence of Citric Acid. A. Conrady. (*Apoth. Zeit.*, 1900, xv., 412; through *Chem. Zeit. Rep.*, 1900, 193.)—The failure of the ferric chloride test for salicylic acid when citric or tartaric acid is present, to which Langkopf has referred (see preceding abstract), is presumably due to the formation of some double compound in which the iron exists in the ferrous state. There is no necessity to treat the material under examination with an immiscible solvent; addition of one drop of nitric acid or of hydrogen peroxide suffices to determine the usual reaction. F. H. L.

Relative Value of different Combustibles. F. Isaac. (*Bull de l'Ass. belge*, 1900, xiv., 19-23.)—The general composition of combustibles, after deduction of water and ash, is shown in the subjoined table:

Dry Substance minus Ash.	Carbon.			Hydrogen.	Oxygen, including Nitrogen.	Ratio O/H	Calories Per Kilo.
	Total.	Fixed.	Volatile.				
Wood	50	25	25	6	44	7	5,000
Turf	60	27	33	6	34	6	6,000
Lignite	73	31	42	5·8	21·2	5	7,000
Coal, from the upper measures, dry, burning with much flame	75	60	15	5·5	19·5	4	8,000
Coal, intermediate ...	85	75	8	3 to 5	3 to 20	2 to 3	8,500
Coal, from the lower measures, burning without much flame, anthracitic	95	93	2	2·5	2·5	1	9,000?
Petroleum Oil ...	83	—	83	4	4	0·3	11,000

As regards the samples of compressed lignite which he has examined, the author has met with three different brands, but all having substantially the same appearance, density, and composition—viz., water, 15; ash, 5; volatile matter, 55; and fixed carbon, 25 per cent.; specific gravity, 1·25.

The dry lignite free from ash has the composition shown in the table, and from this the calorific power of the coal per kilogramme can be calculated by the formula of Dulong:

$$\left[8{,}080 \times \frac{\text{H}}{\text{C}} \times 73 + 34{,}500 \times \left(\frac{\text{H}}{5{\cdot}8} - \frac{\text{O}}{8} \right) \frac{21{\cdot}2}{} \right] \div 100 = 6{,}985 \text{ calories, or, in round numbers, } 7{,}000 \text{ calories.}$$

C. A. M.

Estimation of Sulphur in Petroleum by means of Mahler's Bomb. G. Pfeiffer. (Reprint from *Bull. Soc. sciinte din Bucuresci*, 1900, viii., [6]; through

Chem. Zeit. Rep., 1900, 207.)—The above apparatus may conveniently be used to determine the proportion of sulphur in petroleum. In the bomb are placed 2 or not exceeding 2·5 grammes of the material, and oxygen is admitted to a pressure of 30 atmospheres. In the original article Pfeiffer gives a table of the physical and chemical constants of various Roumanian and Russian petroleums, whence it appears that crude Baicoiu oil contains the maximum of sulphur (0·484 per cent.), and the Russian "Wladikawkas" oil the least (0·100 per cent.). The latter, after removal of spirit, is employed for locomotive firing. F. H. L.

Vandyke Brown. H. Borntraeger. (*Oesterr. Chem. Zeit.*, 1900, iii., 294.)—According to the author, Vandyke brown, or Cassel brown (earth), consists essentially of humic acid; and it may therefore be identified, or its purity judged, by its ready solubility in alkali-metal hydroxides or carbonates. It floats on water, is entirely free from sulphur, and leaves a perfectly white ash when ignited with sulphur and potassium nitrate or chlorate. It may be examined by heating 0·5 gramme to 110° C. to determine the moisture, and then boiling it with 2 grammes of caustic potash and 100 c.c. of water for an hour, weighing the undissolved residue. Vandyke brown must not be confused with Cologne earth, which is a manganese colour. F. H. L.

[In his "Chemistry of Paints and Painting," Professor Church describes three kinds of Vandyke brown, none of which corresponds exactly with the above, as all contain more or less iron. Cassel brown is represented by Church to be synonymous with Cologne (Cullen) earth—an impure variety of lignite. Yet "Kölnische Erde" is given by him as the German equivalent of umber.—F. H. L.]

Measurement of the "Fastness" of Printing Inks. (*Oest. Chem. Zeit.*, 1900, iii., 265-267.) — The dry pigment is ground up with one half to one quarter the quantity of linseed-oil varnish, and is printed on to a piece of rag-paper free from wood-fibre. The pigment with which it is to be compared is treated in the same way. The printed surfaces are partly covered with black paper, and are exposed to diffused daylight until the standard colour is almost entirely faded. The intensity of the colour in both the exposed and covered portions is measured by means of a colorimeter. The percentage of the initial colour lost by the standard piece is divided by the percentage lost by the sample. The resulting number the author calls the "fastness" (Lichtechtheit).

If the pigment be very fast as compared with the standard, it is necessary to renew the paper printed with the latter. The percentage loss of colour is measured in each paper, these percentages are added together, and the sum is divided by the percentage loss in the paper printed with the pigment under examination.

NOTE BY ABSTRACTOR.—The author does not state that the comparative "fastness" of one pigment to another is constant when the exposure is varied. It appears improbable that it should be so, especially when the fading is allowed to proceed very far. The numbers obtained by the above method are therefore of doubtful

valve. See Scheurer and Brylinski (*Bull. Soc. Ind. Mulhouse*, 1898, 273) and G. Lemaine (*Ann. Chim. Phys.*, 1895, vi., 433). A. M.

INORGANIC ANALYSIS.

Determination of Slag in Iron and Steel. L. Schneider. (*Oesterr. Zeits. Berg u. Hüttenw.*, 1900, xlviii., 257 and 275; through *Chem. Zeit. Rep.*, 1900, 167.)—Processes which depend on igniting the metal in chlorine or dissolving it in acids yield low results, as they cause a loss of slag; processes which depend on the use of copper or mercuric chloride, etc., only attack portions of the steel very slowly, and give high results. The following is the best method to adopt, as it yields 98 to 99 per cent. of the true slag present in the metal: In a 200 or 300 c.c. beaker immersed in a larger vessel full of cold water is placed 15 c.c. of bromine and 100 c.c. of water; 5 grammes of the sample in turnings are introduced, and the whole is stirred up at intervals for two or three hours till no more solid matter can be felt. The outer beaker is next warmed to 90° C. for ten or fifteen minutes in order to bring certain sparingly soluble iron compounds into solution; the mass is allowed to settle, and filtered. The residue is first washed with water as long as the filtrate gives an iron reaction, next with a boiling solution of ammonium tartrate containing a large quantity of free ammonia to dissolve basic salts precipitated during filtration, and finally with water again; but if the original metal is rich in carbon, the residue should be rinsed off the paper, and extracted several times with the tartrate to ensure solution of iron carbide and phosphate. The slag is then ignited, and freed from silica with sodium carbonate solution. Allowance must be made for the conversion of the ferroso-ferric oxide into ferric oxide during ignition. It is not advisable to dissolve the bromine in any soluble bromide, as the energy of attack is thereby seriously diminished. F. H. L.

Estimation of Molybdenum in Iron. E. Döhler. (*Chem. Zeit.*, 1900, xxiv., 537.)—Between 5 and 20 grammes of borings are dissolved in 100 c.c. of nitric acid, and the solution is evaporated first on the water-bath and then on sand, without igniting the residue, till the acid is entirely driven off. The mass is taken up in 100 c.c. of 1·19 hydrochloric acid, and heated on the water-bath, with repeated additions of water, until not more than 10 c.c. of free acid remain behind. It is next diluted and filtered into a large flask, where the solution (about 1,000 c.c. in volume) is precipitated with sulphuretted hydrogen with the usual precautions used in precipitating molybdenum. After standing covered for twelve hours, the precipitate is filtered and washed five or six times with cold sulphuretted hydrogen-water containing a little hydrochloric acid; the filtrate is concentrated to half its bulk, and submitted to the action of sulphuretted hydrogen a second time. Usually the whole of the molybdenum is recovered at the first precipitation; but should the second current of gas produce darkening of the liquid, it should be set aside for ten hours, after thorough saturation, and handled as before. The filter or filters bearing the molybdenum sulphide are then perforated, and the precipitate washed into the

original flask with hot ammonium sulphide and hot water. If any residue on the paper is soluble in dilute hydrochloric acid, it consists of iron, and may be neglected; but if it is coloured brown it contains molybdenum. In this case the filter must be incinerated at a low temperature, and fused with 2 parts of sodium carbonate and 1 of sulphur; the melt is taken up in water, filtered into the main sulphide solution, which is heated for two or three hours in order to dissolve the whole of the molybdenum. This liquid is filtered, any residue being well washed and fused as above, and finally the solution is heated almost to the boiling-point, when it is mixed cautiously and gradually with an excess of 1·124 hydrochloric acid. The sulphuretted hydrogen liberated is driven off, the precipitate collected on a paper tared at 120° C., washed till the chlorine reaction disappears, and dried at 120° to constant weight. The crude molybdenum sulphide is then transferred as completely as possible to an agate mortar, thoroughly mixed up, and an aliquot portion is ignited gently in a current of hydrogen till the weight is constant, considering the product as pure MoS_2 with 60·00 per cent. of Mo.

The original silica precipitate, which also contains the graphite of cast iron, includes the whole of the tungstic acid from tungsten-steels; but provided it be efficiently washed, and the proportion of silicon and graphite together do not exceed 1 per cent., it will be wholly free from molybdenum. F. H. L.

Determination of Nickel in Nickel Ores. A. C. Langmuir. (*Journ. Amer. Chem. Soc.*, vol. xxii. [2], pp. 102-106.)—Where a small amount of nickel is to be separated from a large amount of iron, the following method is claimed to be superior to all others in use:

One gramme of the ore is heated with 15 c.c. of concentrated nitric acid and 1 to 2 c.c. of liquid bromine until the latter is expelled, the liquid being then evaporated almost to dryness. This treatment prevents the formation of a sulphur bead. After expelling the excess of nitric acid, about 50 c.c. of concentrated hydrochloric acid are added, and the liquid slowly boiled down to about 5 c.c., the nitric acid being driven off, and any nickel residue insoluble in that acid brought into solution.

The solution is made up to 250 c.c. with hot water, and treated with hydrogen sulphide to remove copper. The filtrate, after expulsion of the precipitant by boiling, is carefully treated with nitric acid to oxidize the ferrous iron, excess being avoided, and is then made alkaline with ammonia after a slight cooling. The precipitate is washed with hot water, and the filtrate boiled down.

The nickel in the ferric hydroxide is recovered by dissolving the latter in warm dilute hydrochloric acid, concentrating till pasty, treating with 10 c.c. of hydrochloric acid (specific gravity 1·10), warming gently, and agitating for five minutes or more with 40 c.c. of ether in a separating-funnel, the ferric chloride being gradually dissolved by the ether, and leaving nickel, aluminium, cobalt and manganese, as chlorides in the aqueous solution. To insure complete removal of the iron, the ether treatment should be repeated.

The aqueous solution and the (hydrochloric acid) washings of the ethereal

solution are boiled to drive off the dissolved ether; enough bromine to colour the liquid strongly is then added, followed by ammonia, and the solution boiled to throw down iron, aluminium and manganese, the precipitate being dissolved in hydrochloric acid, and again treated with bromine-water and ammonia.

The filtrates and washings being added to the concentrated filtrate from the first ferric hydroxide precipitate, the liquid (containing the whole of the nickel) is concentrated to 100 c.c., or till separation of ammonium chloride begins, the latter being then destroyed by boiling nearly to dryness with 50 c.c. of concentrated nitric acid. This acid is next expelled by heating with 10 c.c of concentrated sulphuric acid, the cooled liquid diluted with 100 c.c. of cold water, boiled, and neutralized with ammonia, 25 c.c. of which is then added in excess; and, after dilution to 200 to 250 c.c., the liquid is electrolyzed with a current of about 1·2 ampères, the deposition of the nickel being generally complete in three hours. It is considered probable that this ether method would be serviceable in the separation of zinc, or uranium, from iron. C. S.

Colorimetric Estimation of Nickel in Steel. R. Fieber. (*Chem. Zeit.*, 1900, xxiv., 393.)—When nickel steel is dissolved in nitric acid, the iron precipitated with ammonia, and the liquid filtered, the solution exhibits a blue colour proportional in intensity to the amount of nickel present, while the tint is not modified by any other constituent of the metal, large quantities of chromium excepted. To prepare a set of standards, or to estimate the nickel in any particular sample, 6 grammes of steel are dissolved in 1·2 grammes nitric acid; the solution is concentrated as much as possible, brought into a 200 c.c. flask, and the iron thrown down with ammonia. When the whole is cold it is diluted to the mark, shaken well, and filtered. Estimation is performed by comparison, diluting the experimental solution, if necessary, till it matches one of the standards. The standards are best kept in 200 c.c. flasks; they remain unchanged in colour indefinitely, even if exposed to light. An accuracy of 0·05 per cent. is quite possible, even with steels containing less than 1 per cent. of nickel. F. H. L.

NOTE.—The process is not available on account of the variation in colour of nickel solutions due to small alterations in the experimental conditions. B. B.

On the Separation of Nickel and Iron with Ammonia. F. Ibbotson and H. Brearley. (*Chem. News*, vol. lxxxi., pp. 193, 194.)—The defective results apparently obtained by some workers are attributed by the authors to the absorption of the ammoniacal nickel solution by the ferric hydroxide precipitate, and can be improved by adding ammonium salts before the ammonia, but in larger proportion than necessary to form the corresponding ammonium-nickel salts. A better way, however, is to substitute potassium cyanide, the acid solution of the sample being first treated with ammonia to neutralize the free acid. A slight excess of standard potassium solution is then added, the whole is poured into an excess of ammonia, and an aliquot portion of the filtrate is titrated with silver nitrate in the usual manner.

The aforesaid absorption of nickel by ferric oxide can be prevented by slightly

acidifying the solution and heating it to boiling-point, the ferric hydroxide first precipitated being easily dissolved by the undecomposed ferric chloride. The liquid soon becomes turbid; and from this point onwards the ammonia used should be very dilute, the precipitation of the iron being complete with even less ammonia than is needed to produce a permanent turbidity when the neutralization is effected in a cold solution. The main point is to keep the solution acid throughout, since if it be ever so slightly alkaline the separation is imperfect. C. S.

The repeated use of the Double Chloride of Copper and Potassium for the Solution of Steel or Iron in estimating Carbon. G. W. Sargent. (*Journ. Amer. Chem. Soc.*, vol. xxii. [4], pp. 210-213.)—The tedious method of recuperating the copper-potassium chloride solution by aeration or electrolysis may be replaced by direct chlorination. Three quarts can be treated per diem, and, after standing overnight and being filtered, the solution is free from the odour of chlorine, and has almost recovered its original colour, in addition to which it forms a more energetic solvent than when freshly prepared. The solution recuperated in this manner after each time of use can be re-used a number of times, the eleventh solution and filtration being accomplished almost as rapidly as the first. About 1 pound of manganese dioxide and $1\frac{1}{2}$ pounds of hydrochloric acid will recuperate 3 quarts of the double chloride. C. S.

Potentials of Copper Electrodes in Solutions of Copper Precipitates. C. Immerwahr. (*Zeit. anorg. Chem.*, 1900, xxiv., 269-278.)—The experiments were carried out with the object of obtaining a measure of the solubility of the different precipitates in solutions of the precipitant. For details of the method, see Küster (*Zeit. anorg. Chem.*, xxiv.). The following table gives the results with the principal precipitates. The electrolyte in each case contained a gramme-molecule of potassium in addition to the precipitant. The concentrations are in gramme-molecules per litre. In the last column are the potentials between the electrodes and the electrolytes :

Cu Salt.	Electrolyte.		Concentration of Cü-ions.	Potential.
	Formula.	Concentration		
Acetate in saturated solution	$Na{\cdot}C_2H_3O_2$	0·05	$6{\cdot}6 \times 10^{-2}$	−0·580
$CuCO_3$	K_2CO_3	0·046	$4{\cdot}2 \times 10^{-6}$	−0·456
$Cu(OH)_2$	$Ba(OH)_2$	0·00016	3×10^{-8}	−0·393
$Cu(OH)_2$	$Ba(OH)_2$	0·025	5×10^{-9}	−0·370
CuO precipitated from hot solution	$Ba(OH)_2$	0·025	$1{\cdot}8 \times 10^{-11}$	−0·298
CuO prepared by igniting $Cu(NO_3)_2$	$Ba(OH)_2$	0·025	$1{\cdot}2 \times 10^{-19}$	−0·056

Attempts were also made to obtain values with CuS in solutions of H_2S, NH_4HS and NaHS. The copper electrodes were, however, attacked by the electrolytes.

Similar experiments were carried out with solutions of copper, in which the formation of Cü-ions was prevented by a reagent. Thus, in a solution of Rochelle salt containing copper tartrate the concentration of Cü-ions was $2{\cdot}3 \times 10^{-9}$. In

solutions of copper in ammonia the results varied from $1{\cdot}5 \times 10^{-8}$ to 9×10^{-17}. In solutions of copper cyanide in potassium cyanide, they varied from 7×10^{-21} to $3{\cdot}5 \times 10^{-44}$. In the last two cases the potential altered on standing in consequence of the formation of cuprous salts.

The potential of solutions of some cuprous salts was also measured. The data do not exist to calculate the true concentration of the ions. In the following table they are compared to CuCl = 1 :

Cu Salt.	Electrolyte.		Concentration of Cu-ions.	Potential.
	Formula.	Concentration.		
CuCl	HCl	0·05	1	−0·465
CuBr	KBr	0·05	$9{\cdot}3 \times 10^{-2}$	−0·404
CuI	KI	0·05	2×10^{-5}	−0·187
CuCNS	KCNS	0·05	$2{\cdot}4 \times 10^{-7}$	−0·074

At present it is not possible to calculate the actual amount of precipitate dissolved. A. M.

Estimation of Alkali-Metal Carbonates in the Presence of Bicarbonates. **F. K. Cameron.** (*Amer. Chem. Journ.*, 1900, 23, 471-486.)—The solution is titrated with a standard solution of potassium hydrogen sulphate, using phenolphthalein as indicator :

$$Na_2CO_3 + HKSO_4 = HNaCO_3 + NaKSO_4.$$

The products of the reaction are neutral to the indicator, whereas the potassium hydrogen sulphate is strongly acid to it. It is essential that the sulphate solution be run into the carbonate at a rate not exceeding 2 drops a second until the colour just disappears. The liquid meanwhile must be shaken continuously and vigorously.

After the carbonate has been estimated chloride may be determined in the same solution. To do this a few more drops of the sulphate solution are added, and then the chloride is determined by means of silver nitrate solution in the usual way, using potassium chromate as indicator. A. M.

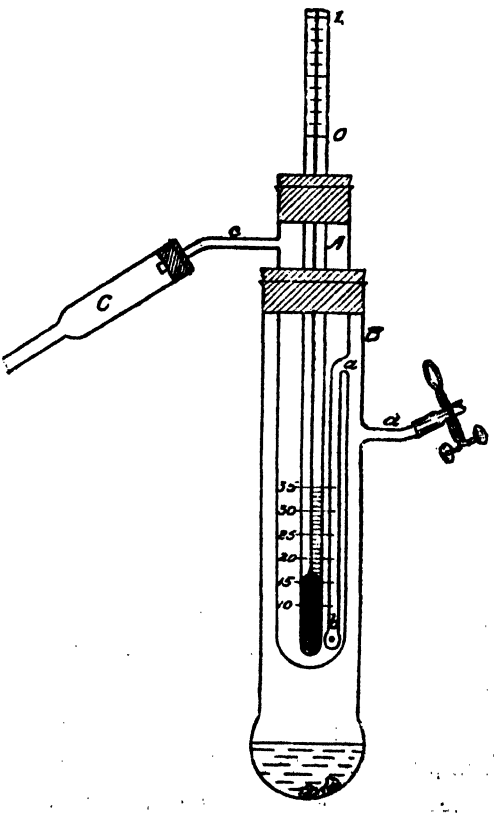
Gas-Volumetric Estimation of Nitrites in Presence of Nitrates or other Soluble Salts. **J. Gailhat.** (*Journ. Pharm. Chim.*, 1900, [6], xii., 9; through *Chem. Zeit. Rep.*, 1900, 207.)—When a neutral solution of a metallic nitrite is mixed with an excess of a neutral boiling solution of an ammonium salt, the following reaction occurs : $NH_4Cl + M'NO_2 = N_2 + 2H_2O + M'Cl$, half of the evolved nitrogen coming from the nitrite and half from the ammonia. The apparatus which Schloesing has recommended for the gasometric estimation of nitrates is fitted with a delivery-tube made entirely of glass, and provided with a stopcock. The flask is two-thirds filled with a saturated solution of ammonium chloride, and the air is expelled by boiling; 10 c.c. of the nitrite solution (5 or 10 grammes per litre) are placed in the funnel, admitted slowly to the flask, the nitrogen is collected and measured in a graduated tube. F. H. L.

Use of Iceland Spar for Standardizing Hydrochloric Acid. H. Thiele and R. Richter. (*Zeits. angew. Chem.*, 1900, 486.)—It has been found that when normal hydrochloric acid is in process of standardization, the molecular weights of sodium carbonate and calcium carbonate being taken at 106·1 and 100 respectively, the strength of the acid, if Iceland spar is adopted as the standard, is represented to be 0·25 per cent. higher than by the silver chloride method, and 0·2 per cent. higher than by the use of sodium carbonate, sodium carbonate and silver thus differing between themselves only by 0·05 to 0·1 per cent. The purity of the spar was then examined, and it was found to contain by gravimetric analysis scarcely 0·02 per cent. of foreign matter (made up principally of the metals with insoluble sulphides). Insignificant traces of strontium, but no barium, were discovered spectroscopically, and it was also ascertained that even after mere drying in the desiccator over potassium hydroxide and sulphuric acid, Iceland spar could not contain any bicarbonate. Rosolic acid had been employed as indicator, but it was found that subsequent addition of methyl-orange showed the same end-point in titration.

The anomaly therefore remained unexplained; but after the above article was written, F. W. Richards published his last researches on the atomic weight of calcium, which make the molecular weight of the carbonate 100·13. Allowing for the 0·02 per cent. of impurities in the Iceland spar, its effective molecular weight in titration thus becomes 100·19; and so all the figures obtained on standardizing hydrochloric acid by the various processes agree excellently. F. H. L.

The Heat- and Acid-Resisting Power of Asbestos. E. van der Bellen. (*Chem. Zeit.*, 1900, xxiv., 392.)—The author has analysed two typical samples of asbestos, and has determined their melting-points by comparison with Seger cones and by the use of a Le Chatelier pyrometer, also testing their power to withstand boiling with a large excess of 1·124 hydrochloric acid:

	Anhydrous Asbestos.	Hydrated Asbestos.
SiO_2	56·79 per cent.	42·09 per cent.
SO_3	0·59 ,,	—
MgO	20·48 ,,	42·16 ,,
FeO	—	1·72 ,,
Fe_2O_3	8·03 ,,	—
Al_2O_3	3·85 ,,	—
CaO	1·00 ,,	0·29 ,,
K_2O (total alkalis as) ...	5·93 ,,	0·32 ,,
H_2O	3·73 ,,	13·59 ,,
Molecular constitution ...	4-5SiO_2, (3MgO + Fe_2O_3 + Al_2O_3 + K_2O), H_2O.	2SiO_2, 3MgO, 2HO.
Ratio of acid to bases ...	1·403 per cent.	0·660 per cent.
Ratio of bases to acid ...	0·608 ,,	1·550 ,,
Melting-point	1150° C.	1550-1570° C.
Solubility in acid ...	5 per cent.	57 per cent.



F. H. L.

Asbestos and Chrysotile. C. Reidemeister. (*Chem. Zeit.*, 1900, xxiv., 537.)—Referring to Van der Bellen's article on "Asbestos" (see preceding abstract), the author points out that the word "asbestos" is unfortunately in regular use in trade to designate two substances which are physically similar, but mineralogically and chemically are quite different in character. One of these, containing the higher proportion of silica, is true asbestos; but although it is found in many localities, it is very difficult to procure commercially. The other material, with the lower proportion of silica and the higher melting-point, which is commonly called asbestos as well, is nothing but chrysotile, a fibrous variety of serpentine. This is the substance exported from Canada, and it ought to be described as "Canadian asbestos," or, as Geinitz has suggested, "chrysotile-asbestos."

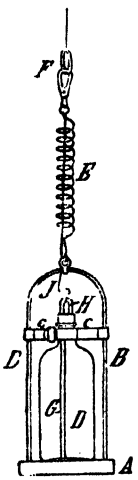
APPARATUS.

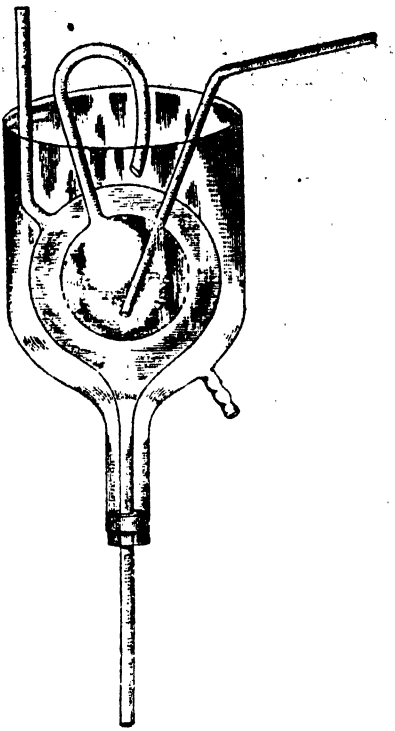
An Apparatus for Determining Molecular Weights by the Boiling-point Method. H. N. McCoy. (*Amer. Chem. Journ.*, vol. xxiii. [4], pp. 353-360.)—The apparatus shown in the drawing consists of a glass vessel *A*, 2·7 centimetres wide and 20 centimetres long, graduated up to 35 c.c., and fitted with a thermometer. Within, *A* is provided with a narrow glass tube *ab*, opening to the exterior at *a*, 7·5 centimetres from the mouth of *A*, and closed at the bottom except for five small holes *b*. *A* is also connected with a Liebig condenser *C* by a branch tube 2·5 centimetres below the mouth, and is surrounded by the glass jacket *B*, 22 centimetres long by 4 centimetres wide, slightly enlarged at the bottom. About 7 centimetres from the mouth of *B* projects a vent branch tube *d* closed by a rubber tube and pinchcock.



The boiling-point of the pure solvent is determined by placing 50 c.c. in the jacket *B* and 12-16 c.c. in *A*, a small piece of tile being inserted in *B* to prevent bumping. Heat being applied, the vapour produced in *B* passes through *ab* and boils the solvent in *A*, the heat being adjusted so that slow distillation occurs. When the thermometer is constant to within ·001° in thirty seconds the true boiling-point is reached. After opening the tube *d* the flame may be withdrawn and the

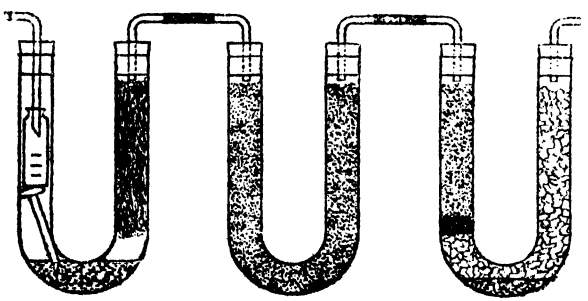
substance under examination introduced into *A*, whereupon heat is again applied and the boiling-point of the solution determined as before, the volume of liquid [illegible] being read off after removing the thermometer. The accession of solvent in the inner tube by condensation of vapour from *B* enables readings to be taken at increased degrees of dilution.

The molecular weight is calculated by the formula $M = \frac{W \cdot T}{\Delta \cdot V}$, wherein W = weight of substance, Δ = elevation of boiling-point, and V = volume of solution. The factor T, which is a constant differing for each solvent, is obtained by dividing the corresponding values of the old formula by the specific gravity of the solvents at their boiling-points, the following being the values for a few ordinary solvents: Alcohol, 1560; ether, 3030; chloroform, 2600; benzene, 3280; carbon disulphide, 1940; acetone, 2220; aniline, 3820; water, 540.



The method is quick and easy, two determinations with different dilutions being obtainable in less than half an hour, and good results are furnished without tedious precautions being required. C. S.

Apparatus for taking Samples of Water beneath the Surface. **F. C. G. Müller.** (*Zeits. Angew. Chem.*, 1900, 388.)—In this apparatus the bottle D is fitted with a rubber cork having two holes, which are simultaneously closed by the U-shaped glass rod H. H is connected directly to the base of the swivel F, whereas the apparatus as a whole is carried by the spring E. A being a lead plate of suitable weight, a sudden jerk on the line lifts H out of the cork, and permits water to fill the flask. F. H. L.



Enamelled Reagent Bottles. **J. Sebelien.** (*Chem. Zeit.*, 1900, xxiv., 538.)—Some years ago enamelled reagent bottles were to be obtained on which the white label was formed of a leadless glaze that would bear immersion in ammonium sulphide for twenty-four hours without discoloration, the black letters consisting of an iridium black, which was capable of resisting strong hydrochloric acid for the same period of time. These bottles appear to be no longer manufactured, and the present articles are made of a more fusible glass, which necessitates the use of a more fusible enamel containing lead, and this is not only blackened by ammonium

...ible, but, being soluble in HCl, allows the lettering, even if it be iridium, to scale off. The author, therefore, considers bottles with etched lettering on a ground of white enamel to be distinctly preferable. When the white lead enamel becomes black owing to the action of sulphuretted hydrogen, the colour may be completely restored by plunging the whole bottle into ordinary hydrogen peroxide solution for about half an hour. F. H. L.

New Upright Condenser. Peters and Rost. (*Zeit. angew. Chem.*, 1900, 28, 688, 689.)—The condensing water passes into the bottom of the inner bulb, passes out through the top, and plays over the surface of the outer bulb. The vapour, which passes up between the two bulbs, is thus exposed to a large condensing surface. The condensation is aided by the evaporation of the water as it passes over the outer bulb. A. M.

Absorption Apparatus for Elementary Organic Analysis. F. G. Benedict. *Amer. Chem. Journ.*, vol. xxiii. [4], pp. 323-334.)—For the absorption of moisture the author recommends the apparatus shown in Fig. 1.

A small glass bottle, to replace the condensing bulb, is inserted in the limb of a $\frac{5}{8} \times 5$ in. U-tube, where it is supported on a short length of glass rod with flattened head, leaving round the bottle an annular space of $1\frac{1}{2}$-2 millimetres, for the passage of the gases escaping from the bottle after the excess of moisture has condensed therein. The other limb of the tube contains a plug of coarse glass-wool, extending to near the bend; through this wool is poured enough sulphuric acid to just seal the bend, leaving a space of about 1 centimetre between the wool and acid to prevent the latter creeping into the carbon-dioxide absorbers, and permit the isolation of the gas bubbles. Most of the water vapour is retained by the seal, and the final traces by the glass wool.

C. S.

REVIEWS.

Traité des Altérations et Falsifications des Substances Alimentaires ("Treatise on the Deterioration and Adulteration of Food"). A. Villiers and E. Collin. Published by Octave Doin, Paris. 1900. 1173 pp., with 633 illustrations; no index. Price 20 francs.

The chief impression left after a perusal of this work is that the conditions under which the French chemist works differ materially from those which affect the English public analyst. His functions to a large extent combine those of public analyst and medical officer of health, and the law, or rather laws, under which he works appear to admit of more definite statements than our own Food and Drugs Acts.

The work is divided into eleven sections, treating of Farinaceous Foods, Stimulants (Cocoa, Coffee, etc.), Condiments, Vegetables, Animal Foods, Dairy Products, Fats and Oils, Sugars, Fermented Liquors, Water, and Preservatives and Colouring Matters. The subjects are treated in a very thorough manner, and the microscopical portions of the book, which occupy more space than is usual in works on food analysis, are excellent; the plates are clear, well drawn, and bring out the salient points in a most distinct manner, and cannot fail to be of great value. The chemical portions, on the other hand, are weak; not that they are incorrect—few points being noted to which real exception can be taken—but they are in but few instances up to date.

The authors appear to have drawn their information almost exclusively from French sources, and the many processes devised in England, Germany, and elsewhere do not seem to have yet filtered through to them, or, if they have reached them, are incorrectly described; thus, the method called by the name of Reichert-Meissl-Wollny contains most of the defects that Wollny pointed out, and guarded against.

A good deal of space is devoted to biological investigations. Good descriptions of the methods of detecting tuberculosis, actinomycosis, and trichinosis in meats occur; the detection of faults of wine is well treated of; and the bacterioscopic examination of water is described. While the discrimination between *B. typhosus* and *B. coli communis*, and the significance of these organisms in water, is ably discussed, no mention is made of *B. sporogenes enteritidis*, nor even of the method of concentrating the micro-organisms by filtration through a reversed Berkefeld filter. The chemical examination of water is based on the methods employed at Montsouris, which were devised for scientific investigation, and, as they require something like 20 litres if carried out as described, can hardly be considered practical.

Some of the methods will be new to English public analysts. The fact that the extensive adulteration of jams with agar is allowed to pass unchallenged in England would show that the method described for the detection of this substance is not generally known.

The analyst who adds this work to his library will be well repaid by the excellence of the plates, even if he does not profit much by the descriptions of chemical processes; the chemist who works by it will be enabled to arrive at correct conclu-

work as to the composition of foods, though frequently more laboriously than if he used methods commonly employed in England; the reader will certainly have his mind broadened by viewing the subject from a French point of view.

The authors, in the preface, recognise the necessity for further research, and propose to fill a portion of the void; if they could be persuaded to study the pages of the ANALYST and other foreign journals, and combine the information they glean with their own researches, the value of future editions would be enhanced.

H. D. R.

COMMERCIAL ORGANIC ANALYSIS. By ALFRED H. ALLEN. Third Edition. With revisions and additions by the author and Dr. HENRY LEFFMANN. Vol. II., Part II. Hydrocarbons, Petroleum and Coal-tar Products, Asphalt, Phenols and Creosotes. London: J. and A. Churchill, 1900. Price 14s.

This volume is the second instalment of the third edition of vol. ii. of Mr. Allen's well known and, to analysts, indispensable work. Owing to the rapid growth of subject-matter, it has been found necessary to split the volume up into parts. Part I., already published, is devoted to the fixed oils, fats, waxes, and products derived from them. Part II., the present volume, treats of hydrocarbons, tars, bitumens, petroleum, shale and coal-tar products; and Part III., in preparation, will comprise the terpenes, essential oils, camphors, and resins. Now that this work consists of no less than eight separate volumes, it may be suggested to the publishers that it would be a great convenience if the main contents of each were lettered on the back.

In the revision, especially of the first half of the volume, Mr. Allen has again had the assistance of Dr. Leffmann; the latter half, particularly the section on "phenols," has received much of his own personal attention. The revision has necessarily been extensive, and the text has been largely rewritten. Space has been economized by the omission of some portions of the text of former editions which more properly belong to works on theoretical organic chemistry. The hydrocarbons are systematically arranged and named according to the most modern system. Acetylene, which, when the last edition was published, was of merely theoretical interest, now forms the subject of a separate sub-section, which, however, is rather unduly condensed. A very complete account is given of asphalt, the analysis of which has of late years attracted much attention in the United States. The best-known methods are described, but it is unsatisfactory to note that all are more or less arbitrary, and do not even give comparable results on the same sample. Asphalt paving is extensively used in American cities, and some official specifications are given, showing the composition of the mixtures used.

The subject of lubricating oils, which in the second edition was treated partly under Fats and partly under Hydrocarbons, is now collected into a single section, which is a better arrangement. Under Viscometry, or Viscosimetry, a description is given of Doolittle's torsion viscometer, which is said to be much used in American laboratories. The chief advantage claimed for this instrument over the common form of jet viscometer is that the results obtained are not influenced by differences in the specific gravities of the liquids tested. Pure cane-sugar solutions of arbitrary strength are used for standardizing. Mixtures of glycerol and water of known viscosity would, we

think, be preferable; and if it could be shown that the indications of this instrument are in proportion to the true viscosities of all liquids tested by it, both those of low as well as of high viscosity, it would deserve to come into more general use, and to replace the imperfect jet viscometers at present in vogue. It is rather strange that the Abel apparatus should be described as the best for determining the flashing-points of lubricating oils (p. 136), seeing that the Pensky-Martens and Gray testers (both modifications of the Abel) have been specially designed for the purpose. The Abel apparatus is usually put together with soft solder, which melts at 170° to 180° C. With regard to the statement on p. 146, that paraffin dissolves in warm fixed oils, and does not separate on cooling, it may be pointed out that some kinds of mineral lubricating oil mix with rape oil perfectly when warm, but on cooling or standing solid hydrocarbons are apt to separate, and cause troublesome deposits in lubricators.

The latter half of the volume, on cyclic hydrocarbons from coal-tar and their derivatives, has been very thoroughly revised and largely added to. Special tests are given for many benzene derivatives now used as drugs, food-preservatives, or disinfectants. Mr. Allen has largely added to the data concerning phenols, phenolic disinfectants, and wood-tar creosote; but no reference is made to the disinfectant known as "Izal," obtained from coke-oven tar. On p. 254 an excellent method is given for estimating the phenols in disinfecting powders with non-alkaline base, which may be still further simplified by dispensing with the use of Soxhlet's extractor. Percolation with small quantities of ether about three times in a tapped cylindrical funnel, having a loose plug of asbestos at the bottom, extracts the whole of the phenols in about half an hour. Powders with lime base may be analysed by boiling them with 10 per cent. solution of caustic soda, making up to a known weight, settling, decanting or drawing off an aliquot (weighed) portion of the clear liquid, concentrating, and throwing up the phenols with acid. This saves the tedious process of neutralizing the powder with strong sulphuric acid as described on p. 255.

Dr. Leffmann has added at the end of the volume an appendix describing some new forms of extracting and drying apparatus, also tables of comparison of Beaumé degrees and specific gravities of liquids lighter than water, and a useful table of comparisons of thermometric degrees. The text contains very few errata, one of the most puzzling being the reference on p. 252, first line, to "p. 559," which is a page of the second edition, and should be "p. 301." Also, on p. 255, in the first line of the third paragraph, the reference to the obsolete "distillation process" is a similar slip. In the figure on p. 79, the arrow referred to on p. 80, line 2, is missing. "Gasolene" (or gasoline ?), on p. 22, line 9, is a misprint for probably "rhigoline."

Chemists of the present generation are deeply indebted to Mr. Allen, not only for having equipped them with such a valuable work as "Commercial Organic Analysis," but for devoting the best years of his life to the labour of keeping the work up to date. He is to be congratulated upon having secured the assistance of able collaborateurs in carrying on the work so ably begun.

L. A.

ERRATA.

This volume, p. 148, line seven from bottom, *for* "325° C.," *read* "315° C."; line twelve from bottom, *for* "350°" *read* "350° C."

THE ANALYST.

OCTOBER, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE DETERMINATION OF OXYGEN IN COPPER BY IGNITION IN HYDROGEN.

By L. Archbutt, F.I.C.

(*Read at the Meeting, June* 6, 1900.)

In consequence of some anomalous results obtained during the autumn of 1893 in determining oxygen in commercial copper by Abel's silver nitrate method, which I had up to that time employed with confidence, my attention became directed to a paper on "The Analysis of Copper," by W. Hampe (*Zeits. für anal. Chem.*, 1874, pp. 176-234), in which the estimation of oxygen is directed to be made by heating the copper to redness in a current of hydrogen. The unfavourable results previously obtained by Abel (*Journ. Chem. Soc.*, 1864, pp. 166-172), which led him to conclude "that correct indications of the proportion of oxygen existing in a specimen of copper cannot be obtained by treatment of the metal with hydrogen," did not encourage further experiment in the same direction; but the experimental results reported by Hampe in his paper were so satisfactory that I determined to make a careful trial of his method, of which the following is a description:

Estimation of Oxygen (*Hampe*).

The clean copper is converted into filings with a not too coarse file, the filings are passed through a hair sieve in order to separate any coarse particles, fragments of iron are removed by a magnet, and the powdered copper is washed either with a dilute solution of caustic potash, followed by water, or with pure alcohol or ether, in order to remove grease. The purified copper is dried. For the reduction a bulb-tube of Bohemian glass is used, drawn out at both ends. This is connected with a drying apparatus, through which a current of air is passed from a gasometer. The empty bulb-tube is first heated in the stream of air, allowed to cool, and at once closed with indiarubber stoppers. The tube having been weighed, 30 to 50 grammes of the prepared copper are placed in the bulb, the tube is again weighed, and a current of dry, air-free CO_2 is passed through it. This CO_2 is prepared from marble and hydrochloric acid, and is purified by passing through vessels containing sodium carbonate

and silver nitrate, and dried by passing over sulphuric acid and calcium chloride. The apparatus is set in action two hours previous to use, in order to drive all air out of the purifying train.

After the stream of CO_2 has passed over the copper for about five minutes, a very moderate heat is applied, in order to expel every trace of superficial moisture. With many coppers which contain arsenic, too strong heating will result in the formation in the bulb, or just beyond it, of a sublimate of As_4O_6. After cooling in CO_2, a stream of dry air is immediately passed through the bulb-tube to displace this gas, and the tube is again stoppered and weighed. The weight is, usually, only a few milligrammes less than the previous weight.

A very slow stream of hydrogen is now conducted over the copper, which is heated at first gently, and afterwards to a red heat, which temperature is maintained for about fifteen minutes. During the heating water is formed, and by impure copper there is also formed a black sublimate containing arsenic, antimony, and lead, so that the end of the tube must be long enough, and the stream of hydrogen slow enough, to insure the whole of this sublimate being retained within the tube.

During the formation of water there is noticed, with commercial copper, an evolution of H_2S. The formation of this gas, already observed by Dick, but not explained, can be accounted for in the author's (Hampe's) opinion only by the presence in the copper of sulphur dioxide, a part of the sulphur of which is converted into H_2S. Cuprous sulphide cannot exist in copper along with oxygen compounds, and would not be decomposed by heating in hydrogen. To retain the escaping H_2S, the bulb-tube must be connected with several small flasks containing silver solution or alkaline lead solution, and the sulphur can then be estimated by known methods. Arsenic and antimony cannot be found in the precipitate. After the copper has completely cooled in the stream of hydrogen, and this gas has been displaced by dry air, the tube and copper are again weighed. As control, a duplicate experiment is desirable. The mean loss of weight, less the weight of volatile sulphur, is oxygen. The correction for sulphur seldom exceeds 0·002 per cent. in refined copper. The following results were obtained by Hampe:

A. Synthetically prepared Samples.

	Oxygen Present (per cent.).	Oxygen Found (per cent.).
1. Copper containing copper oxide	0·247	0·237
2. Copper containing "copper mica"	0·262	0·267
3. Copper containing bismuth antimonate, of which the oxygen content must have been from	0·141 to 0·170	0·159

B. Copper from Oker.

	Oxygen per Cent., after correcting for Volatile Sulphur.			
	First Experiment.	Second Experiment.	Third Experiment.	Mean.
1. Tough copper ...	0·117	0·117	—	0·117
2. ,, ,, ...	0·154	0·153	0·165	0·157
3. Dry copper ...	0·806	—	—	0·806

C. Copper from Mansfield.

	Oxygen, per Cent., after correcting for Volatile Sulphur.			
	First Experiment.	Second Experiment.	Third Experiment.	Mean.
1. "Black copper"	0·443	—	—	0·443
2. Dry refined copper	0·727	0·765	—	0·746
3. Tough ("dichtgepoltes") copper ...	0·147	0·162	—	0·155
4. Tough ("zähe gepoltes") copper ...	0·077	0·072	0·077	0·075
5. Overpoled copper	0·045	0·044	—	0·045

In connection with the above analyses of dry copper, it is interesting to note that Dick, in 1856, found about 1·4 per cent. of oxygen in a specimen of copper "in the driest state," which Percy had procured specially for experiment. This result of Dick's was obtained by rolling the copper as thin as possible, cutting the rolled metal into small pieces, exposing these to a current of dry hydrogen at a red heat and weighing in a calcium chloride tube the water formed. Hampe refers to Dick's experiments, but apparently makes no mention of Abel's work in the same direction, which is strange, as Abel tried for a long time to estimate the oxygen in copper by a method similar to the above-mentioned process used by Dick, and came to the conclusion "that although the larger proportion of the oxygen contained in a specimen of copper may perhaps be abstracted during the first two or three hours' treatment, its complete removal from the metal in the form of water requires very long continued exposure to the action of hydrogen." In several experiments a continuous increase in the weight of the calcium chloride tube was observed, which "appeared likely to continue for an indefinite period," and which was attributed partly to traces of atmospheric oxygen obstinately retained by the copper. After numerous failures to obtain satisfactory results, Abel finally abandoned the method as impracticable.

Blount much more recently (*Analyst*, 1896, pp. 57-61) came to the conclusion that the action of hydrogen on copper at any temperature below the softening-point of a glass combustion tube is only superficial, and he has described a method in which the copper is actually fused in a current of hydrogen. Blount found, as Dick had done, that the reduction is accompanied by such violent spirting of the molten copper that an estimation by loss of weight is impracticable; but by conducting the operation in a porcelain tube, and absorbing the water formed in a sulphuric acid drying tube, he has worked out an elegant and successful process. My own experiments, however, and several years' subsequent experience, have convinced me that the reduction takes place easily and completely at a red heat, and that Hampe's process is accurate as well as, when certain unnecessary details are omitted, extremely simple. By the courtesy of Mr. Blount, an opportunity has recently been afforded of proving that the results obtained by the two methods are practically identical. An account of my experiments and of the results obtained may, therefore, be of interest to the Society.

I commenced by following Hampe's directions closely, but arrangements were made for absorbing and weighing the water formed, as a check on the loss of weight undergone by the copper. An apparatus for the supply of dry oxygen-free hydrogen was therefore fitted up, which consisted of: (*a*) Kipp generator, containing Leclanché

zinc rod and dilute pure sulphuric acid (1 : 4); (*b*) a small washing bottle, containing 50 per cent. solution of caustic soda; (*c*) a tower, 210 millimetres high by 46 millimetres diameter, containing pieces of stick soda; (*d*) a combustion tube, containing about 400 millimetres of copper gauze rolled into a close spiral and kept red hot; and (*e*) a U-tube, 300 millimetres long, filled with freshly-fused caustic potash broken into small lumps (as recommended by Dittmar). The hydrogen generated and purified in this apparatus was passed through a weighed drying tube, containing sulphuric acid and pumice, for two hours at the rate of 200 c.c. per hour, and for two hours more at four times that rate. The total volume of hydrogen passed was about 2 litres, and, after displacing the hydrogen remaining in the tube by dry air, the weight of the tube was found to be exactly the same as at the commencement.

The copper was used in the form of bright turnings, small enough to pass through a tube $\frac{1}{8}$ inch in diameter. These were thoroughly washed by decantation with ether to remove grease, and dried by heating on the water-oven and cooling in a desiccator. Finer division of the copper than this is not necessary. Filings may be used if more convenient, but they will contain a more or less considerable admixture of steel from the teeth of the file, which must be carefully picked out by a magnet, and they must be very well washed with ether to remove grease and dirt. There does not appear to be the least necessity to pass the filings through a hair sieve, as Hampe directs.

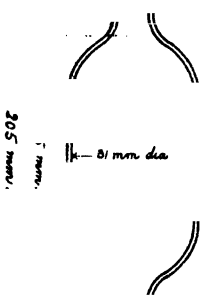


Fig. 1.

Very convenient bulb-tubes for containing the copper are made for me of Jena glass, of the shape and dimensions shown in Fig. 1. They are suspended for weighing by means of a platinum wire hanger with sufficiently large loops at either end to slip easily off and on the tube. These tubes can be used without serious alteration of shape for a large number of operations, in fact, until the glass becomes opaque. During the combustion a black deposit of lead, arsenic, etc., usually forms near the exit end, but is easily cleaned off afterwards with a solution of bromine in hydrochloric acid. The tube is then thoroughly washed with water and dried in the water-oven. The tubes scarcely alter in weight with repeated use. The following are the weights in grammes of three different tubes after being used for three successive combustions:

(1)	(2)	(3)
53·593	48·155	48·654
53·594	48·155	48·654
53·593	48·155	48·654

The clean dry tube, when cold, is wiped outside and allowed to remain supported across a beaker, not in a desiccator, for ten minutes. It is then weighed. One end having been closed by a tiny cork, a small funnel is attached to the other end, and about 30 to 35 grammes of the prepared copper are dropped in. The cork and funnel are detached, the copper is shaken into the bulb, and the tube is wiped and weighed

as before. The weight of copper taken for assay is thus ascertained. I prefer to weigh the tube open at the ends, as I have found that indiarubber stoppers are not only unnecessary, but they are apt to cause errors in the weighings.

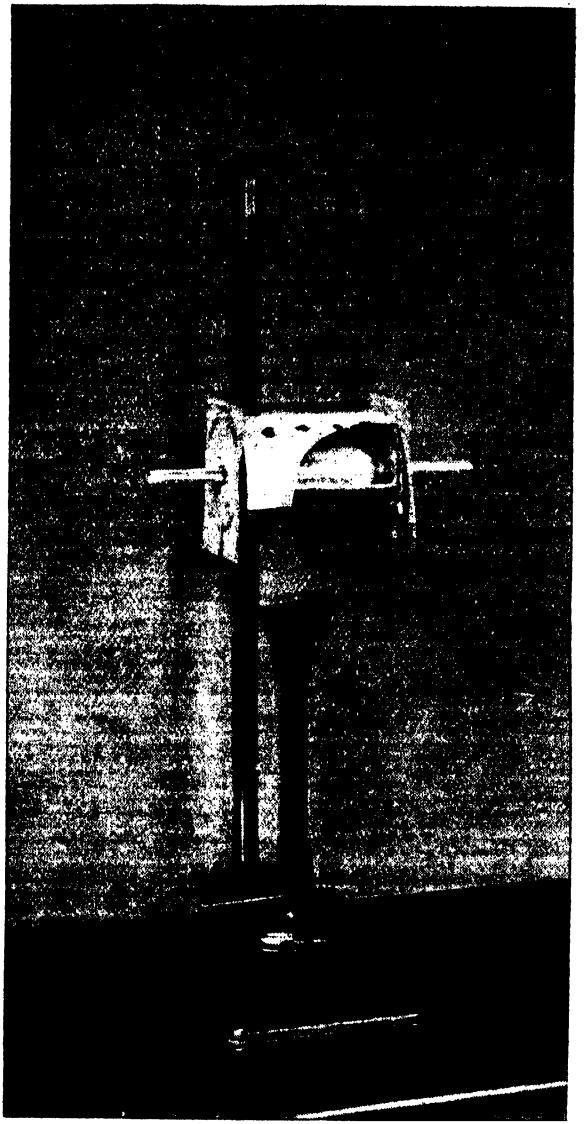

FIG. 2.

The bulb-tube containing the copper is supported on a sheet-iron tray lined with asbestos millboard, a piece of perforated sheet asbestos is bent over the top and kept in shape by an iron-wire frame, and flat pieces of asbestos, perforated in the centre to receive the ends of the bulb-tube, are placed at the sides (see Fig. 2). The bulb, thus

surrounded on all sides by asbestos, is heated by means of a Bunsen burner giving a broad flat flame.

The following three experiments were made with firebox-plate copper containing 0·063 per cent. of arsenic:

COPPER FIREBOX PLATE. A.

	First Experiment.	Second Experiment.	Third Experiment.
Weight of copper taken	29·7526	35·0023	33·5010
Weight of copper and tube before heating ...	58·4844	63·6016	62·5867
,, ,, after heating in CO_2 ...	58·4834	63·6025*	62·5833†
,, ,, after heating in hydrogen ...	58·4354	63·5441	62·5268
Loss of weight in hydrogen	·0480	·0584	·0565
Water absorption tube after	49·1466	49·3808	49·4428
,, ,, ,, before	49·0904	49·3138	49·3808
Weight of water formed	·0562	·0670	·0620
Containing oxygen	·0500	·0595	·0551

* Copper became slightly oxidized at one end. † Heated to redness.

PERCENTAGE OF OXYGEN FOUND.

	By Loss of Weight of Copper.	By Weight of Water formed.
Experiment 1	0·161	0·167
,, 2	0·167	0·170
,, 3	0·169	0·165
Mean	0·166	0·167

The copper remaining after Experiment 1 was transferred to another tube (the first having developed a minute crack) and reheated, with the following results:

	Fourth Experiment.
Weight of copper and tube before heating	58·2991
,, ,, ,, after heating in CO_2	58·3001
,, ,, ,, after heating in hydrogen to full redness for half an hour	58·3000
Loss of weight in hydrogen	·0001

This experiment shows how easily a constant weight in hydrogen is obtained. In fact, by watching the progress of an experiment one soon acquires confidence in the method. As soon as the copper reaches a dull red heat, water begins to condense rapidly in the first cool place, and has to be chased along by a small flame; after heating for about half an hour, it ceases to condense. In the above experiments the heating was continued for about two hours longer, the current of hydrogen being at the rate of 200 to 300 c.c. per hour.

The following experiments were made with two other firebox-plate coppers, "B" containing 0·031 per cent., and "C" 0·485 per cent., of arsenic. In Experi-

ment 7 the heating in CO_2 was carried to rather too high a temperature, and a sublimate of As_4O_6 formed in the end of the bulb-tube. In Experiment 8 no sublimate was formed.

From the foregoing experiments it appears that practically the same results are obtained, whether the oxygen be estimated from the loss of weight of the copper or from the weight of water formed. The former method is much the simpler. It seems hardly necessary to go to the trouble of recovering the trace of sulphur which passes off as H_2S. It can only influence the result in the third decimal place, and such accuracy is not required in the present state of our knowledge.

If the water formed in the combustion is not weighed, there is no need to purify the hydrogen from traces of oxygen. This was not done in Experiment 7, whilst in Experiment 8 it was, and it will be observed that the loss of weight of the copper is practically the same in each case. The tube containing the red-hot copper gauze

spiral was therefore removed from the purifying train, and the twenty-three samples of copper included in the table on the opposite page were assayed for oxygen thus:

1. The prepared copper was heated in purified, dry CO_2 for half an hour, during which time 500 c.c. of the gas were passed through the bulb, the temperature being high enough to expel moisture, but not high enough to sublime As_4O_6 from the copper.
2. The dry copper was heated to redness in hydrogen, which had been purified from acid vapours and water, but not from traces of oxygen. The temperature was maintained at a red heat for one hour, about 1 litre of gas being passed through the bulb.

I have included in the table the percentages of arsenic and phosphorus found in

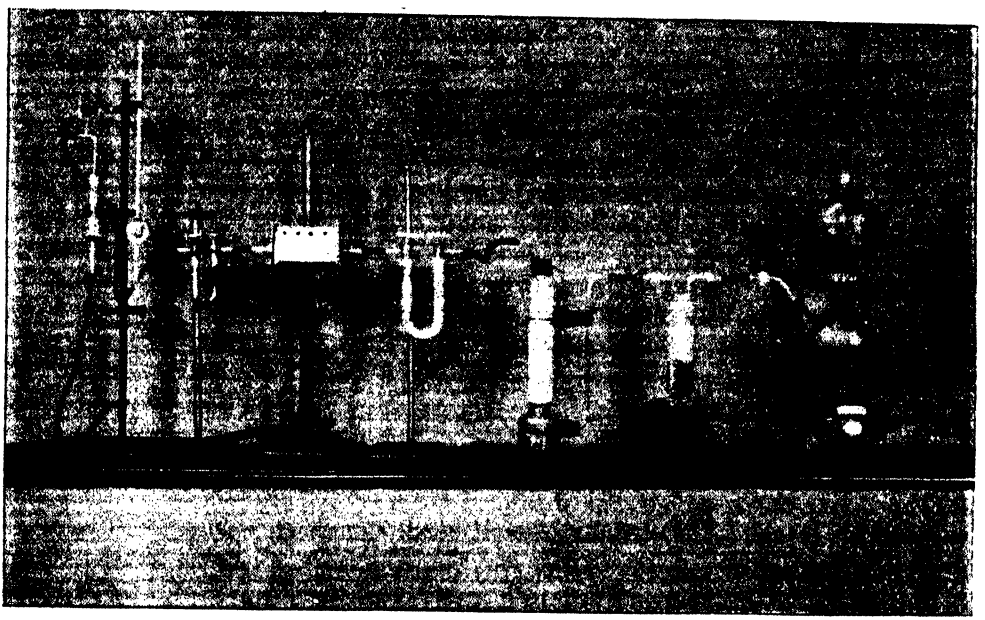

FIG. 3.

these coppers. Copper containing phosphorus is invariably free from oxygen, or contains only traces of that element, and a considerable proportion of the loss on ignition in hydrogen of such copper is probably made up of the traces of oily hydrocarbons which usually distil from copper when heated, however carefully it has been washed with ether.

The loss of weight in carbon dioxide is seen to have been very trifling in all these experiments except one (No. 26*b*). In fact, it was so small that I have now abandoned this part of Hampe's process, and merely wash the copper with ether, and dry it well in the water-oven before heating in hydrogen. Although the water resulting from the combustion in hydrogen is not weighed, a trap of some kind beyond the bulb-tube is necessary, and may conveniently consist of a U-tube containing pieces of glass rod and sufficient sulphuric acid to fill the bend. Fig. 3 is from a photo of the complete

apparatus which I now employ for the combustion in hydrogen. It comprises (1) Kipp generator; (2) washing-bottle, containing caustic soda solution; (3) tower, containing stick soda; (4) U-tube, containing re-fused dry caustic potash in small pieces; (5) bulb-tube, containing the prepared dry copper; (6) U-tube, containing strong sulphuric acid; and (7) pipettes, for measuring the rate of flow of hydrogen.

Process.—The copper (30 to 40 grammes), which must be free from superficial oxide, is thoroughly cleansed with ether, carefully dried, introduced into the dry bulb-tube, and weighed, as already described. The apparatus is joined up, and a current of hydrogen (about 1 litre per hour) is passed through it until the issuing gas burns quietly, which is usually the case after fifteen minutes have elapsed. The current of hydrogen is then reduced by about one-half, and if much arsenic is present in the copper it is still further reduced; the copper is then heated up, with a flame just touching the iron support, until water begins to condense beyond the bulb-tube. If any sublimate of As_4O_6 be observed, the current of hydrogen is made very slow, and the tube is heated more strongly, so as to reduce the oxide to a mirror of arsenic within the tube. Any water condensing between the bulb and the U-tube is chased along by a small flame. Gradually the copper is raised to full redness, and, when water ceases to condense, the current of hydrogen is increased to 1 litre per hour. After continuing to heat the copper thus for one hour, the gas is turned out, but the current of hydrogen is kept up until the copper is quite cold. The bulb-tube is then disconnected, the hydrogen is displaced by aspirating a current of dry air through the tube, and the latter is weighed and the loss calculated as oxygen per cent. of the copper taken.

The following results were obtained by Mr. Blount and myself, working independently on the same specimens of copper. Mr. Blount's determinations were made by fusion of the copper in hydrogen, and weighing the water produced; my results were obtained by simply heating to redness in hydrogen and observing the loss in weight of the copper, as described above. The agreement is sufficiently close to show that both methods give practically identical results. The comparatively large discrepancy in the case of No. 3 sample may be due, Mr. Blount thinks, to the fact that the copper was in rather coarse pieces for his process, and he had to work on comparatively small quantities: the small constant plus error due to the almost inevitable gain of an absorption tube would, therefore, have a larger effect on the final result in this case than it would under the normal conditions of working when the copper is large. The results in the second column were obtained by my assistant, Mr. P. G. Jackson, A.I.C.

6	0·25	0·25

Discussion.

Mr. Blount said he was glad to find that processes of the same class as the old silver nitrate process might be reckoned as deleted. There was, in fact, only one method of determining the oxygen in copper—namely, by reduction in hydrogen. The only point upon which it was possible to base a discussion was the fact that there was some doubt—or had been until that occasion—as to the practicability, at a temperature short of the fusing-point of copper, of determining by reduction in hydrogen the whole of the oxygen present. In his own experiments he had doubted this so much that he was ultimately led to abandon the notion of reducing at a temperature lower than fusing-point. He felt bound to say, however, that the reduction in hydrogen of the oxides present in copper, when the copper had to be fused, was not an altogether convenient proceeding, and if it were possible, as Mr. Archbutt had shown it to be, to reduce the oxides without raising the copper to its fusing-point, a great step would have been taken in advance. Nevertheless, he (Mr. Blount) could not help thinking that there were certain reasons which would lead one to prefer the method he had ventured to recommend, of fusing the copper in hydrogen, and weighing, not the copper remaining, but the water produced. It seemed evident that the determination of an impurity occurring in small proportion, such as oxygen in copper, must be made more or less by determining the difference between two comparatively large weights—*e.g.*, of the vessel in which the impurity was contained. When the substance constituting the impurity was isolated—as, for instance, in the case of bismuth, the proportion of which in commercial copper was generally under 0·01 per cent.—the errors would be quite tangible; and in the same manner the increase in the weight of the absorption tube in determining the oxygen by fusion of the copper in hydrogen was so small that any error would assume relatively large proportions. But the method of determining the oxygen by difference between the weights of the copper before and after reduction in hydrogen was still more open to error, rendering necessary not only the most minute accuracy in weighing the original mass in the tube and the final mass, but also many precautions against the escape of volatile constituents other than oxygen. There could be no guarantee that arsenic, for example, would remain unvolatilized. The fact that such admirable results were obtained by the author was a testimony to his skill and that of those whom he had trained, rather than to the excellence of the process. In the preparation of the copper for the determination of oxygen by this method it was necessary to subdivide it; and although the author had succeeded in overcoming the difficulties due to contamination from files, drills, etc., it was really unnecessary to face them when one could work satisfactorily upon lumps of copper obtained without any risk of such contamination. From a purely utilitarian point of view, the question of speed was of considerable moment, and it might be mentioned that the method which he had described in 1896 enabled as many as twelve determinations of oxygen in copper to be made in a working day, with the same apparatus and by one operator.

Mr. Jenkins said that he was personally indebted to the author for having introduced this method to his notice several years previously. He thought that Mr. Blount had altogether overemphasized the objections which may be brought

against the method. The machining of the metal into small fragments was easily done, without any contamination with oil, etc., not only in the case of copper, but of steel and other materials. It was shown by the figures given in the paper that the results obtained by absorption of the water were practically the same as those obtained by difference. It would certainly in many cases be more convenient to make the determination by Mr. Archbutt's method than by Mr. Blount's method, seeing that the former did not involve working at so high a temperature, and it was highly satisfactory that Mr. Archbutt and Mr. Blount, working at considerable differences of temperature, should get such closely-agreeing results.

Mr. ALLEN said that he had an extensive experience of the burning of metals in oxygen, which was a process somewhat analogous to the one now under consideration, and he must say that he would give preference to a method in which drillings or finely-divided particles of metal were used. He altogether deprecated the suggestion that there would be contamination by oil from the drill or other tool. There was no difficulty in getting drillings free from oil in the case of steel, and it would be still easier in the case of copper. Mr. Blount, however, had given good reasons for believing the fusion process to be quicker and equally accurate, and therefore the matter was one of convenience rather than of accuracy. He had heard with some surprise that where a sample of copper contained arsenic it was devoid of phosphorus, and *vice versâ*. He would like to hear whether the author could suggest any possible explanation of this very curious fact.

Mr. ARCHBUTT, in reply, said that, after all, it did not matter whether the determination was made by fusion or by loss of weight at a red heat; the material point which he had sought to establish was that both methods gave practically the total percentage of oxygen present. Every sample of copper in which he determined the oxygen, and which he also completely analysed for other elements, was in the form of turnings from a test-bar which was subjected to mechanical tests. It seemed to him that this was a necessity if any information was to be obtained as to the extent to which the chemical composition bore upon the mechanical qualities of the metal. He had found these turnings very convenient to work upon. In obtaining them, as far as possible anything in the way of grease was excluded, but, nevertheless, the precautions were taken of washing the turnings with ether, and of picking out any iron with a magnet. He was glad to gather, from Mr. Blount's remark as to the importance of speed, that engineers and purchasers of copper take so large an interest in the bearing of the chemical composition upon the wearing qualities of the metal, as this would afford the means of obtaining information which really did not exist at present. He did not know that he was in a position to state exactly why phosphorus and arsenic never occurred together in copper, but that was his experience. He had never met with a firebox plate containing phosphorus; but phosphorus was generally present in copper used for making tubes; such copper was practically free from oxygen, and was, he believed, deoxidized by adding phosphorus to it. He had so frequently found phosphorus absent when arsenic was present that he had ceased to test for it in such cases. Arsenical copper always contained oxygen, and such copper could not contain phosphorus.

Mr. BLOUNT entirely endorsed Mr. Archbutt's view, that the sample for analysis

should come from the actual test bar, though it did not follow necessarily that it should consist of turnings.

Dr. Dyer said he believed that small variations in the proportion of oxygen present had considerable effect upon the electrical conductivity of the copper. He would like to ask the author what quantity of oxygen would be expected in good electrical copper, and, more especially, how far variations in the proportion of oxygen affected the strength and durability of the copper for mechanical purposes.

Mr. Archbutt said that he had no experience of the composition of copper for electrical purposes, but there seemed to be a definite relationship necessary between the proportions of oxygen, lead, arsenic, etc., in order to yield a good tough copper, though exactly what that relationship was he could not at present say. He had a number of figures showing a remarkable relationship between the cuprous oxide determined by Abel's method and the arsenic and lead, but exactly what that meant was not yet clear.

A NEW COLOUR REACTION FOR CITRAL AND CERTAIN OTHER AROMATIC COMPOUNDS.

By Herbert E. Burgess.

(*Read at the Meeting, May* 2, 1900.)

In various endeavours I have made to discover a quantitative reaction which could be used for the estimation of citral (especially in oil of lemon), I was led to try the action of mercury salts on aldehydes, with a view to determine the amount of reduction, or, if possible, to weigh the compound so formed. Up to the present time I have been unable to base any satisfactory quantitative method on my results, owing to the fact that many other allied aromatic compounds form salts with the reagent I employ, and also that these mercury compounds are not easily crystallizable, and are probably of indefinite composition and transitory.

I have, however, noticed well-defined colour reactions with many of the aldehydes, alcohols, and other constituents found in various essential oils, and it is to these reactions that I wish to draw attention now.

The reagent mentioned above is prepared as follows:

Ten grammes of mercuric sulphate are dissolved in and made up to 100 c.c. with 25 per cent. pure sulphuric acid.

Then 2 c.c. of the substance to be examined are placed in a small phial fitted with a cork, and 5 c.c. of the reagent added. The whole is then vigorously shaken, any change in colour noted, and again examined after standing for about ten minutes. A porcelain tile will be found useful when only small quantities of an oil can be obtained. The sensitiveness of the colour reaction is not in any way impaired by the use of such small quantities. One drop of the oil is placed on the tile and 3 to 4 drops of the reagent added, and well stirred with a glass rod.

Twenty-five per cent. sulphuric acid itself gives no reaction with the substances I have examined.

The following reactions are characteristic:

Citral.—Bright red colour forms on shaking, which rapidly disappears, and at the same time a whitish compound is formed, which floats on top of aqueous portion.

Citronellal.—A bright yellow colour forms on shaking. The compound formed retains the yellow colour for some time.

Limonene.—A very faint flesh colour at first forms, but almost instantly disappears, leaving a white compound.

Linalyl Acetate.—A brilliant violet colour, which remains permanent, increasing slightly in depth.

Linalol.—Quickly gives a deep violet colour.

Carophyllene.—A yellowish compound, but not any violet colour.

Eugenol.—A slight violet colour on standing for some time.

Cinnamic Aldehyde.—No reaction.

Terpineol.—Flesh colour and precipitate.

Formic Aldehyde.—No reaction.

Acetic Aldehyde.—No reaction.

Benzaldehyde.—No reaction.

Anisic Aldehyde.—No reaction.

The following essential oils have also been examined:

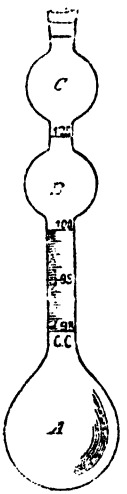
Oil of Cassia.—Yellowish compound formed, floating on the oil. No reduction on shaking.

Oil of Cinnamon.—Brown compound formed and slight violet-coloured aqueous portion. On standing, the whole becomes a black, solid mass.

Oil of Cloves.—On shaking and standing for some time, a violet colour is formed in the aqueous portion, and increases on standing.

Discussion.

The President having invited discussion,



Mr. Chapman said that it would be interesting to know something of the nature of the compounds which the author had observed to be formed with the mercuric sulphate. A great deal of interest attached to many colour reactions, and more especially to those which afforded means of readily identifying some of the constituents of essential oils. But their general usefulness was to a great extent limited by the fact that they were, more than any other reactions, subject to the disturbing influence of impurities. The compounds existing in essential oils were very often extremely difficult to separate in a state of purity, when working with small quantities of material, and consequently it was possible that these colour reactions might on that account have a somewhat limited application.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Examination of Brown and Taylor's Official Method of identifying Butter. J. A. Hummel. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 327.)—In the manufacture of renovated butter, the butter-fat is melted and then cooled rather rapidly in a stream of cold water. This melting and rapid cooling induces a semi-crystallization of the fat. Samples of genuine and renovated butter were examined with a polarizing microscope magnifying 120 diameters having a selenite plate below the slide. Normal butters gave a uniformly blue field. Renovated butters gave a blue field mottled with yellow. A. M.

New Method for the Determination of Essential Oils in Drugs and Spices. Neumann-Wender and G. Gregor. (*Oest. Chem. Zeit.*, 1900, iii., 233-235.)—The method depends upon the fact that petroleum ether, of specific gravity 0·640 to 0·670, does not mix with alcohol of 40 to 60 per cent. strength (Hefelmann, *Pharm. Centralhalle*, 1896, 683), whereas essential oils can be readily shaken out of alcoholic solutions by means of the petroleum ether.

Ten to 20 grammes of the coarsely-powdered substance are heated for six hours with 70 c.c. of 96 per cent. alcohol. The residue is again treated for six hours with 25 c.c. more of the alcohol. The extracts are united and made up to 100 c.c.; 50 c.c. of this are then taken and distilled with steam until the distillate is no longer milky. A distillate of 95 c.c. is generally sufficient. This is made up to 100 c.c., 50 c.c. of it are introduced into the apparatus shown in the illustration, and are made up to the 100 c.c. mark with water acidified with a few drops of sulphuric acid; 25 c.c. of petroleum spirit are then introduced, and the apparatus is well shaken and allowed to stand some hours. The decrease in volume of the alcoholic solution gives the quantity of ethereal oil. A. M.

The Gluten Constituents of Wheat and Flour and their Relation to Bread-making Qualities. H. A. Guess. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 263.)—The analytical work was performed as follows:

(*a*) Five grammes of the finely-ground wheat meal or flour were placed in a 250 c.c. flask, which was then filled to the mark with 1 per cent. salt solution, shaken at intervals for an hour, and allowed to settle for two hours. The liquid was then decanted through a filter, 100 c.c. of it taken, and the proteids precipitated with a few c.c. of 10 per cent. solution of phosphotungstic acid. The precipitate was allowed to settle, 50 c.c. of the clear filtrate were evaporated with sulphuric acid, and the amide nitrogen determined.

(*b*) One gramme of sample was put into a 500 c.c. flask with 100 c.c. alcohol (specific gravity 0·90), shaken thoroughly, and heated with occasional shaking for one hour just below the boiling-point. It was then allowed to settle for one hour, and the clear liquid decanted off. Twenty-five c.c. fresh hot alcohol were added, allowed to settle for twenty minutes, decanted, and the operation repeated three times. In the extract the alcohol was distilled off, and the nitrogen in the residue determined, the amide nitrogen (*a*) subtracted, and the remainder calculated as gliadin (N × 5·7).

(*c*) To the residue from the alcohol extraction, after cooling, 250 c.c. of 1 per cent. salt solution were added. It was allowed to settle for one hour, and decanted through a filter. Two hundred and fifty c.c. fresh salt solution were added, shaken at intervals for one hour, allowed to settle two hours, and decanted through the same filter. The filter and contents were added to the residue in the flask, and the nitrogen determined and calculated to glutenin.

The author found that the quality of the gluten depends upon the ratio in which its two constituents are present. The higher the ratio of gliadin to glutenin, the more elastic is the gluten, and consequently the better is the result of a baking test.

The author publishes the result of the analysis of eighty wheats from the Canadian North-West. The gliadin in these varies from 3·65 to 9·21 per cent. The glutenin varies from 3·30 to 5·64, and the ratio from 0·70 to 2·90. A number of flours were also examined. The results show that, whilst the gliadin remains fairly constant, the glutenin increases as one goes through the different grades in descending scale. Thus, in Keewatin flour the gliadin was always about 8 per cent., but the glutenin varied from about 2 per cent. in the patent grade to over 5 per cent. in the Glenwood grade.

As an aid in grading wheats and flours for commercial purposes, the author proposes a "composite factor," which is the product obtained by multiplying the percentage of gluten (*i.e.*, gliadin + glutenin) by the ratio of gliadin to glutenin. In the case of the Keewatin flours, the factor comes out at 37 to 58 for patent grades, and 15 to 21 for Glenwood grade, the intermediate grades giving intermediate figures.

A. M.

Detection of Cherry Syrup in Raspberry Syrup. O. Langkopf. (*Pharm. C. H.*, 1900, xl., 421; through *Chem. Zeit. Rep.*, 1900, 219.)—The author's process depends on the presence of hydrocyanic acid in cherry syrup. If one drop of an alcoholic solution of guaiacum is mixed with a little 1 : 10,000 copper sulphate solution, a milky liquid is produced which turns blue with an exceedingly minute trace of HCN. From 50 or 100 c.c. of the syrup to be examined 2 c.c. are distilled, and the distillate collected in some of the reagent, when 5 per cent. of cherry syrup in raspberry causes the appearance of the blue tint.

F. H. L.

The Examination of Gum Acacia. R. G. Shoults. (*Amer. Journ. Pharm.*, 1900, lxxii., 267-270.)—According to the United States Pharmacopœia (1890), pure gum acacia does not reduce Fehling's solution. The author, however, shows that

this statement is not correct. He found that powdered samples which caused only a slight reduction at the temperature of the water-bath, yielded much heavier precipitates when the supernatant liquid was filtered and again boiled; and that samples which yielded no deposit at first gave a marked reduction after being dried at 130° C. and then boiled with the Fehling's solution. In fact, this phenomenon was observed after simple powdering of the gum without drying.

He considers that if dextrin were used as an adulterant, a white sample would be liable to contain unconverted starch, which would be detected by means of iodine. A high specific rotatory power, in combination with the detection of starch, would certainly indicate dextrin. On the other hand, a dextrin free from starch would be more or less yellow in colour.

For the calculation of the amount of dextrin (specific rotatory power = 198) the author subtracts the specific rotatory power of pure acacia (18) from the observed specific rotatory power of the sample, and divides the results by the increase in the rotatory power produced by an addition of 1 per cent. of dextrin (viz., 1·8). Thus, if a specimen of powdered acacia had a specific rotatory power of 126, this would correspond to $126 - 18 = 108$; $108 \div 1{\cdot}8 = 60$ per cent. of dextrin. C. A. M.

Euquinine. Zimmer and Co. (*Special pamphlet;* through *Chem. Zeit. Rep.*, 1900, 159.)—Euquinine, or euchinine ("quininæ ethyl-carbonas"), is quinine ethylic carbonate. It forms hard, white, needle-shaped crystals, melting at 95° C., sparingly soluble in water, easily in alcohol and ether. It has a basic reaction, and yields crystalline salts. Like quinine, euquinine shows a blue fluorescence in sulphuric acid solution, gives the thalleioquin reaction, but not the Herapathite (iodo-sulphate) test. It possesses only a faint bitter taste, and is more permanent when exposed to light than the compounds of quinine itself. F. H. L.

Determination of Bismuth in Organic Preparations. C. Gaebler. (*Pharm. Zeit.*, 1900, xlv., 567; through *Chem. Zeit. Rep.*, 1900, 219.)—In "Airol" (bismuth oxyiodogallate) the metal cannot be determined by incineration, as the bismuth volatilizes. By precipitation as oxalate, however, useful results may be obtained. "Orphol" (the β-naphtholate) can be safely ignited; according to the formula, it should contain 80·3 per cent. of Bi_2O_3. With bismuth salicylate, incineration, extraction of the residue with nitric acid, and ignition is quite accurate. "Xeroform" (bismuth tribromophenol) can neither be analysed by ignition nor by the oxalate process; it should be treated with strong nitric acid, thrown down with ammonium carbonate, and the precipitate converted into Bi_2O_3. F. H. L.

ORGANIC ANALYSIS.

Influence of Temperature on the Specific Rotatory Power of Saccharose. **F. G. Wiechmann.** (Special pamphlet, 1900.)—In this paper the author quotes and discusses the discordant statements which have been made by different observers as to the effect of varying temperature upon the opticity of cane-sugar solutions, records numerous results obtained by himself and his assistants, and finally comes to the conclusion that, under the practical working conditions existing in technical sugar analysis, the specific rotatory power of saccharose may be regarded as constant.

F. H. L.

The Halphen Reaction for Cotton Oil. **P. N. Raikow.** (*Chem. Zeit.*, 1900, xxiv., 562, 583.)—This article contains an account of some incomplete investigations of the mechanism of the Halphen reaction, as well as sundry speculations upon the true cause of the colour. Tortelli and Ruggeri have proved that the active substance in the Becchi test must be of the nature of an unsaturated acid; Raikow has demonstrated that the active substances in the Becchi and Halphen tests are so much alike as regards their removal from or destruction in the oil, that the latter may well be an unsaturated acid also, while his previous work suggested that the two substances might even be one and the same. When, however, 10 c.c. of cotton oil are shaken in a stoppered tube for two hours with dilute sulphuric acid, and increasing quantities of potassium permanganate are added by degrees, if the residual oil is collected by means of ether, filtered, and the solvent removed, a point is soon reached (5 grammes of permanganate) where the product gives a normal Becchi test but fails to yield the Halphen reaction entirely. This shows that the active substances are not the same, and also that the body which produces the Halphen colour is far more easily attacked by nascent oxygen than the substance responsible for the Becchi colour.

Raikow has mentioned (ANALYST, this vol., 106) that a Halphen red appears when the usual mixture of cotton oil, carbon bisulphide, sulphur, and amylic alcohol is simply exposed to sunlight. If such a mixture, after becoming red, is left in the light, it gradually and slowly loses its colour, turning yellow almost as at first, similar changes occurring in a sealed tube. If the original mixture, before becoming red, is kept in the dark in an open tube, it does not turn red even in eight months; and if the red insolated mixture is placed in the dark before it loses its colour it remains red indefinitely. If the red colour is produced by heating on the water-bath, further heating does not destroy it. A mixture which has been insolated till it has become yellow again may be heated on the water-bath without effect; and if more amylic alcohol, carbon bisulphide, and sulphur are added, further heating only produces an insignificant tint, such as is exhibited by olive oil containing 0·5 per cent. of cotton oil. These experiments indicate that the red body is neither produced nor destroyed in the dark; in sunlight it is first produced, and then decomposed into something different from the original active substance of the oil. Three closed tubes were exposed to south light for seven winter months, (*a*) containing cotton oil alone, (*b*) cotton oil and carbon bisulphide without free sulphur, and (*c*) cotton oil and flowers of sulphur. Tubes *b* and *c* were then tested with amylic alcohol, bisulphide,

and sulphur; they gave no reaction; tube *a* gave both Halphen and Becchi tests normally. Light alone, therefore, does not render cotton oil indifferent to the Halphen test, but in presence of sulphur and carbon bisulphide the active substance is destroyed. Part of the contents of tube *b* were freed from bisulphide by means of a current of warm air; the residual oil gave a reaction of sulphur with phloroglucinol and vanillin. There is no evidence to show whether this sulphur existed in the free state, as a compound of bisulphide with some constituent of the oil, or as a compound of sulphur and cotton oil; the latter supposition is the more likely, explaining well why carbon bisulphide ultimately makes cotton oil fail to respond to the Halphen test. In sunlight free sulphur renders the oil inactive more rapidly than bisulphide; presence of amylic alcohol hastens either process notably. The Halphen reaction is always accompanied by the evolution of sulphuretted hydrogen, and this evolution is more marked in the presence of amylic alcohol than in its absence. This liberation of gas, indeed, may be employed as a check on the intensity of the Halphen red. When two similar tubes are charged with equal volumes of the Halphen mixture, if the colours in both develop equally, moist lead papers placed over the mouths of the tubes show identical brownish-black tints; if the reds are different, parallel differences are to be seen in the stains of lead sulphide.

All the foregoing observations give the active substance the character of an unsaturated fatty acid. Yet 95·8 per cent. of the acids of cotton oil are solid, saturated bodies, and, according to Hazura and Grüssner, the 4·2 per cent. of liquid acids are composed of linolic and oleic, which occur in nearly all vegetable oils, and which do not give the Halphen reaction. Therefore it may be asserted that the red colour depends on some unsaturated acid not hitherto isolated, which is only present in a very small proportion.

Finally, Raikow calls attention to Barbaglia's work upon valeraldehyde and benzaldehyde when heated with sulphur, and to Gattermann's statement that the thiocarbonyl group is a chromophore, whence it seems not improbable that the action of sulphur upon the unsaturated acid of cotton oil may be either to convert a CH_2 group into CHS, or a CH group into CS. When, accordingly, the Halphen colour is produced by heat alone, the thiocarbonyl group suffers no further change; but if the reaction proceeds in sunlight, or if the heated red mixture is insolated, a second stage of the reaction occurs in which the thioaldehyde or thioketone is altered or polymerized, liberating H_2S, and losing its red colour [*cf.* the reactions of benzaldehyde, *Journ. Chem. Soc.*, Abs., 1891, p. 1049, and of valeraldehyde, *loc. cit.*, 1885, p. 136]. Thus the thiocarbonyl group is wholly broken up, yielding a derivative indifferent to sulphur, and this explains why cotton oil which has lost its Halphen red will not give the test a second time. Cotton oil never yields so strong a red in sunlight as on the water-bath, because in the former case production of the CS group is accompanied by its almost simultaneous destruction. It is rather curious, in spite of the extremely small quantity of the active substance present in the oil, that so large an amount of permanganate should be required to decompose it. This may be explained by the hypothesis that the active body is less susceptible of oxidation than at least part of the other unsaturated acids, whence it follows that the said active substance must be no less nearly saturated than oleic and linolic acids. F. H. L.

Maize Oil (Corn Oil). H. T. Vulte and H. W. Gibson. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 453.)—Three samples were examined. No. I. was six or seven years old. No. II. was a sample freshly prepared by hydraulic pressure, and was of undoubted purity. No. III. was a product of the mash of distilleries:

	I.	II.	III.
Specific gravity at 15·5° C.	0·9213	0·9213	0·9255
,, ,, 100° C.	0·8716	0·8711	0·8756
Viscosity (water = 1) 20° C.	9·79	10·57	—
,, (rape oil = 100) 20° C.	70·42	73·89	—
Index of refraction at 15° C.	1·4767	1·4766	—
,, ,, 20° C.	1·4761	—	1·4765
Ash per cent.	0·065	—	0·0655
Acid value	3·70	2·25	20·65
Iodine absorption	119·7	118·6	113·3
Saponification value	192·7	192·6	191·8
Hehner value	92·8	92·2	88·2
Reichert value	4·3	4·2	9·9
Acetyl value	11·1	11·5	—
Glycerol per cent.	10·55	10·35	—
Unsaponifiable matter per cent.	1·39	1·43	—
Maumené—rise in temperature	75° C.	74° C.	—
,, —specific ,, ...	179	176	—
Bromine thermal value	21·9° C.	21·8° C.	—
Valenta's test	74° C.	80° C.	65° C.
Livache test—per cent. gain	5·97 in seven days	5·19 in ten days	—

The fatty acids gave the following results: Specific gravity at 100° C., 0·8529; melting-point, 22·4° C.; iodine absorption, 121·0; saponification value, 199·1; bromine thermal value, 21·6° C.

The iodine values were determined by Hübl's method, using an excess of 100 per cent. and allowing to stand twenty-four hours. A. M.

The Composition and Analysis of Artificial Turpentine. G. Fabris. (*Annali del Laboratorio delle Gabelle*, 1900, iv., 143-150.)—The substitutes for turpentine which have been on the market for some time consist, according to the author, of mixtures of rosin oil, colophony, and oil of turpentine. Their colour and consistency depend on the relative proportion of these constituents, and they usually have a mingled odour of colophony and rosin oil.

Six commercial samples examined by the author were all completely soluble in 95 per cent. alcohol, and on distillation yielded volatile compounds (turpentine oil) below 250° C.

On analysis they gave the following results: Substance volatile below 250° C., 6·5 to 13 per cent.; acid value, 105 to 113·8; saponification value 113·6 to 119·2; difference between saponification and acid values 5·3 to 9·2.

From these figures the author calculated approximately the composition of the samples from the data that the rosin oil used boiled above 300° C. and had no appreciable acidity; that oil of turpentine boils at 151 to 170° C., and is not acid when

pure; and that colophony commonly has an acid value of 161 to 170. They were calculated to have the following composition: Turpentine oil (substance volatile below 250° C.), 6·0 to 13 per cent.; colophony (from acid value) 65·2 to 67·9 per cent.; and rosin oil (by difference) 19·1 to 28·8 per cent.

In addition to the distinct difference in appearance and odour, natural turpentine (French or American) contains more than 15 per cent. of constituents volatile below 200° C., whilst the highest amount found by the author was 13 per cent. in one sample, the others yielding only 6 or 7 per cent. The artificial products also contain rosin oil, which is readily recognisable.

Larch or Venetian turpentine might possibly be confounded with the artificial preparations, but it invariably contains more than 15 per cent. of oil of turpentine. According to Dieterich, the acid value of Venetian turpentine varies from 65 to 75, and the saponification value from 110 to 125. In three commercial samples the author found 20 to 25 per cent. of oil of turpentine and acid values of 90·1, 90·2, and 96·8. The difference between the acid and saponification values is thus much greater than in the artificial products.

In order to detect rosin oil, 5 grammes of the turpentine are dissolved in 20 c.c. of 95 per cent. alcohol, a few drops of phenol-phthalein added, and the solution rendered just alkaline with potassium hydroxide. In the case of artificial turpentine the liquid becomes turbid, and, on standing, oily drops of rosin oil separate out, whereas Venetian turpentine tested in the same way gives a perfectly clear solution. C. A. M.

Oil of Bitter Orange. **G. Fabris.** (*Annali del Laboratorio delle Gabelle*, 1900, iv., 139, 140.)—Oil of bitter orange, which is also known as *Essence d'orange bigarade*, is extracted from the peel of the bitter orange. Having only a very limited use, it is not, according to the author, easily obtained pure in commerce.

It is a yellow liquid, with a bitter aromatic taste, and an odour of orange rather more delicate than oil of sweet orange. Its rotatory power varies within far wider limits than that of the sweet oil ($+92°$ to $98°$), but it does not differ much from the latter in its other properties. Two pure specimens examined by the author gave the following results: Specific gravity at 15° C., 0·853 and 0·852; and rotation at 20° C., 92°·40′ and 92°·0′. On account of the greater variation in the rotatory power, this oil can be more easily adulterated than oil of sweet orange. But the author considers that the rotation considered in conjunction with a fractional distillation should be sufficient to detect the more common and grosser forms of adulteration. C. A. M

Detection of Salicylic Acid in Presence of Citric Acid. **A. Klett.** (*Pharm. C. H.*, 1900, xli., 452; through *Chem. Zeit. Rep.*, 1900, 238.)—The following test, due to Jorissen, will indicate the presence of salicylic acid in lemon-juice by giving a blood-red colour: 10 c.c. of the liquid are mixed with 4 drops of a 10 per cent. solution of potassium or sodium nitrite, 4 drops of acetic acid, and 1 drop of 10 per cent. copper sulphate, the whole being heated to the boiling point. (*Cf.* this vol., p. 238.) F. H. L.

Detection of Salicylic Acid and Vegetable Albumin by Means of Millon's Reagent. C. J. Lintner. (*Zeits. angew. Chem.*, 1900, 707.)—When prepared in the usual manner, by dissolving mercury in nitric acid, Millon's reagent tends to give somewhat uncertain results; the author therefore prefers to use solutions of mercuric nitrate and sodium nitrite, keeping them separately and adding them in succession to the substance under examination. For the detection of salicylic acid, the sample should be boiled for two minutes with a few drops of 10 per cent. mercuric nitrate, then 2 or 3 drops of dilute sulphuric acid and a very small quantity of 1 per cent. sodium nitrite solution, avoiding excess, should be added. The red colour appears usually with the first drops of nitrite, and generally becomes more intense as the mixture cools. It will remain unaltered for a day. Dilute nitric acid can be employed to acidify the liquid, but it gives a yellow instead of a blue shade of red to the reaction, and thus diminishes the delicacy of the test. This limit of delicacy, both with Millon's reagent and the above modification, is at about 1 part of salicylic acid per 500,000; the modified test yields rather brighter and more permanent tints.

To detect vegetable albumin in seeds, etc., a combined reagent should be prepared of the mercuric nitrate solution, 5 vols.; the sodium nitrite, 1 vol.; and dilute sulphuric or nitric acid, 1 vol. If, for example, longitudinal sections of barley grains are placed in this liquid, the cut surfaces gradually turn red-violet, which renders the glutinous layer and the embryo very conspicuous; the husk becomes a dark brownish-red. F. H. L.

Detection of Indican in Pathological Urine. A. Klett. (*Chem. Zeit.*, 1900, xxiv., 690.)—The ordinary calcium hypochlorite test for indican is very apt to fail, especially if the reagent be added in excess; and it is better to use ammonium persulphate, which gives a blue coloration unaffected by excess. To 10 c.c. of urine are added 5 c.c. of 25 per cent. hydrochloric acid, some persulphate, and then chloroform. Klett calls attention to Strzyowski's test for albumin and bile pigments (ANALYST, 1899, xxiv., 49), and observes that ammonium persulphate is a most serviceable reagent in the examination of urine. F. H. L.

The Relation of the Reducing Power of Normal Urine to the Amount of certain Nitrogen Compounds Present. J. H. Long. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 309.)—Normal urine contains only a small proportion of sugar (see Allen, ANALYST, 1894, 178.) Among the other substances present which have the power of reducing copper, the most important are uric acid and creatinine. The author has determined their reducing power, and has estimated the amount present in a number of normal urines. For this work a sensitive copper solution was required. It was found that the oxidizing power increases with the amount of caustic soda and ammonia present. The solution adopted had the following composition: Copper sulphate, 8·166 grammes; sodium hydroxide (100 per cent.), 15 grammes; glycerol, 25 c.c.; ammonia (specific gravity 0·9), 350 c.c.; water to make 1 litre. One c.c. of this oxidizes 1 milligramme of sugar in 0·2 per cent. solution; 50 c.c. of the solution are taken, diluted to 100 c.c.; solid paraffin is added, which when melted covers the

surface. The liquid is boiled gently and the solution under examination is added slowly; 1 molecule of dextrose = 5·88 molecules of CuO.

It was found that 1 molecule of creatinine, $C_4H_7N_3O$, reduces 2 molecules, CuO, and 1 molecule of uric acid, $C_5H_4N_4O_3$, almost 3.

The following table gives the results of the examination of 24 samples of healthy urine, obtained mostly from young men:

	Minimum.	Maximum.	Mean.
(*a*) Excretion in twenty-four hours	765 c.c.	1920 c.c.	1167 c.c.
(*b*) Specific gravity at 20° C.	1·018	1·035	1·025
(*c*) NH_3, milligrammes per litre	227·7	1001·0	620·0
(*d*) Uric acid, milligrammes per litre ...	423·7	1020·0	658·7
(*e*) Creatinine ,, ,, ...	653	1930	1392
(*f*) Urea, grammes per litre	14·83	37·27	24·37
(*g*) Total reducing power, grammes CuO per litre	2·245	8·738	6·204
(*h*) Reducing power of uric acid	0·592	1·381	0·935
(*k*) ,, ,, creatinine	0·920	3·133	1·961
(*l*) Sum of *h* and *k*	1·897	4·023	2·896
(*m*) Ratio of *l* to *g*	0·328	0·631	0·466

The reducing power, which remains unaccounted for, is probably due principally to saccharine matter. Calculation shows that the quantity of the latter present amounts in the mean to about 1·4 grammes dextrose per litre. The value (*m*) was found to be highest for men of strong physique with a diet containing meat. A man consuming a diet largely meat gave values 0·63 and 0·60. The same individual some weeks later, after a change to bread and vegetables largely, gave a value 0·3.

The urea figures given above were determined by the Knop-Hüfner process. Higher results were naturally obtained by the Liebig process. The ratio of urea to uric acid is 36·9. A. M.

Artificial Silks. C. Hassac. (*Oest. Chem. Zeit.*, 1900, 235-237, 267-269, 297-299.)—The materials examined were:

1. Chardonnet silk (made from collodion) from Près de Vaux, near Besançon.
2. ,, ,, from Fismes, in North France.
3. ,, ,, from Walston, in England.
4. Silk made from collodion by Lehner's process at Glattbrugg, near Zurich.
5. Cellulose silk made with ammoniacal copper oxide, by Dr. Pauly's process, at Oberbruch, near Aix-la-Chapelle.
6. Gelatin silk.

Nos. 1, 2, and 4 are very similar in *appearance*. They excel real silk in lustre, but they are stiffer and have not the characteristic feel of the real material. No. 3 feels rough and appears hairy. It reminds one of mohair rather than of silk. No. 5 resembles Nos. 1 and 2 in appearance, but its lustre is even better, and when made up it has also the characteristic feel of real silk.

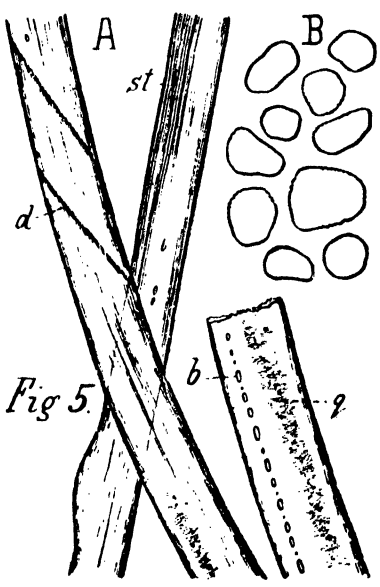

Fig 5.

PAULY'S CELLULOSE SILK.
d, Mark where two fibres have been pressed together; *st*, fine grooves; *b*, air-bubbles; *q*, cross-lines inside fibres. B, Cross-section. (×150.)

Under the *microscope* the Chardonnet silks much resemble one another, except that the Fismes product is grooved more. They can, however, be distinguished by their cross-sections (see Figs. 1, 2, 3). Lehner silk (Fig. 4) is characterized by deep grooves running lengthwise along the fibres and by small air-bubbles. Cellulose silk (Fig. 5) is regular in cross-section. On the surface are fine grooves running lengthwise (*st*), and in the centre of the fibres are fine lines running across (*q*). Gelatin silk (Fig. 6) is almost circular in section and free from grooves or bubbles. The fracture is even and the thickness constant.

The figures represent the materials swollen by immersion in water and magnified 150 diameters.

In *polarized light* all the artificial silks show double refraction, except gelatin silk, which is singly refracting. In this they resemble natural silk. In No. 5 the interference colours are even over considerable lengths of the fibres, whereas in the collodion silks great play of colours is observed in consequence of the variations in thickness.

Behaviour with Reagents. — The collodion silks, Nos. 1 to 4, always contain a small amount of nitro-compound, and consequently give a fine blue with a solution of *diphenylamine* in sulphuric acid.

When immersed in *water*, all artificial silks swell. If placed in absolute alcohol or glycerin, the fibres contract again.

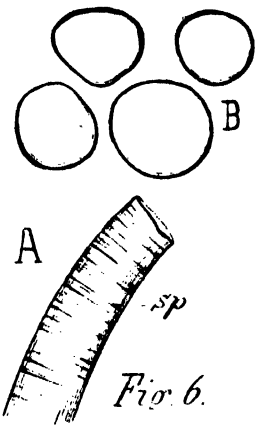

Fig. 6.

GELATIN SILK BY PROFESSOR HAMMEL'S PROCESS.

sp, Splits in a bent fibre. B, Cross-section. (×150.)

In *concentrated sulphuric acid* the collodion silks swell rapidly and dissolve. Cellulose silk becomes gradually thinner and dissolves away. Gelatin silk only dissolves on strongly heating.

Concentrated hydrochloric acid has not much action on artificial silks in the cold. When warmed it dissolves gelatin silk rapidly.

Acetic acid only causes a slight swelling, except in the case of gelatin silk, which on boiling dissolves almost completely.

Half-saturated *chromic acid* solution in the cold rapidly dissolves all artificial silks. Real silk takes longer. Cotton, flax, and other vegetable fibres are not dissolved.

Forty per cent. potash lye dissolves gelatin silk rapidly. Collodion and cellulose silks swell, but do not dissolve, even on boiling; but the liquid assumes a yellow colour. Real silk (white) is dissolved on boiling, but does not colour the liquid.

Schweizer's reagent (ammoniacal copper oxide) causes the collodion silks to swell rapidly and then dissolve. Cellulose silk swells less rapidly. Gelatin silk does not dissolve, but is coloured bright violet.

Alkaline copper-glycerin solution is a very useful reagent. Real silk dissolves immediately on warming to 80°. Tussah silk dissolves on boiling about a minute, as also does gelatin silk. The other artificial silks are in no way affected.

Solution of *iodine and potassium iodide* colours artificial silks an intense red or

reddish-brown. When washed with water the colour disappears, and collodion silks show a transient grayish-blue. Cellulose silk does not show this blue coloration.

Solution of *iodine and dilute sulphuric acid* (v. Höhmel's paper reagent) colours real silk yellow, gelatin silk yellowish-brown to reddish-brown, collodion silks deep blue with a shade of violet, cellulose silk pure blue.

Solution of *zinc chloride and iodine* colours collodion silks bluish-violet, cellulose silk grayish-blue to grayish-violet; gelatin silk, like real silk, becomes yellow and disintegrates.

As regards *inflammability*, the artificial silks, with the exception of gelatin silk, behave like cotton. Gelatin silk behaves in this respect like real silk.

In the following table the first column shows the moisture in the air-dry material. The second column the moisture after standing twenty-four hours in an atmosphere saturated with water vapour. The third shows the specific gravity, determined by weighing in benzene, air-bubbles being removed by manipulation under the receiver of a vacuum pump. The fourth column shows the number of elementary fibres which go to 1 square millimetre after soaking in water. This was determined by measuring the sectional area under the microscope. The fifth column shows the number of fibres in the air-dry state which go to 1 square millimetre. This was calculated from the previous figures and the known coefficients of swelling, as satisfactory sections could not be cut dry. The tensile strengths were measured on the instrument of Teclu (*Centralorgan f. Wkd. u. Technlg.*, i., 200).

	Moisture		Specific Gravity.	No. of Fibres to 1 sq. mm.		Tensile Strength. Kg. per sq. mm.		Extension. Per cent.
	Air-dry. Per cent.	Saturated. Per cent.		Wet.	Dry.	Wet.	Dry.	Dry.
Real silk ...	8·71	20·11	1·36	9,710	9,710	37·0	37·0	21·6
1. Chardonnet	11·11	27·46	1·52	640	1,135	2·2	12·0	8·0
2. Fismes ...	10·92	27·12	1·52	370	656	1·6	7·8	11·6
3. Walston ...	11·32	28·94	1·53	683	1,620	1·0	22·3	7·9
4. Lehner ...	10·45	26·45	1·51	413	1,180	1·5	16·9	7·5
5. Cellulose ...	9·20	23·08	1·50	742	1,550	3·2	19·1	12·5
6. Gelatin ...	13·98	45·56	1·37	265	945	nil	6·6	3·8

It will be seen that the cellulose silk made by Dr. Pauly's process is the most satisfactory. A. M.

INORGANIC ANALYSIS.

Titration of Mercury Salts with Thiosulphate. **J. J. Norton.** (*Zeits. anorg. Chem.*, 1900, xxiv., 411.)—Sherer having stated (*cf.* Sutton's "Volumetric Analysis") that mercurous nitrate, mercuric nitrate, and mercuric chloride can be accurately determined by titration with standard thiosulphate, the present article is a study of the processes suggested. Norton finds that neither mercurous nor mercuric nitrate can be analysed by Sherer's method; but that mercuric chloride is amenable to the process if the following directions are followed closely: The solution, containing up to about 0·2 gramme of metallic mercury, is brought into a 1-litre flask, diluted to 100 c.c., heated to 60° C., and a $\frac{N}{20}$ solution of thiosulphate is run in till the precipitate, which is at first white, becomes brownish. The liquid is then diluted with

cold water, some asbestos fibres added to assist filtration, and the whole filtered through asbestos with the aid of the pump. After thorough washing, the filtrate is made up to a definite volume, treated with 3 grammes of potassium iodide, and the excess of thiosulphate is titrated with iodine and starch. The process should not occupy more than fifteen minutes. Addition of hydrochloric acid is not necessary.

F. H. L.

Test for Tin. **A. Rogers** (*Journ. Amer. Chem. Soc.*, 1900, xxii., 220) and **J. P. Longstaff** (*ibid.*, 450).—The separation of the tin is conducted in the usual way with zinc, and the black flakes dissolved in hydrochloric acid. To a few drops of this solution a little water is added, and then ammonium molybdate. A blue colour shows the presence of tin.

Longstaff points out that he published the method last year in the *Chem. News* (lxxix., 282). The zinc which is used for reduction must be quite free from tin. With dilute solutions the molybdate should be added at once, before the tin can become oxidized. One part of stannous chloride can thus be readily detected in 100,000 parts of solution. By using the special precautions described in the *Chem. News*, it is possible to detect 1 in 1,500,000.

A. M.

Valuation of Zinc Dust. **A. Fraenkel.** (*Mitth. Techn. Gew. Mus. Wien*, 1900, x., 161; through *Chem. Zeit. Rep.*, 1900, 219.)—One gramme of the sample is weighed into a dry stoppered 200 c.c. flask, mixed with 100 c.c. of potassium bichromate solution (30 grammes per litre) and 10 c.c. of 1 : 3 sulphuric acid, and agitated for five minutes. Another 10 c.c. of acid are then added, and the shaking continued for ten or fifteen minutes, when everything, except a small earthy residue, should be dissolved. The liquid is diluted to 500 c.c., and in 50 c.c. thereof the excess of bichromate is estimated by introducing 10 c.c. of 10 per cent. potassium iodide and 5 c.c. of sulphuric acid, titrating the liberated iodine with decinormal thiosulphate.

F. H. L.

Estimation of Cobalt in New Caledonian Ores. **T. Moore.** (*Chem. News*, 1900, lxxxii., 66.)—These ores consist mainly of the hydroxides of manganese, iron, aluminium, cobalt, and nickel, with small quantities of calcium, magnesium, zinc, and lithium; occasionally also barium and copper. The proportion of cobalt may reach 8 per cent., averaging 5 per cent., and the ores are sold simply upon the amount of that metal. To estimate the cobalt, 2·5 grammes are dissolved in strong hydrochloric acid, and evaporated to a syrup; the soluble matter is taken up in water, and the Fe and Al precipitated by the basic process. To the filtrate 20 c.c. of saturated sodium acetate and 10 c.c. of acetic acid are added, and the whole heated nearly to boiling. A current of sulphuretted hydrogen is next passed through the solution till it is almost cold, when the sulphides of cobalt, nickel, and zinc are collected, washed with H_2S-water, dried, and ignited. The ignited oxides and any sulphide adhering to the walls of the flask are dissolved in strong HCl and a few drops of HNO_3, evaporated twice to dryness with more HCl, and the chlorides dissolved in 5 or 10 c.c. of water. To remove any traces of iron which

may have escaped precipitation, this solution is treated with a cream of zinc oxide. The filtrate, diluted to about 50 c.c., is mixed with 10 or 15 c.c. of 10 per cent. hydrogen peroxide and 10 c.c. of 10 per cent. sodium hydroxide. The precipitate of cobalt sesquioxide and nickel monoxide is boiled for a minute, cooled, and treated in a stoppered bottle with excess of potassium iodide and HCl until the decomposition is complete, titrating the liberated iodine with thiosulphate ($I \times 0{\cdot}46511 = Co$). The caustic soda employed must be examined for impurities capable of liberating iodine, as samples containing nitrites are not uncommon. The examples quoted are satisfactory. F. H. L.

APPARATUS.

The Use of Floats in Burettes. Kreitling. (*Zeits. angew. Chem.*, 1900, 829.)—This is a lengthy article on the behaviour of an Erdmann float in a graduated burette, and the author's conclusions are as follows: It is advisable never to use a float in a burette, for the readings obtained with this device vary considerably at different times and with different observers. In etched burettes graduated without a float, the device should on no account be adopted, for it is liable to cause errors the magnitude of which cannot be predicted. F. H. L.

The Distillation of Ammonia in the Determination of Nitrogen. F. G. Benedict. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 259.)—Ammonia is entirely removed from an alkaline liquid after boiling for quite a short time. If a condenser be used, part of the ammonia condenses in it, and requires a large amount of distillate to wash it through—not less than 150 c.c. If, on the other hand, the condenser be done away with, and the steam be led directly into a beaker containing standard acid, the latter becomes very hot, and must be cooled before titrating. Some of the acid may be lost also. The advantages of both these methods are combined in the following: A condenser is used, the tube of which dips below the surface of the acid in the receiver. After boiling for fifteen minutes, the water is gradually run out of the condenser, and steam is allowed to pass through for five minutes. By that time all the ammonia is distilled from the interior of the condenser. A. M.

REVIEW.

FOOD AND DRUGS. A Manual for Traders and others, being a Consolidation of the Sale of Food and Drugs Act, 1875, the Sale of Food and Drugs Act Amendment Act, 1879, Margarine Act, 1887, and Sale of Food and Drugs Act, 1899. By CHARLES JAMES HIGGINSON. London: Effingham Wilson, 11, Royal Exchange, 1900. Price 2s. 6d.

THIS is a useful little work, which contains, besides the text of the four statutes above cited as chief contents, those clauses of the four Acts which are concurrently in force, consolidated in such a manner that one can see at a glance in how far they modify or enlarge each other. The more important of the many High Court decisions which interpret the clauses of the Acts of Parliament are also shortly and clearly referred to. O. H.

THE ANALYST.

NOVEMBER, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

ON UNIFORMITY IN SOIL ANALYSES.

By A. D. Hall.

(Read at the Meeting, June 6, 1900.)

The following recommendations have been drawn up by a committee of the Agricultural Education Association,* with the aim of securing a certain uniformity in the conduct of soil analyses. The object the committee has in view in seeking for such uniformity is: (1) To enable analyses executed and published by any investigator to be intelligible to his fellow-workers, and therefore on occasion to be serviceable in their research; (2) to insure that the large number of soil analyses now being carried out at various institutions in this country shall be mutually comparable, and available for tabulation and general discussion; (3) to put on record a method of procedure that will serve as a guide to investigators beginning such work.

As the desirability of uniformity in methods of analysis has sometimes been called in question, the committee wishes to indicate in what respects it considers agreement should prevail, and the weight it attaches to its recommendations. In the first place, the committee would disclaim any idea of dictating methods in cases of what may be termed research; every worker in so incompletely surveyed a field as soil analysis affords must have ideas of his own for the examination of special points. The recommendations of the committee deal with those determinations about which there is a general consensus of opinion—such determinations, in fact, as would generally accompany a record of results of field experiments, etc. Secondly, the committee does not wish to formulate any recommendations as to the interpretation of soil analyses, recognising that the interpretation is still largely uncertain, and must depend to a great measure on the judgment and local knowledge of the analyst. Further, the committee's recommendations do not deal with the analytical processes or details of manipulation to be adopted in the determination

* The committee consisted of T. S. Dymond, of the Essex County Laboratories; M. J. R. Dunstan, University College, Nottingham; C. M. Luxmoore, Reading College; T. B. Wood, Cambridge University Agricultural Department; and A. D. Hall, South-Eastern Agricultural College, Wye.

of any given constituent; these are matters dependent on the skill and discretion of the individual, and for them the individual is responsible.

The committee wishes to define what may be termed the necessary "conventions" of soil analysis, for soil analysis is not like an atomic weight determination, or even the assay of a manure, in which a number having an absolute value can be sought for. The only absolute figures possible are those to be obtained by an ultimate elementary analysis of the whole soil. This, however, is never attempted: by tacit consent certain portions only are reserved as soil for analysis, and are, again, only submitted to a partial resolution, the portion reserved and the mode of attack varying with each chemist; yet the figure expressing the proportion in the soil of a constituent like potash may vary two- or three-fold, according to the method of attacking the soil that is adopted; hence the importance of agreement on such a point is manifest.

In its preliminary inquiries the committee found that no agreement existed among the chemists, either of this or other countries, on such points as the preparation of the soil for analysis, the nature of the solvent to be employed, the time of its action, etc.; and as there is no absolute criterion by which they can be decided, they must be regarded as "conventions," to be settled by considerations of expediency and mutual agreement. But as the results obtained will very largely depend upon the conventions adopted, this committee has attempted, after discussion and investigation, to so far define a common plan of action as will render the results obtained more generally serviceable, without hampering the individuality of each worker.

Recommendations.

1. *Taking Sample.*—Under ordinary conditions the sample shall be taken to a depth of 9 inches, but in case of shallow soils to such lesser depth as marks a natural line of demarcation.

The committee approves of the use of the auger as one method that may be adopted for taking samples. Several cores should be taken and mixed for analysis.

2. *Drying.*—The sample shall be air-dried for analysis. The drying may be accelerated by heating to a temperature not exceeding 40° C., but in all cases the soil should be finally left for a day or two, spread in a thin layer, and exposed to the air, at the ordinary temperature of the room.

3. *Sifting.*—A sieve with round holes, 3 millimetres in diameter, shall be used to separate the fine earth for analysis from the stones and gravel. Gentle pressure with a wooden or caoutchouc pestle, or other means, may be adopted to break up aggregates of clay and silt, but care should be taken not to crush any of the stones or lumps of chalk.

For determination of the "available constituents" the "fine earth" is used without grinding. For the other determinations, 100 grammes or more of "fine earth" is sifted through a woven sieve of 40 meshes to the inch, or a sieve with round holes of 1 millimetre in diameter. What is retained by the sieve is ground till it will pass through, and the whole mixed.

Perforated zinc, with holes $\frac{1}{8}$ inch and $\frac{1}{25}$ inch diameter, is commercially

obtainable, and forms a convenient material for the construction of the two sieves. Considerable diversity of opinion exists concerning the sieve to be used for obtaining "fine earth" for analysis; the Rothamsted chemists employ a woven sieve of ¼ inch mesh; the 3-millimetre round-holed sieve was originally suggested by Wolff; the Berlin Laboratorium für Bodenkunde employs a 2-millimetre round hole, but also analyses the finest particles separated by washing; Grandeau, and the French Comité Consultatif des Stations Agronomiques use a 1-millimetre woven sieve, and Petermann in his examination of the Belgian soils does the same. The committee suggests 3 millimetres as a convenient size; lumps of earth can be readily reduced to that diameter, whereas sifting down to 1 millimetre involves either so much crushing of lumps of earth as results in considerable fracture of the stones, or else wet sifting. The ¼ inch square mesh sieve passes in some cases a large proportion of hard stones that are further reduced with much difficulty, and yield unweathered material, not likely to be serviceable for plant nutrition for many years. The further grinding is recommended to obtain material from which a small sample for analysis can be fairly drawn.

4. *Determination of Moisture.* — The sample is dried in the steam-oven to constant weight.

5. *Determination of Loss on Ignition.*—The result shall be so expressed as not to include the carbon dioxide expelled from the carbonates nor the moisture previously determined.

6. *Determination of Nitrogen.*—Unless otherwise specified, the nitrogen shall be determined by Kjeldahl's method.

7. *Determination of Carbonate of Lime.*—The carbon dioxide evolved on treatment of the fine earth with acid is calculated as carbonate of lime.

This is regarded as a convenient measure of the "available basicity" of the soil, without discriminating between carbonates of lime and magnesia.

8. *Determination of "Total" Mineral Constituents.*—The fine earth is boiled with strong hydrochloric acid in an open flask for a short time in order that the acid may attain constant strength, and digested at the ordinary water-bath or steam oven temperature for 40 to 48 hours, the flask being loosely stoppered. In this solution the phosphoric acid and potash are determined, and other mineral constituents as desired.

The object of the committee is to obtain as thorough an extraction of the soil as is possible short of ultimate analysis. The time of the extraction is made sufficiently long to minimize errors due to variations in the actual time, the strength of the acid, or the temperature.

Unignited soil is taken since ignition effects a drastic and variable alteration of the constitution of the soil—*e.g.*, no constant proportion is found between the potash extracted from ignited and unignited soil. Hydrochloric acid is taken as the most generally effective solvent; even peaty soils are found to yield as much phosphoric acid to hydrochloric acid as to nitric acid, or aqua regia.

9. *Determination of Available Phosphoric Acid and Potash.*— Unless otherwise specified, the method described by Dr. B. Dyer (*Journ. Chem. Soc.*, 1894, Trans., p. 115) shall be followed, the quantities used being 200 grammes unground fine earth

and 20 grammes citric acid in 2,000 c.c. water, no further addition of citric acid being made.

10. *Expression of Results.*—Unless otherwise stated, results shall be expressed as percentages calculated on the fine earth in an air-dry state.

It has been thought desirable that some of the experimental results obtained by members of the committee should be set out in detail, in order to show the reasons upon which some of the recommendations are based. The experiments deal with the effect of ignition on the relative amounts of potash and phosphoric acid dissolved from soils by hydrochloric and nitric acids. In all cases HCl aq. or HNO_3 aq. means the acid of constant strength obtained by boiling the strong acid in the air at ordinary pressures.

1. Effect of ignition of soil on the amount of potash and phosphoric acid dissolved by nitric and hydrochloric acids.

(*a*) Soil digested for two days with HCl aq. (T. B. W., L. L. B., and G. D.):

		Percentages dissolved from Raw Soil.		Percentages dissolved from Ignited Soil.	
		Potash.	Phosphoric Acid.	Potash.	Phosphoric Acid.
Heavy clay	(7)	0·69	0·24	0·62	0·19
Peat	(8)	1·11	0·61	1·25	0·33

(*b*) Soil digested for two days with HNO_3 aq. (T. B. W., L. L. B., and G. D.):

		Percentages dissolved from Raw Soil.		Percentages dissolved from Ignited Soil.	
		Potash.	Phosphoric Acid.	Potash.	Phosphoric Acid.
Sticky clay	(1)	0·37	0·20	0·48	0·15
Red sand	(2)	0·39	0·27	0·54	0·22
Poor sticky soil ...	(3)	0·42	0·13	0·58	0·23
Good loam	(4)	0·41	0·26	0·34	0·15
Loam	(5)	—	0·40	—	0·26
Sand	(6)	0·14	0·12	0·19	0·10
Heavy clay	(7)	0·49	0·17	0·52	0·18
Peat	(8)	0·94	0·29	0·98	0·36

In the above experiments more potash and less phosphoric acid are generally obtained from the ignited soil, but there are several exceptions.

(*c*) Soil evaporated twice to dryness on water-bath with HCl aq., each operation taking about an hour (A. D. H.):

	Potash Extracted from Soil.	
	Raw.	Ignited.
Light sand	0·337	0·101
Rich loam	0·280	0·307

(*d*) Soil digested with HCl aq. and extract weighed (T. S. D.):

From raw soil	12·76 per cent. extracted.
From ignited soil	15·52 ,, ,,

2. Effect of continued digestion with hydrochloric acid.

(*a*) (C. M. L.):

	Insoluble Residue.	Potash.
Evaporated twice with HCl aq. ...	79·25	0·210
Digested two days with HCl aq. ...	75·70	0·305

(*b*) (A. D. H.):

Evaporated once with HCl aq., once with HCl aq. and a little HNO_3, then taken up with HCl aq. ...	0·280 per cent. K_2O.
Digested 24 hours with HCl aq. ...	0·372 ,, ,,

3. Comparative solvent action of hydrochloric and nitric acids.

(*a*) Digested on water-bath for two days; soil A, sandy pasture, poor in organic matter. Soil B, stiff clay, arable, rich in organic matter (C. M. L.):

	Phosphoric Acid extracted by		Potash extracted by	
	HCl aq.	HNO_3 aq.	HCl aq.	HNO_3 aq.
A	0·478	0·366	0·330	0·271
A	0·503	0·384	0·343	0·278
B	0·428	0·300	0·324	0·185
B	0·384	0·339	0·326	0·193

(*b*) Soils digested for two days on water-bath as before. Soil A, loam; B, London clay (pasture); C, chalky clay (T.S.D.).

	Phosphoric Acid extracted by		Potash extracted by	
	HCl aq.	HNO_3 aq.	HCl aq.	HNO_3 aq.
A	0·24	0·24	0·19	0·10
B	0·20	0·16	1·08	0·34
C	0·23	0·20	0·89	0·49

A, insoluble residue, from HCl aq. 86·48 per cent.; from HNO_3 aq. 88·50 per cent.

(*c*) Soil digested for two days on water-bath as before, peaty water-logged soil, giving on ignition a loss of 46·34 per cent. (A. D. H.):

Extracted with HCl aq. gave ... ... 0·157 per cent. phosphoric acid.
,, ,, HCl aq. and one-tenth HNO_3 aq. gave 0·159 per cent. ,, ,,
,, ,, HNO_3 aq. gave ... ... 0·165 per cent. ,, ,,

(*d*) Soils digested for two days on water-bath as before (T. B. W., L. L. B., and G. D.):

Nature of Soils.	Moisture when Air-dry.	Loss on ignition.
1. Boulder clay	3·52 ...	5·44
2. Red sandstone	2·7 ...	6·95
3. Poor sticky soil	2·67 ...	6·23
4. Good loam	3·5 ...	10·8
5. Loam	2·3 ...	8·6
6. Sand	0·7 ...	2·3
7. Heavy clay	3·62 ...	5·63
8. Peat	10·98 ...	35·52

	Potash extracted by		Phosphoric Acid extracted by	
	HCl aq.	HNO_3 aq.	HCl aq.	HNO_3 aq.
1.	0·59	0·37	0·17	0·20
2.	0·65	0·39	0·30	0·27
3.	0·63	0·42	0·21	0·13
4.	0·20	0·41	0·24	0·26
5.	0·42	0·24	0·45	0·40
6.	0·17	0·14	0·13	0·12
7.	0·69	0·49	0·24	0·17
8.	1·11	0·94	0·61	0·29

With one exception as regards potash, and two exceptions as regards phosphoric acid, hydrochloric was always a more effectual solvent than nitric acid. Some light on the superior solvent action of hydrochloric acid was obtained by estimating the silica soluble in a solution of sodium carbonate in both the original soil and the residue left after extraction by hydrochloric and nitric acids.

Soluble silica per cent. calculated on original soil:

Soil.	Raw Soil.	Ignited Soil.	Residue from HCl Extraction.	Residue from HNO_3 Extraction.
1.	0·30	0·77	11·18	7·22
4.	0·16	0·22	8·40	5·56
7.	0·32	0·26	8·94	6·94
8.	0·28	0·44	15·24	10·44

Silicates have been decomposed by the acids and silica set free, as shown by the comparatively small amounts of silica to be obtained from the raw soil; and more silicates have been broken up by the hydrochloric than by the nitric acid.

Discussion.

Dr. Dyer said that agricultural chemists must feel much indebted to the author and to the other members of the committee who had been working in connection with this matter. The subject was one which had been much in need of attention. He was very pleased to find that all idea had been discarded of laying down absolutely uniform methods for the actual determinations. It was very desirable that there should be uniform methods for dissolving from the soil the constituents to be determined, but nothing was more irksome than to have stereotyped methods for the determinations to be made in the solution obtained. Of course, in many branches of analysis the methods were necessarily arbitrary, where all that was required was to get comparable numbers under definite conditions, and not actually to determine the total percentages of given substances; but in determining the quantity of phosphoric acid in a given solution, or the quantity of nitrogen in a given material, provided that the process gave accurate results, that was all that was required. The mechanical question as to sieves was of importance, and he (Dr. Dyer) saw no reason at all, from his own experience, for disagreeing in any way with the adopted selection of admittedly arbitrary sieves. The ¼-inch sieve that had been largely used here was merely the sieve that had happened to be adopted in soil-sampling at Rothamsted; and when the same soils were under observation year after year, if the results were to be comparable, it was necessary to maintain the system of "sieving" which had been

followed at the commencement. But there seemed to be no reason at all why that should be adopted generally, and the meshes described by Mr. Hall seemed to be quite as reasonable as any others that could be suggested. With regard to the depth of the soil, in relation to sampling, it might be interesting to Mr. Wood and other agricultural chemists to know that at Rothamsted, where the depth of 9 inches had been adopted as indicating the surface soil, Sir John Lawes and Sir Henry Gilbert had arrived at the conclusion that 9 inches was probably a little too deep for average purposes. If they were beginning over again, they would sample the surface soil to a slightly less depth than that. He (Dr. Dyer) had recently had a conversation with Sir Henry Gilbert on this subject, and learnt that at Rothamsted the view now held was to the effect that a more suitable depth would be one-fifth of a metre, viz., something under 6 inches—a convenient international measure. Anything deeper than that would be regarded as subsoil. But, of course, local conditions might altogether alter this. For instance, if the ploughing had always been shallow in a certain field, the depth of ploughing would really fix what was the surface soil, as distinguished from the subsoil. Very often, in a clay soil, the clay had been originally the same all through the surface soil, in the case of arable land being determined first by turf and later by the plough; but where a light loam rested on a chalk rock, there might be only 5 or 6 inches of actual soil, and if samples taken 2 or 3 inches deeper—and therefore including some of the chalk—were regarded as representing the top soil, there would obviously be a departure from what was rational and reasonable.

With regard to solvents, it was recommended by the committee that hydrochloric acid should be used for the determination of what was called, for the sake of brevity, "total" mineral constituents; and it was directed that the fine earth should be boiled with strong hydrochloric acid in an open flask, and digested on the ordinary water-bath for from forty to forty-eight hours, the flask being loosely stoppered. There was no suggestion that the solution should be evaporated to dryness. He (Dr. Dyer) thought that some reference to this point might well be introduced, because it was quite possible that some people might be found who, working under these directions, would assume that they were to use for the phosphoric acid determination an aliquot portion of that solution when filtered, without evaporation to dryness, to remove silica. The usual practice was to evaporate the whole thing to dryness—very often twice—in order to render all the silica insoluble, which, of course, was very essential for an accurate determination of phosphoric acid, and, indeed, of other constituents also. Unless the solution were sent to dryness, the silica would be more or less of a nuisance all through the analysis. He thought it should be pointed out that the aliquot portions of the solution might be afterwards evaporated to dryness, preliminarily to a further analysis, and the silica in that way removed. One difficulty in operating on the unignited soil was, that if a large quantity of organic matter was present, it was converted by the hydrochloric acid into more or less sugary substances, which, unless destroyed by evaporation to dryness with nitric acid, rendered very difficult the precipitation of the iron and alumina.

Of course, the great difficulty about ignition was, as the author had pointed out, that its effect on different soils was not the same. Very many clay soils (those at Rothamsted, for instance) contained nearly 2 per cent. of total potash, obtainable by

fusion, though only a small fraction of 1 per cent. was obtained by means of hydrochloric acid, even after ignition; and obviously the extent to which the silicates containing potash were decomposed depended a good deal upon (among other factors) the quantity of lime present in the soil. But even in the same soil the temperature and period of ignition affected to a considerable extent the quantities dissolved out afterwards. For getting uniform results it would appear to be better to work on the unignited soil, but precautions must be taken in some cases for the subsequent destruction of organic matter in the solution by boiling with bromine or by some other means. He had, after making a very great many careful and minute experiments, come to the conclusion that in the determination of phosphoric acid it did not matter at all whether hydrochloric or nitric acid was used as a solvent. The determination was virtually one of the total percentage present, and was therefore of a quite definite nature. If strong nitric or hydrochloric acid was used, with evaporation to dryness and redigestion, identical results were almost invariably obtained in either case; but the inconvenience of using hydrochloric acid lay in the fact that if the molybdic acid method was used, as it always would be, the presence of hydrochloric acid was a nuisance. It was almost necessary, for working with certainty and comfort, to evaporate to dryness with nitric acid, and so eliminate, or nearly eliminate, any chlorides present. A comparatively small quantity of hydrochloric acid in a determination by the molybdate method was apt to keep some of the phosphoric acid in solution, and while the precipitate was being washed, the filtrate would become turbid, and would have to be refiltered. This might to some extent be got over by the use of large quantities of ammonium nitrate; but there was really in his experience no reason for any hydrochloric acid being present, for a separate quantity of the solution could be taken for the phosphoric acid determination and evaporated to dryness, and redigested with nitric acid only.

He did not quite like the expression of the results on the air-dried soil. He quite believed in working on the air-dried soil, but he thought it would be more convenient to calculate the results on the soil dried at 100° C., because that was a definite basis. Air-dryness depended a great deal upon the condition of the atmosphere at the time of drying the soil, and upon the quantity of humus in the soil itself—a factor which varied considerably. The experience of Mr. Wood, that a larger quantity of potash was obtained after ignition, corroborated that of the late Dr. Voelcker, formed during an investigation made many years since on the effects of "paring and burning," which used to be a common agricultural operation, resulting in the liberation from clay soils of quantities of potash previously locked up from the reach of plants in the form of insoluble silicates. But in any case, when there was any clay in the soil, the potash extracted by either hydrochloric acid or nitric acid was only a small fraction of the total potash present, and it varied not only according to the way in which the soil was ignited, but according to the period of ignition and the strength of the acid used for extraction. In clay soils it was quite impossible, even using the same process, to get concordant results in the case of "total" potash determinations; but seeing that the quantity of potash extracted by strong mineral acids was always largely in excess of anything that was really available for plant use, it would not be very material whether one obtained 0·25 or 0·35 per cent., though it

was certainly desirable that, if this determination were made, the processes used should as nearly as possible be uniform.

He was naturally pleased to hear—he had been unaware of it until the previous day—that the process which he had described as an attempt to determine what might be called the "available" mineral matter in soils commended itself to the committee. An immense mass of work had been done on the subject, chiefly in America, since the publication of the paper in which the process was described. Solvents of all kinds had been tried—weak hydrochloric acid, weak nitric acid, weak oxalic acid, and various saline solutions. It was, however, probably not very material what weak acid solvent was used; the process must of necessity be a very arbitrary one, and, as far as he had been able to understand the American results, the citric acid process seemed to act as well as any other.

Dr. C. M. Luxmoore said that the chief object of the committee had been to deal with the question of soil analyses in connection with field experiments. The greater part of the work of soil analyses with which he had been connected at Reading was of a more thorough nature, and he thought that this would make some difference in regard to the question of depth. In the case of the soils (chiefly from the county of Dorset) which had recently been examined, a process had been adopted which probably would not always be practicable in the case of field experiments. Each sample was taken in three boxes, and displayed a section of the soil to a depth of 18 inches from the surface, so that the division could be made wherever seemed to be right. He had endeavoured, as far as possible, to insure that the surface soil should always be arbitrarily taken at some multiple of 3 inches. The advantage of this was that, if the surface soil actually analysed were taken down to, say, 6 inches, and then certain determinations were made in the soil from the lower depths, it was easy to calculate with considerable approximation the percentage composition of the first 9 inches of soil for purposes of comparison, even though the first 9 inches had not actually been analysed. If only one sample were taken to a certain depth, he thought it best to adhere, where possible, to the first 9 inches. Sir Henry Gilbert had expressed to him also the views referred to by Dr. Dyer, but he could not help thinking that the immense amount of work already done on 9-inch samples was a very strong argument against changing except for some definite reason. It was, however, provided in the report of the committee that any well-defined line of demarcation should be observed. With regard to the question of sieves, he would point out that the Rothamsted determinations made in the soil which passed through a ¼-inch sieve were not very much affected by that circumstance, because most of them had been determinations of nitrogen, and the nitrogen in the small stones or gravel introduced by this sieve was a small factor and more or less constant, the gravel being present in very similar proportion in the different plots. The questions of evaporation to dryness and of the use of the molybdate process were among the matters which had been deliberately left out of the report as being matters of analytical practice. It was the custom at Reading to take the hydrochloric acid solution and filter it right away; the insoluble residue was washed, dried, ignited, and weighed; and the filtrate evaporated to dryness and the residue redissolved. It seemed to be important that the solution should be filtered before being evaporated

to dryness. Evaporation to dryness before filtration has an irregular effect on the dissolution of the soil constituents, and this leads to a want of concordance in the results. In the course of evaporation of the filtered liquid to dryness it was easy to add a little nitric acid to destroy any organic matter. The phosphoric acid was always determined in a solution obtained from the precipitate given by ammonia, so that practically the chlorine was eliminated in that way. The ammonia precipitate, which included iron oxide, alumina, and phosphoric acid, was dissolved, an aliquot portion of the solution taken, and the phosphoric acid determined in it. The only serious objection which Dr. Dyer had taken to the recommendations of the committee was in regard to a point on which Mr. Hall and he (the speaker) felt very strongly, namely, the calculation of the results on the air-dried soil. At first sight it seemed as though drying in the water-oven was the more convenient basis to work upon, but he was disposed to doubt that. In one sense it was definite, but really the temperature of a water-oven, say 95° C., was perfectly arbitrary, as all soils lost further quantities of water on heating to a higher temperature. The air-dry condition seemed the more natural one to take as a basis, and therefore the only question was whether the air-dry soil was sufficiently definite. Of course, the soil gained and lost moisture day by day as it was exposed to the air, according to the temperature and the state of the atmosphere; but the variations were not at all considerable. Within the moderate limits of indoor temperature and of indoor atmospheric conditions as to moisture, they did not amount to more than about 1 per cent., which, calculated on the constituents of most importance, was comparable with the kind of error that could not possibly be avoided, namely, experimental error. He was not, of course, speaking of the difference between air-dried soil and soil dried at 100° C., but of the variations in air-dried soil itself depending upon the temperature indoors, which variations, as before stated, were not very great. In the case of the air-dried soil the analytical results would include the percentage of moisture, which was a rather useful item, as indicating the kind of soil that had to be dealt with.

Mr. EMBREY said that the author seemed not to have mentioned some important points in connection with what might be called the rough analysis of soils, such as the method of washing (which was by no means uniform), to estimate the fine sand and clay. He thought that in most parts of England it would be practically useless to adhere to a depth of 9 inches, the depth of the plough rarely exceeding 5 inches. In his own county (Gloucester) 7 inches was the greatest depth to which it was worth while going for any practical purpose. Any difficulty in this direction, however, might perhaps be got over by always stating the depth of soil taken. With regard to the calculation of results on the air-dried soil, in the case of some heavy soils that were very wet it might be a week before they were ready for analysis, while, on the other hand, a light soil might be ready in two or three days, and the question would arise as to how the time should be fixed when the calculation was to be made, a matter which would seem to be exceedingly difficult of determination.

Mr. HALL said that the point of most importance was perhaps that of depth. He could really only add to what had been said by Dr. Luxmoore, and had been indicated in the paper, that above all things the matter was one to be decided by each particular worker. When one was really seriously engaged upon the work of soil

analysis, taking one's own samples, it was sometimes necessary to take two or three samples from the same place at different depths if any trustworthy opinion was to be pronounced. But in cases where it was only possible to send instructions for taking a sample it was necessary to fix a depth. In his experience there existed a large number of soils (including some of the best soils in the country) showing no line of demarcation; and the committee wished rather to indicate that, if there was no guiding line to make one take any other depth, 9 inches should be taken. But, of course, any natural feature that might exist should not be disregarded. Certainly he agreed with Dr. Luxmoore that they did not wish to make any recommendations in regard to the determination of phosphoric acid and to the question of evaporation to dryness, which were essentially points for the analyst himself, who would recognise the necessity for getting rid of the silica and organic matter, but should be left to himself to decide as to the means of doing it. The committee had made a number of determinations to ascertain what were the variations in the weight of air-dried soil. A sample of soil was laid out on a table and weighed day after day under varying conditions; and, as Dr. Luxmoore had said, the widest variation was rarely as much as 1 per cent., which, on the final proportion of phosphoric acid, potash, or other constituent of importance, became negligable. He quite agreed with Dr. Luxmoore in regarding the air-dried soil as a more fixed entity than the soil dried at 100° C., or rather, at something between 95° and 100°, the temperature of the water-bath. If the temperature of drying were varied between 95° and 110°, it was possible to dry off varying quantities of moisture; and there was really no line of demarcation that could be drawn between water of combination and moisture that was merely mechanically retained, though he thought that the figure obtained for moisture in the air-dried soil was of some utility. Reference had been made to the question of mechanical analysis, but, speaking frankly, the committee had considered that point and had shirked it. There existed, so to speak, two diametrically opposed schools of procedure amongst mechanical analysts, the separation of the particles being effected in the one case by a current of moving water, and in the other case by decantation by the time factor; and he did not think, from his own reading, that the two were yet in line. Work was being done on this point by some of the members of the committee, but they were agreed that the time had not arrived for any joint recommendations.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

On the Instability of the Total Solids of Milk, and the Value of their Determination in Milk Analysis. A. Reinsch and H. Lührig. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 521-531.)—The author refers to the fact pointed out by Vieth and others that from the time of milking the proportion of the total solids of milk undergoes a constant diminution. This diminution, he finds, is not accompanied by any decrease in the specific gravity of the milk, and he consequently infers that it must be due to the production and loss of volatile bodies during the processes of evaporation and drying, a view which finds confirmation in the fact that, on distilling milk which has been kept, volatile acids and other bodies are found in the distillate. The author shows, however, that if the total solids be determined by calculation from the specific gravity and the percentage of fat by Fleischmann's formula, then the result is accurate up to the time of curdling, since neither of these factors is liable to material alteration during this time.

Referring to the question of the determination of the specific gravity of milk serum as a means for the detection of added water, the author observes that in the summer months samples frequently reach the analyst in a curdled condition, rendering only an approximate determination of the fat possible, and that in such cases the specific gravity of the serum forms the only reliable indication. From a series of experiments made at different times of year, the author concludes that no sufficient change takes place in the serum within three days from the time of curdling to affect the accuracy of such deductions. H. H. B. S.

The Detection of Abrastol in Wine. A. Sanna Pintus. (*Staz. Speriment. Agrar. Ital.*, 1900, xxxiii., 274-277.)—Abrastol, or asaprol-etrasol, is the calcium salt of β-naphthol-β_3-sulphonic acid, and is used as a clarifier and antiseptic in wines. It is a white, inodorous neutral powder, with a bitter taste, and is soluble in water and alcohol, but not in ether.

To detect it, the author decolorizes a few c.c. of the wine with animal charcoal in the cold, and adds an equal volume of a solution of mercuric nitrate containing nitrous acid. An immediate yellow coloration, with a golden fluorescence, is obtained in the presence of abrastol; on exposure to the air for a few minutes the colour changes to rose. Since part of the abrastol is retained by the animal charcoal, an excess of the latter must be avoided. Usually 2 grammes will be found sufficient to decolorize 10 c.c. of wine. In the case of white wines, with which no treatment with charcoal is required, the test is capable of detecting 0·01 per cent. of the antiseptic.

The reagent is prepared by dissolving 100 grammes of mercury in 97 c.c. of nitric acid (42° Bé), and adding 35 c.c. of water to the solution. C. A. M.

ORGANIC ANALYSIS.

On the Separation of Oleic Acid from other Unsaturated Acids. K. Farnsteiner. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 537-539.)—The author takes exception to Lewkowitsch's criticism of his method for the separation of oleic acid as barium oleate (ANALYST, 1900, xxv., 64), on the grounds that Lewkowitsch's experiments were not made with pure oleic acid, and that the details necessary to render them exact and scientific are wanting. Referring to Table II. in Lewkowitsch's paper, he remarks that it is not clear whether the figures denote the quantities of the barium salt dissolved in percentages of the whole, or whether they refer to the quantity of the barium salt contained in 100 parts of the benzene solution. H. H. B. S.

Determination of Carbonates and Alkali (Free and Total) in Soap. R. Henriques and O. Mayer. (*Zeits. angew. Chem.*, 1900, 785.)—The author determines the carbon dioxide gravimetrically, using an excess of $\frac{N}{2}$ hydrochloric acid. The residue is then raised to the boil, the fatty acids filtered off, and washed till neutral. The aqueous liquid is titrated with seminormal soda to give the total alkali; the fatty acids are dissolved in warm alcohol and titrated with alcoholic seminormal alkali to give the combined alkali. If, however, the soap has been made with oils containing fatty acids soluble in hot water, the foregoing process becomes more or less inexact. In this case the total acids and the true soap must be determined separately by decomposing the sample in a stoppered funnel with hydrochloric acid, extracting the fatty acids with ether, washing them, titrating with alcoholic alkali, and weighing the soap so reproduced. F. H. L.

The Composition of Jasmine Oil. Jeancard and Satie. (*Bull. Soc. Chim.*, 1900, xxiii., 556, 557.)—Referring to the investigations of Verley and of Hesse and Müller (ANALYST, xxv., 46), the authors point out that most chemists studying this oil have extracted it from the pomade, and that their results are therefore liable to error, for the lard or beef-fat forming the basis of the pomade is prepared by being heated with jasmine water, and sometimes with rose water and neroli water, and is preserved by an addition of benzoin or alum.

Thus, the authors have found in a kilo of jasmine pomade 0·05 gramme of benzoin, 0·25 gramme of neroli oil, and 3·0 grammes of jasmine oil. On extracting the pomade with the usual solvents, foreign substances are dissolved to a considerable extent, and may compose about 11 per cent. of the oil finally obtained.

In order to obviate this, they have extracted the oil by *enfleurage* in the usual manner, but substituting untreated vaseline for the prepared fat.

Two samples thus obtained gave the following results:

	Specific Gravity at 17·5° C.	Rotatory Power $l=20$ millimetres.	Saponification Value.	Esters as Linalyl Acetate.	Esters as Benzyl Acetate
I.	0·9099	+0° 30′	103·6	36·26	27·70
II.	0·9201	+0° 32′	120·0	44·10	33·75

Two oils obtained by distillation of the flowers in a current of steam were also examined, Sample III. being prepared directly from the flowers, and IV. distilled from the residue left from the *enfleurage*.

	Specific Gravity at 17·5° C.	Rotation $l = 100$ millimetres.	Saponification Value.	Esters as Linalyl Acetate.	Esters as Benzyl Acetate.
III.	0·9246	+1° 40′	155	54·39	41·65
IV.	0·8900	+3° 50′	77	26·95	20·62

C. A. M.

The Examination of Oil of Lemon. G. Fabris. (*Annali del Laboratorio Chim. Cent. delle Gabelle*, 1900, iv., 53-121.)—According to the author, the substances most generally employed to adulterate oil of lemon are turpentine, with oil of orange, to raise the rotatory power of the mixture to that of the normal oil. He gives the following table of the rotation of different samples in a 100-millimetre tube at 20° C.:

	$[\alpha]_D$
Oil of turpentine, French	−20°
,, ,, common	−5° 30′
,, ,, American	+4° 30′
Oil of lemon, distilled	+52° 15′
Lemon terpenes, distilled in laboratory from pure oil ...	+60° 40′
Terpenes of Messina lemons	+55° 50′
Limonene (Schimmel and Co.)	+102° 4′
Oil of orange	+97° 10′
Oil of lemon, pure	+60° 42′

From a long series of experiments with mixtures of these substances the author has arrived at the conclusion that there is no method in existence capable of detecting every extraneous addition to oil of lemon; although in his opinion the best means of detecting the most common and probable form of adulteration is the method of fractional distillation as described by Schimmel and Co. (*Report*, October to November, 1896), and that of Soldaini and Bertè (ANALYST, xxv., 104). He considers that whilst these methods only give vague indications as to the nature and amount of foreign substances added to the oil, and cannot detect oil of turpentine in small proportion, or lemon terpenes if not added in large excess, yet that they are capable of detecting 5 per cent. of oil of turpentine (or less of lævorotatory turpentine), and the presence or absence of oil of orange can be inferred from the rotation of the distillation residue.

Other analytical tests, such as the determination of different physical and chemical constants, and various colour reactions, are, in his experience, less sensitive, though they should not be omitted. Of the colour-tests the following are specially recommended:

The Guaiacum Test.—In this test (Hager, *Seif. Oel. u. Fette*, 1898, 179) a pinch of powdered guaiacum resin is placed in a test-tube, into which are then introduced 5 or 6 c.c. of alcohol and 0·5 c.c. of the oil of lemon; or better, 0·2 gramme of

guaiacum resin is dissolved in 100 c.c. of alcohol (about 95 per cent.), and 6 or 8 c.c. of a solution containing 0·5 c.c. of the oil added. On boiling the contents of the tube for a moment, the liquid assumes a brown tint, which soon changes to violet in the case of pure lemon oil. With oil of turpentine a pronounced violet is observed. When left for fifteen minutes and then diluted with 10 c.c. of alcohol, the liquid containing oil of lemon becomes faint brown; with turpentine it assumes an intense blue colour; and with a mixture a faint but distinct blue tint. A comparative test should be made with an oil of lemon of known purity.

The author states that old or badly kept lemon oil tends to give a blue colour, and that French turpentine oil reacts much more rapidly than American turpentine.

Oil of orange does not give any coloration with guaiacum resin.

Potassium Iodide Test (Marpmann).—When turpentine is dropped on to a crystal of potassium iodide, a black coloration is obtained after some time, whilst lemon oil gives a yellow colour, and mixtures a brown shade. According to the author, a mixture containing less than 5 per cent. of turpentine does not differ materially from pure oil of lemon as regards the colour produced.

Amyl Nitrite Test.—Two c.c. of the oil are treated with 6 to 8 c.c. of 96 per cent. alcohol, and after the introduction of 10 or 12 drops of ethyl or amyl nitrite, and 2 or 3 drops of hydrochloric acid (specific gravity, 1·17) the liquid is boiled for an instant and then left to cool. With lemon oil a yellow or orange colour is obtained; with turpentine a rose to blood-red colour; and with mixtures a rose coloration varying in shade with the proportion of turpentine. The author found that a mixture containing 2 per cent. of French turpentine oil gave a marked rose colour, but that in the case of American turpentine the test was not sensitive for less than 5 per cent.

C. A. M.

The Composition and Analysis of Oil of Bergamot. G. Fabris. (*Annali del Laboratorio Chim. Cent. delle Gabelle*, 1900, iv., 123-136.)—This oil is expressed almost exclusively in the province of Reggio Calabria, near the coast, the machinery used being of the most primitive type. The yield of oil varies with the season, locality, and maturity of the fruit, but in the mean 1,500 bergamots are required to produce 1 kilo. of the oil. The best and most valuable oil is that obtained from the ripe fruit in January. The oil which separates from the pressed liquid has a more or less pronounced yellowish-green colour, whilst that recovered from the aqueous part of the pressings is light yellow, and has a special odour due to the heat.

The oil expressed from unripe or damaged fruit which has fallen from the trees is known as *Nero of Bergamot.* It has a brownish-green colour and an odour which is not very fragrant.

The principal constituents of bergamot oil are terpenes (among which have been identified limonene and bergaptene) and linalyl acetate. The specific gravity of the pure oil varies from 0·882 to 0·886 at 15° C., according to Schimmel and Co. (*Report*, 1896, ANALYST, xxiii., 13), but according to Campolo (*Staz. Sper. Agrar. Ital.*, 1895, xxviii., 433) it should be 0·887. The rotatory power in a 100 millimetre tube at 15° to 20° C. varies from +8° to 20°. When distilled by Soldaini and Bertè's method (ANALYST, xxiv., 50; xxv., 104), it boils at 74° C. to 120° C. under a pressure

of 20 to 30 millimetres, and the rotatory power of the successive fractions diminishes from right to left. The residue (about 7 per cent.) is a semi-solid mass.

The amount of linalyl acetate is variable. Schimmel and Co. give 34 to 48 per cent., with a mean of 33 per cent.; Helbing and Passmore 42·4 per cent.; and Campolo (*loc. cit.*) 37·57 to 39·87. It is usually accepted that a good oil should contain about 39 per cent. (*cf.* Bornträger, ANALYST, xxi., 137; and xxii., 41).

The amount of esters varies with the kind of season, locality, and maturity of the fruit. Thus, the oil from green bergamots was found to contain 31 per cent., that from half-ripe fruit 33·2 per cent., and that from over-ripe fruit 37·7 per cent. (Schimmel and Co.'s Report, April, 1896; *cf.* Charabot, *Comptes Rend.* cxxix., 728).

Nero of bergamot and distilled oil are much poorer in esters than good expressed oil, the first containing only 23 to 25 per cent., and the second 12 per cent. as the maximum.

Seven specimens of good oil examined by the author gave the following results: Specific gravity at 15° C., 0·8860—0·8870; rotation at 20° C., +11° 35′ to +15°; linalyl acetate, 34·10 to 41·00 per cent.; residue on evaporation 4·0 to 5·55 per cent., containing 1·05 to 2·05 per cent. of linalyl acetate. All were soluble in 90 per cent. alcohol.

A sample of distilled oil showed on analysis: Specific gravity at 15° C., 0·8700; rotation at 20° C., 30° 15′; linalyl acetate, 10·15 per cent.; residue on evaporation 1·45 per cent.; linalyl acetate in residue 0·50 per cent.

With a sample of Nero of bergamot the corresponding figures were: Specific gravity, 0·885; rotation at 20° C., +9° 30′; linalyl acetate, 25·50 per cent.; residue on evaporation 2·70 per cent.; and linalyl acetate in residue 1·75 per cent.

The substances used to adulterate bergamot oil are very numerous, and include fatty oils, resins, Canada and Gurjun balsams, turpentine, oils of lemon, orange, and cedar-wood, and the distillation products of bergamot oil itself.

Of these, fatty oils, resins, and balsams increase the specific gravity and residue on evaporation. Resins, especially colophony, increase the proportion of esters and the acidity of the oil, normal bergamot oil being only very slightly acid. The residue of a pure oil on evaporation should not exceed 6 per cent. Fixed oils and resins will be indicated by the saponification value of the residue, and the former, with the exception of castor-oil, by the solubility-in-alcohol test.

The author shows by the figures obtained with experimental mixtures that 15 per cent. of turpentine can be added to bergamot oil without causing the constants to deviate to any extent from their normal limits. Soldaini and Bertè's method of fractional distillation affords a valuable criterion, but even with it a notable quantity of dextro-rotatory turpentine may escape detection.

Oil of lemon and oil of orange increase the rotatory power and diminish the specific gravity, quantity of esters, and residue left on evaporation. Indications of such an addition will be furnished by Soldaini and Bertè's method of fractional distillation. Pure bergamot oil, unlike orange and lemon oil, gives no coloration with Schiff's reagent (absence of aldehydes). Moreover, on testing 2 or 3 c.c. of pure oil of bergamot in 10 to 15 c.c. of absolute alcohol, with a small quantity of metaphenylenediamine hydrochloride, the liquid does not change colour, or only

becomes slightly yellow; if, however, oil of lemon be present, a deep yellow or brown colour is produced. A comparative test should be made with bergamot oil of known purity.

An addition of the distillation products of bergamot oil lower the specific gravity, the percentage of esters, and the residue on evaporation. In the author's opinion, however, they can be added in considerable quantity without materially changing the characteristic properties of a pure oil. C. A. M.

The Causes of the Variation in the Amount of Esters in Oil of Lavender. Jeancard and Satie. (*Bull. Soc. Chim.*, 1900, xxiii., 549-554.)—As the commercial value of lavender oil depends upon the amount of esters it contains, the authors have examined a large number of samples in order to determine what influence the altitude, the maturity of the plant, and the process of distillation have on the composition of the oil.

Eleven samples of oil were prepared from flowers gathered in the same district, at the same time, and under the same conditions, but at different altitudes, varying from 1,000 to 1,800 metres. From the results the authors conclude that the altitude has no influence on the physical properties of the oil.

The oil extracted from the flowers only was found to be far superior to that obtained from the leaves and stems. The comparative analytical results were:

	Yield per 1,000 Kilos.	Specific Gravity at 26° C.	Rotation at 26° C., 100 m.m.	Esters, per cent.	Soluble in 70 per cent. Alcohol.
Oil from leaves and stems	0·500 k.	0·8850	− 7° 12′	41·65	2·4
Oil from flowers	1·985	0·8814	− 6° 40′	39·44	2·4

As regards the influence of the method of extraction, the authors show that if the distillation be too rapid the whole of the esters are not obtained. Moreover, during the distillation there is a partial saponification of the esters, which are reduced from, say, 39 to 35·5 per cent. In order to determine the conditions of this saponification, lavender oil was boiled with twenty times its weight of distilled water (this being about the proportion used in actual practice) under a reflux condenser, and the percentage of esters determined from hour to hour. It was found that the loss of esters from saponification amounts at first to about 2 per cent. per hour, but gradually diminishes towards a point of equilibrium where the saponification is compensated by an equal acetylation.

The amount of saponification is proportionately increased by the presence of carbonates in the water. C. A. M.

The Estimation of Carvol. H. Labbé. (*Bull. Soc. Chim.*, 1900, xxiii., 280-286.)—For the determination of carvol in the presence of limonene and other hydrocarbons which normally accompany it, the author describes two methods. These are based upon the facts that carvol readily forms a dihydrogen disulphonate which is soluble in a solution of bisulphite, whilst limonene is not soluble to any appreciable extent in a boiling solution of sodium bisulphite, nor does its presence interfere with the carvol reaction.

I. Five grammes of the mixture are boiled under a reflux condenser with about 15 grammes of sodium bisulphite and some sodium carbonate. After about an hour and a half the contents of the flask are cooled, and the supernatant oil extracted with anhydrous ether, the neck of the flask and the condenser being washed with the same solvent. The ethereal extract is separated, dried over anhydrous sodium sulphate, and filtered into a small weighed flask fitted with a tube 15 centimetres in length to act as a condenser. After the greater part of the ether has been evaporated under reduced pressure, the last traces are removed by warming the flask. The weight of the residue subtracted from the weight of the mixture taken gives the quantity of the carvol.

The following experiment may be quoted in illustration of the accuracy of the method: Taken limonene, 4 grammes (80 per cent.); carvol, 1 gramme (20 per cent.). Found limonene, 3·976 grammes (79·52 per cent.).

In one experiment, in which the mixture was boiled for five hours, the amount of limonene was 2 per cent. too low. Under the conditions mentioned above, the error, which is invariably less than 1 per cent., is attributed to an inevitable loss of limonene in the manipulation.

II. From 1 to 1·5 gramme of carvol were boiled with 10 c.c. of a standardized solution of sodium bisulphite containing 0·2 to 0·3 gramme per c.c. The sulphur dioxide liberated in the reaction was collected in a slightly alkaline solution, which was subsequently titrated with a standard solution of iodine. The residue in the flask was also titrated, and the total amount of sulphur dioxide found was deducted from that in the sodium sulphite originally taken. The amount of sulphur dioxide taken up by the carvol was calculated into carvol by using the formula $C_{10}H_{14}O(SO_3NaH)_2$ for the dihydrogen disulphonate.

In this test experiment the quantity of carvol found was 100·3 per cent. In another commercial sample the carvol amounted to 96·9 per cent. C. A. M.

Estimation of Metacresol in Presence of its Isomers. F. Raschig. (*Zeits. angew. Chem.*, 1900, 759.)—"Cresylite," a product made by nitrating cresol, has been used for years as a substitute for "lyddite," etc., in the manufacture of explosive shells. This substance consists of trinitro-*m*-cresol; for when a mixture of the three cresols is treated with hot nitric acid, only the meta-compound is nitrated, the others being oxidized to oxalic acid. In the preparation of cresylite, therefore, *o*- and *p*-cresol cause a waste of acid, and accordingly, to the manufacturer, the mixture is the more valuable the higher the percentage of *m*-cresol it contains. The author's process is based on the above reaction with nitric acid. Exactly 10 grammes of the sample, which should distil between 190° and 200° C., are weighed out into a small flask, mixed with 15 c.c. of sulphuric acid of 66° Beaumé, and placed for an hour in a steam-heated oven. The product is then poured into a wide-necked flask which holds at least 1 litre, and is made to form a thin coating on the walls of the vessel by rotating it under a cold-water tap. Into the sulphonating flask are next brought 90 c.c. of nitric acid, 40° Beaumé, and by agitation the residue of sulphonic acids is dissolved. The solution is then poured quickly into the large flask, and the whole is

shaken thoroughly for about twenty seconds till the sulphonated cresols have dissolved. The vessel is placed in a draught cupboard until the reaction is finished; the liquid becomes turbid and clear again, when oily drops of trinitrocresol separate. After waiting five minutes, the mass is poured into 40 c.c. of water contained in a basin, and the flask rinsed with the same volume of water. The whole is set aside for at least two hours till quite cold, the solid matter broken up with a rod, and filtered with the pump. The precipitate is washed with 100 c.c. of water, dried on the paper at 95° to 100° C., and weighed. It is most important not to decrease the quantity of nitric acid prescribed, to add it rapidly and all at once to the sulphonic acids; to use a large flask for the nitration, and to see that the neck is sufficiently wide.

The process is accurate within 1 per cent. in the presence of either or both *o*- and *p*-cresol, yielding 174 per cent. of trinitro-*m*-cresol. The presence of 10 per cent. of phenol does not affect the results, for the picric acid remains in solution. A larger proportion of phenol is not likely to be met with commercially, but it would be shown by a lower boiling-point of the original sample, or by the nitro-derivative softening or melting when heated to 95° C. Xylenols would also cause the nitro-product to melt on warming or to remain liquid on cooling. F. H. L.

The Tragacanth Method of assaying Alkaloids. J. B. Nagelvoort. (*Amer. Journ. Pharm.*, 1900, lxxii., 270-272.)—This method is slightly modified from the original one of Rusting, and is recommended for the rapid and accurate assay of fluid extracts. Three grammes of the extract are mixed with 5 c.c. of water in a small dish and the alcohol evaporated. The residue is transferred to a 100 c.c. flask, 60 c.c. of ether added, and the solution rendered alkaline. A 5 or 10 per cent. solution of sodium hydroxide is next introduced in successive small quantities, care being taken to avoid having an excess of alkali. The flask is then well shaken for about a minute, 2 grammes of powdered tragacanth introduced, and the contents again shaken. After standing for some time, 40 c.c. of the clear supernatant liquid are transferred to an Erlenmeyer flask of known weight, the ether distilled, and the residue dried at 50° C. with the aid of a current of air supplied by a rubber "spray" ball.

For the assay of quinine tannate 1·5 grammes are mixed with a little water, 75 c.c. of ether introduced, the liquid made alkaline with sodium hydroxide, shaken with tragacanth as above, and 50 c.c. of the supernatant liquid evaporated.

Fluid Extract of Hydrastis.—This is assayed by diluting 10 grammes with 20 c.c. of water in an Erlenmeyer flask, and slowly evaporating down to less than 20 grammes. The liquid is then cooled, made up to 20 grammes in weight, shaken with some kieselguhr, and filtered. Ten grammes of the filtrate are transferred to a flask, 25 c.c. of ether added, and afterwards 3 c.c. of 10 per cent. ammonium hydroxide, and the whole well shaken. The shaking is repeated after the addition of 25 c.c. of petroleum spirit, and, lastly, 2 grammes of powdered tragacanth are introduced and the contents of the flask shaken once more and left to settle.

Forty c.c. (= 4 grammes of fluid extract) of the clear liquid are removed, and the

ether evaporated by rotating the flask in water at 30° to 35° C. for a few minutes. The flask is then cooled, well corked, and placed in a freezing mixture for the hydrastine to crystallize out. The supernatant liquid is decanted, and the crystals dried and weighed in the usual manner. C. A. M.

The Detection of Urobilin in Urine. T. Roman and G. Delluc. (*Journ. Pharm. Chim.*, 1900, xii., 49, 50.)—The ordinary test with an alcoholic solution of a zinc salt may be simplified in the following manner: 100 c.c. of the urine are acidified with 8 to 10 drops of hydrochloric acid and shaken with 20 c.c. of chloroform. After separation of the liquids, about 2 c.c. of the chloroform layer are tested with 4 c.c. of a solution of 1 gramme of crystallized zinc acetate in a litre of 95 per cent. alcohol. At the junction of the two layers the green fluorescent ring characteristic of urobilin will appear, and on shaking, the fluorescence, which is rose-coloured by refracted light, will be distributed throughout the liquid.

It was found that certain commercial alcohols produced the fluorescence without any addition of a zinc salt, but this was proved to be due to the presence of traces of zinc probably derived from the vessels in which the alcohols were rectified.

C. A. M.

Determination of the Softening Point of Pitch. J. Klimont. (*Zeits. angew. Chem.*, 1900, 761.)—Schenk has described a process according to which powdered pitch is put into a tube and a drop of mercury brought on to the surface. The whole is warmed, and the temperature at which the pitch swells is called the melting-point, while the temperature at which the mercury sinks into the pitch is called the liquefying-point. The test requires some experience to carry out successfully, for the powder coats the drop of mercury, and prevents the operator seeing it. The two following methods are better: Finely-powdered pitch is run into a test-tube through a long funnel until, after consolidation by tapping on the bench, the hemispherical bottom is just full. The tube is fastened to a thermometer and brought into a water-bath (a glycerin-bath if the sample is "hard"). The liquid is warmed slowly with a 2 centimetre flame. The softening-point is taken when the dust on the walls of the tube agglomerates into minute drops, the liquefying-point when the whole surface of the pitch becomes smooth and brilliant. In the other process some of the sample is softened and kneaded into a little rod 5 millimetres long and 3 millimetres in diameter. This is held with tongs, one point melted, inserted into a test-tube, and made to adhere to the bottom, so that it stands up vertically. The tube is filled with mercury till the rod is just covered, placed in a water- or glycerin-bath and warmed gently. Directly the rod rises and shows a black spot on the mercury the softening-point is read off; when the point broadens and becomes a drop the liquefying-point is noted. All three processes yield practically identical figures.

F. H. L.

INORGANIC ANALYSIS.

Electrolytic Determination of Lead. C. Marie. (*Bull. Soc. Chim.*, 1900, xxiii., 563, 564.)—The principal methods of separating lead are based on its precipitation as sulphate or sulphide, and the latter is converted into sulphate by treatment with nitric acid.

Lead sulphate is soluble in nitric acid containing ammonium nitrate, and the solution for electrolysis is prepared in the following manner: The sulphate is placed in the vessel of Bohemian glass in which the electrolysis is to be carried out, and heated on the water-bath with nitric acid, to which a few crystals of ammonium nitrate are added. When the sulphate has been completely dissolved, the solution is diluted with hot water and electrolysed in the usual manner at a temperature of 60° to 70° C. About 5 grammes of ammonium nitrate are required to dissolve 0·3 gramme of lead sulphate, and the nitric acid should be used in such proportion that the liquid after dilution contains 10 per cent. of free acid. With an electrode of roughened platinum, 90 sq. c.m. area, and a current of 0·3 A, 0·4 gramme of lead dioxide should be deposited in three hours.

The method can also be used in the analysis of glass containing lead; the finely powdered glass being treated with hydrofluoric acid and sufficient sulphuric acid to convert the bases into sulphates, and the lead sulphate dissolved as described above.

C. A. M.

The Determination of Arsenic in Metals and Alloys. A. Hollard and L. Bertiaux. (*Bull. Soc. Chim.*, 1900, xxiii., 300-302.)—The advantages claimed by the author for the following method are that it can be employed in the presence of antimony, that it is very rapid, and that only one distillation is necessary.

The arsenic chloride which distils over on boiling 5 grammes of the sample with 50 grammes of ferrous sulphate and 150 c.c. of hydrochloric acid is conducted through a U-tube containing some glass balls, heated to a temperature of 150° to 175° C. in an oil-bath, and collected in a cylinder containing 50 c.c. of water. Any antimony present remains in the distillation flask or the U-tube. The distillation is stopped as soon as 35 c.c. of liquid have passed over, and the cooled distillate titrated with a standard solution of iodine.

C. A. M.

The Analysis of Chrome and Tungsten Steels. A. G. M'Kenna. (*Proc. Engin. Soc. of West. Pennsylvania*, 1900, 119.)

Sulphur.—Five grammes are rapidly dissolved in hydrochloric acid, and the evolved gases are passed into an ammoniacal cadmium chloride solution, the last traces of gas being expelled by boiling. The sulphur is then determined by titration with iodine.

Silica and Tungsten.—The iron solution from the above is evaporated to dryness first with nitric acid and again with hydrochloric. The solid mass is then dissolved in hydrochloric acid, and the silica and tungstic acid filtered off, washed, ignited in a platinum crucible, and weighed. A few drops of hydrofluoric acid are now added, and the crucible is heated to bright redness for five minutes to volatilize silica. The

residue is WO_3, but may contain a little iron, which must be determined by fusing with sodium carbonate, dissolving in water, and filtering off the iron precipitate and weighing in the usual way.

Manganese.—The filtrate from the above is evaporated to small bulk, 50 c.c. of concentrated nitric acid are added, and the solution is boiled till all the hydrochloric acid has been removed. It is then made up to 200 c.c. with concentrated nitric acid and heated to boiling, 10 grammes of potassium chlorate are added, and the solution is boiled down to 75 c.c. The manganese is thus entirely precipitated as MnO_2. This is filtered on an asbestos plug whilst hot, and washed a few times with freshly-boiled concentrated nitric acid. It is redissolved in hydrochloric acid with a little potassium nitrite, the solution is freed from iron by means of ammonia, and the manganese is precipitated with bromine and weighed as Mn_3O_4.

Chromium.—The filtrate from the manganese contains the chromium as chromic acid. The filtrate is cooled and diluted to about 500 c.c. Excess of standard ferrous sulphate solution is then added and titrated back with permanganate.

Phosphorus.—A weighed portion of steel is dissolved in nitric acid with the addition of hydrochloric acid. The solution is evaporated to dryness, ignited, taken up again with hydrochloric acid. The silicon and tungsten are filtered off, 35 c.c. of strong ammonia are added, then a slight excess of nitric acid, finally 100 c.c. of molybdate solution. The flask is well shaken, allowed to stand an hour. The precipitate is then filtered on to a tared filter, washed with 1 per cent. nitric acid, dried for an hour and weighed. The phospho-molybdate contains 1·63 per cent. phosphorus.

Carbon.—The carbon is separated by means of chloride of copper and potassium. It is burnt in oxygen, the carbon dioxide is absorbed in barium hydrate solution, and the barium carbonate is filtered off and weighed. A. M.

A Rapid Method for the Determination of Carbon in Iron or Steel by Combustion. G. W. Sargent. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 277.)—The combustions are performed in a porcelain tube heated in a three-burner furnace. This is not allowed to cool between two determinations; as soon as one is completed, the platinum boat is removed and another containing a fresh carbon residue inserted in its place. The products of combustion are passed first through moist sand, to retain hydrochloric acid or chlorine, next through a red-hot copper tube containing copper oxide, then through a spiral immersed in water to cool the gas, and finally through 6 inches of dehydrated calcium chloride. The carbon dioxide is then absorbed in potash bulbs as usual. The air and oxygen used are first purified by passing through a red-hot copper or platinum spiral, next through potash bulbs, then through an empty tube, and finally into the porcelain tube. The ends of this spiral, as also of the copper tube, are kept cool by means of a current of water circulating round them. The combustion is performed for the first ten minutes with oxygen at the rate of 4½ bubbles per second, then for further ten minutes with air at 5 bubbles per second. The combustion is then complete, and a fresh one is at once started. Twenty-five combustions per day can thus be done in one apparatus. A. M.

On the Analysis of Chrome-Iron Ore by the Borax Method. R. W. Emerson MacIvor. (*Chem. News*, lxxxii., 97.)—This note is occasioned by the publication of R. Fieber's paper on "A Simple Method of decomposing Chromite" (*Chem. Zeit.*, xxxiv., 333, and *Amer. Journ. Sci.*, 1900, x., 55), in which the following method is described: 0·5 gramme of the ore is fused in a platinum crucible with 3 grammes of sodium potassium carbonate for ten minutes; when cold, 3 grammes of borax are added, and the whole again fused, at first over a Teclu burner, then for forty-five minutes over the blow-pipe. If decomposition is incomplete, more of the mixed carbonate is added, and the fusion repeated. This process does not materially differ from that given in fairly old text-books, and leaves uncertain how many fusions are necessary to decompose the ore. A process used by Professor Dittmar and the author, and further improved by Dittmar alone, does not suffer from this defect, the undecomposed ore rarely exceeding 2 milligrammes per gramme of ore. These small quantities may be assumed to contain 50 to 60 per cent. of Cr_2O_3 without serious error. The outline of the process is as follows: 4 grammes of a flux, composed of equal weights of borax glass and $NaKCO_3$, previously melted together, are fused in a platinum crucible over an Iserlohn lamp, allowed to solidify, and 0·5 gramme of ore added. The covered crucible is then heated till the ore sinks to the bottom, then inclined, the lid being placed horizontally in front, and heated, whilst the contents are stirred with a platinum wire. After half an hour's heating, the melt is allowed to solidify, 2·5 grammes of $NaKCO_3$ added, and the whole again fused. The cold melt is extracted with hot water, alkaline chromate passing into solution. For a complete analysis it is best to work on 1 gramme of ore. A. G. L.

The Determination of Iron in Puddle Slags. L. Blum. (*Zeit. anal. Chem.*, 1900, xxxix., 156, 157.)—The ordinary volumetric methods used for this determination invariably give too high results in the presence of vanadic acid, (a frequent constituent of slags), owing to the fact that vanadic acid is reduced by stannous chloride or nascent hydrogen, and that the vanadium salts are oxidized by potassium permanganate or potassium bichromate.

In order to avoid this source of error and to obtain absolutely reliable results, the author recommends the following method of analysis: The solution of 0·5 gramme of the substance, containing the iron in the form of chloride, is freed from silica, neutralized with ammonium carbonate, and boiled with ammonium acetate. The precipitate is filtered off, dissolved in hydrochloric acid, and reprecipitated, in order to effect a complete separation from manganese. It is again dissolved, tartaric acid added, and made alkaline with ammonium hydroxide. An excess of ammonium sulphide is then added, and the beaker left for some time in a warm place. The vanadium sulphide and any small quantities of phosphoric acid, aluminium or calcium remain in solution.

The precipitated iron sulphide is filtered off, washed with water containing ammonium sulphide, and dissolved in dilute hydrochloric acid. The solution is oxidized with nitric acid, any precipitated sulphur separated, and the iron precipitated with ammonium hydroxide, ignited, and weighed as ferric oxide.

Although this method is tedious, the author regards it as the only one applicable to the determination of iron in the presence of vanadium and manganese.

C. A. M.

The Estimation of Manganese as Pyrophosphate. W. Böttger. (*Berichte*, 1900, xxxiii., 1019-1022.)—In Autenrieth's modification of Gibbs' method of determining manganese there is a risk of the precipitated salt being oxidized by the atmospheric oxygen, and to obviate this the author recommends the following modification: A quantity of an ammonium salt is added in the proportion of five to ten molecules to each molecule of manganese salt, which must be present in a neutral solution, this is then heated to the boiling-point, and treated with an excess of a solution of di-sodium phosphate. The hydrochloric acid which results from the reaction is neutralized with ammonium hydroxide, and the liquid boiled until the amorphous precipitate of manganese ammonium phosphate becomes crystalline. The precipitate is washed with cold, slightly ammoniacal water, and ignited in a blow-pipe flame or Hempel's oven until free from ammonia.

The results obtained in this way by the author varied from 99·8 to 100·4 per cent. of the theoretical. C. A. M.

The Separation of Nickel and Cobalt. O. F. Tower. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 501.)—The author has made an investigation of the causes of the failure of Villiers' process for the qualitative separation of nickel and cobalt (*Compt. rend.*, cxix., 1263, and cxx., 46). The method as commonly carried out is as follows: The solution of the sulphides of the two metals in *aqua regia* is evaporated to dryness, and after suitable dilution sufficient tartaric acid is added to prevent precipitation by sodium hydroxide. This last reagent is then added until the solution is strongly alkaline, and hydrogen sulphide is added to saturation. Cobalt sulphide is precipitated, while nickel sulphide remains in solution, imparting to the solution a dark colour. When nickel is present only in very small quantities the colour is brown; with larger quantities it is a jet black.

The oxidation of the solution results, however, in the separation of so much sulphur that if nickel is present and cobalt is not, the black solution colours the sulphur, making it very difficult to distinguish it from precipitated cobalt sulphide. Furthermore, according to the process used in this separation, sodium chloride is present in the solution, and although this aids in the complete precipitation of cobalt sulphide, it may cause some nickel sulphide to be precipitated which in the absence of cobalt sulphide may be mistaken for it. A. M.

Determination of Cobalt in Presence of a Large Excess of Nickel. T. Moore. (*Chem. News*, 1900, lxxxii., 73.)—The solution containing the chlorides of the two metals and free from excess of acid is treated, if necessary, with zinc oxide to remove iron, and filtered. The filtrate is diluted to 300 or 400 c.c., 1 drop of hydrochloric acid added, and brought nearly to the boiling point. Bromine water and a moderate excess of zinc oxide are next introduced, the whole boiled for five minutes to expel

the bulk of the bromine, filtered, and the precipitate washed thoroughly. It is then rinsed off the paper into a beaker; the paper is extracted with very weak hydrochloric and sulphurous acids, the solution evaporated to dryness, taken up in a few drops of water, and added to the main precipitate. The latter is well boiled to disintegrate it, allowed to cool, mixed with 5 or 10 c.c. of hydrogen peroxide rendered strongly alkaline with sodium hydroxide, boiled for two or three minutes, and cooled again. It is then digested in a closed bottle with potassium iodide and hydrochloric acid, and the free iodine titrated as already described (*cf.* Abst. in this vol., p. 279).

F. H. L.

On the Separation of Cobalt from Nickel by means of Persulphates. F. Macrow. (*Zeit. Anorg. Chem.*, xxv., 197.)—After the author had completed his work on the action of potassium persulphate on cobalt salts (*Zeit. Anorg. Chem.*, xxiv., 262), the patent of Salomon and Coehn on the separation of cobalt from nickel was published in the *Zeitschrift für Electrochemie* (vi., 43, 532). They state that all persulphates precipitate cobalt quantitatively from solutions of cobalt and nickel salts, and oxidize the cobalt only in a mixture of their hydroxides. As the author had found that potassium persulphate does not completely precipitate cobalt from its salts, and only oxidizes a part of the hydroxide, the other part going into solution, he now repeated his investigations, using a larger excess of persulphate and warming for a longer time, and also studied the action of the persulphate on nickel salts and hydroxide. Potassium persulphate was again the only persulphate used. The same results as before were obtained, no quantitative separation being possible. The precipitation of cobalt from solutions of its salts is not complete, whilst a very small quantity of nickel is also precipitated. If the hydroxides are used, only a part of the $Co(OH)_2$ is oxidized, the other part being dissolved. The same is the case with $Ni(OH)_2$, although this dissolves more easily than the former; on the addition of dilute acids to the oxidized precipitates, cobalt, as well as nickel, is found in solution.

No quantitative determinations were made, the qualitative tests being conclusive. An analysis of the blackish precipitate obtained from $Ni(OH)_2$, after drying over H_2SO_4 and $CaCl_2$, gave results indicating the composition $Ni_3O_4 \cdot 6H_2O$; but the substance retains persulphate, and is not perfectly homogeneous. A. G. L.

Preparation of Potassium Xanthate for Nickel Determinations. E. D. Campbell. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 307.)—In 1895 the author with W. H. Andrews published a method for the determination of nickel in nickel steel (ANALYST, xx., 116). To obtain satisfactory results, the potassium xanthate used must be properly prepared. A weighed amount of fused potassium hydroxide is placed with absolute alcohol (2·5 c.c. per gramme potash) in a tightly-stoppered flask, and digested cold, with occasional shaking, until solution is complete, except for the potassium carbonate present. The solution is poured off, cooled in ice-water, and pure carbon bisulphide added gradually with constant stirring, until 1 c.c. has been added for every gramme of potash. The liquid is kept in ice-water till the temperature is reduced to 10° C. The precipitated xanthate is filtered off, washed once with alcohol and twice with ether, and dried at 100° C. A. M.

Estimation of Selenium and Tellurium. **E. Keller.** (*Journ. Amer. Chem. Soc.*, 1900, xxii., 241.)—The method depends upon the fact that selenium may be entirely precipitated from solution in concentrated hydrochloric acid by means of sulphur dioxide, whereas tellurium is precipitated only when the acid is diluted somewhat.

To determine these elements in a sample of commercial copper, 100 grammes are weighed out, 2 to 4 grammes of ferrous sulphate added, and dissolved in 400 c.c. of nitric acid. The nitrous fumes are expelled, the solution is diluted and cooled, and sufficient ammonia is added to dissolve all the copper. The ferric hydroxide, containing the selenium and tellurium, is filtered off, and freed from copper by redissolving and reprecipitating. It is then dissolved in a minimum of dilute hydrochloric acid, the liquid is cooled, and sulphuretted hydrogen is passed to saturation. The sulphides are filtered and washed, and digested with a solution of sodium sulphide, which takes up the sulphides of selenium and tellurium. The solution, after filtering, is acidified with nitric acid and evaporated to dryness, taking care not to lose any selenium dioxide. Two hundred c.c. of strong hydrochloric acid (specific gravity 1·16) are now added, and the liquid is boiled until all the nitro-hydrochloric acid is destroyed and the two elements are reduced to the selenous and tellurous state. After cooling, the solution is filtered through asbestos, and the filter is washed with strong hydrochloric acid. Sulphur dioxide is then passed through the filtrate. After settling, the selenium is collected on a weighed Gooch filter, and washed with strong hydrochloric acid about three times, then washed successively with warm dilute hydrochloric acid, pure water, and alcohol. After drying, it is weighed.

The filtrate containing the tellurium is diluted with an equal bulk of water, boiled for a few minutes, and sulphur dioxide is passed through at the same time. After cooling and settling, the tellurium is filtered, washed, and weighed in the same manner as the selenium. A. M.

The Colorimetric Estimation of Vanadium. **L. Maillard.** (*Bull. Soc. Chim.*, 1900, xxiii., 559-563.)—This method is based upon the reaction described by Barreswill in 1847, in which, on treating a strongly acidified solution of a vanadate with ether saturated with hydrogen peroxide, or with ozonized ether or turpentine, a red coloration due to pervanadic acid is obtained.

For the standard, the author uses a 10 per cent. solution of pure sodium metavanadate, which is diluted as required to 1 : 100 or 1 : 1,000.

Ten c.c. of the neutral solution under examination are acidified with 1 to 5 c.c. of hydrochloric acid in a graduated cylinder, into which are then introduced 3 to 10 c.c. of ether saturated with hydrogen peroxide. On shaking the closed cylinder there is an immediate red coloration, while the supernatant ether remains colourless. The aqueous layer is then diluted to 15 c.c., and the colour matched in the colorimeter with that given by the standard solution of metavanadate under the same conditions.

The reagent is prepared by mixing equal volumes of ether and ordinary commercial hydrogen peroxide (10 volumes), and allowing the flask to stand for some time.

A series of determinations are described to show that the method is accurate.

and that the presence of impurities, such as chlorides, sulphates, nitrates, and phosphates, do not interfere with the results.

The red coloration is perceptible in a solution containing 1 part of vanadic acid in 84,000. C. A. M.

The Preparation of Standard Solutions of Sulphuric Acid. A. Marshall. (*Journ. Soc. Chem. Ind.*, 1899, 4, 1091.)—Pure sulphuric acid is mixed with water so that it contains between 62 and 82 per cent. H_2SO_4. The density is then determined, and the exact strength of the acid is calculated from the formula

$$P = D(85{\cdot}87 + {\cdot}05T - {\cdot}0004t^2) - 69{\cdot}80,$$

where P is the percentage of H_2SO_4 in the acid, and D is the density of the acid at T° C., referred to water at t° C. The density need not be determined beyond the third decimal place, and the temperatures need to be known within half a degree only. The above formula may be used for any temperatures from 0° to 40° C. The error in the percentage of H_2SO_4 found is not greater than $\pm 0{\cdot}1$.

The author also gives tables from which the strength of the acid can be obtained accurately to 0·01 per cent.

The strength of the acid being known, a simple calculation gives the amount which must be weighed out to make the required standard solution. A. M.

REVIEWS.

FLESH FOODS: THEIR CHEMICAL, MICROSCOPICAL, AND BACTERIOLOGICAL EXAMINATION. By C. AINSWORTH MITCHELL, B.A. (Oxon.). London: Charles Griffin and Co. Price 10s. 6d.

THIS work fills a distinct gap in literature, for no book covering the whole of the ground taken here has yet appeared in the English language. It commences with a description of the structure and chemical composition of the muscular and other animal tissues, as well as the blood, a section on the identification of blood-stains being included. The characteristics of the flesh of the various animals usually used for food are described, along with their chemical composition, special attention being given to the chemistry of the fats, this latter being a subject upon which the author, in conjunction with Mr. Otto Hehner, has done much original investigation. The general appearance of healthy and diseased flesh are described, as are also the few chemical tests which have been proposed for the detection of unsound flesh, and the relative digestibility and the heat-values of the various flesh foods conclude the chapter. The next is devoted to the methods for examining animal fats. The preservation of flesh and the composition and examination of preserved flesh products are next dealt with, as also is the examination of tinned foods for decomposition, metallic contamination, etc.; preservation of food by means of chemical antiseptics, the effects of their application and their detection, are described. The composition and analysis of sausages forms the subject of another chapter. The animal proteids and their derivatives are next dealt with, several of the schemes for their classification which have been proposed of late years being

given, also the chemical reactions and physical properties of these bodies, with methods for their determination; the processes of artificial digestion, both by chemical and enzymic agent, being appended. The changes produced in flesh by cooking are next described, as well as the effect of that process on animal parasites, bacteria, toxines, etc. Poisonous flesh, its various causes, and the symptoms of poisoning produced thereby, are next dealt with; a list of the principal ptomaines is given, the detection and isolation of which are reserved for the last chapter in the book. Next comes an account of the animal parasites occurring directly or indirectly in flesh usually used for food, together with their detection; this, which is fully illustrated by figures of the various organisms, forms a novel feature in works of this kind. The effect of cooking and curing on the destruction of these obnoxious organisms is also discussed. Next follows a description of the methods for examining flesh for bacteria, a description of the most important of those which usually occur in flesh foods, the diseases caused by them and their thermal death-points. From the above it will be seen that the scope of the work is an exceedingly wide one, and as a consequence the information it contains must necessarily appear in a much condensed form to bring it within the compass of a small handbook. This has, however, been done so intelligently that the general value of the book is not impaired, and it will be found of great value not only to Medical Officers of Health and others who are engaged in the inspection of food, but also to analysts, to whom samples of unwholesome food are frequently referred. The general get-up of the book is excellent, the figures good, and it possesses a copious index. W. J. S.

LUBRICATION AND LUBRICANTS. By L. ARCHBUTT and R. M. DEELEY. London: C. Griffin and Co. Price 21s.

The whole of the extensive subject covered by the title is treated of in this volume. Starting with the discussion of friction generally, the authors pass to those physical measurements, such as viscosity, which serve to ascertain the quality of lubricants and their suitability for a proposed use. They give a full and accurate account of the numerous experiments which have been carried out by Mr. Beauchamp Tower and others to determine precisely what is the behaviour of a lubricant under different conditions. There is a large chemical section of the book which is as excellently rendered as those who know the chemist of the partnership of authors would expect. It is this section that analysts will naturally most eagerly consult, but they may be assured of good return for their labour if they will also study the more mechanical portions of the book. Oil-testing machines, bearings of various design, and the lubrication of machinery, are the subjects occupying the remainder of the volume. To give a full appreciation of this admirable treatise would require the issue of a pamphlet rather than the summary of a review, and in view of this impossibility it is sufficient to say that those chemists who are accustomed to examine and pronounce upon the quality of lubricants will do well to fortify their knowledge and to check their conclusions by consulting a work which is as full of fact as it is of suggestion. B. B.

THE ANALYST.

DECEMBER, 1900.

PROCEEDINGS OF THE SOCIETY OF PUBLIC ANALYSTS.

THE monthly meeting of the Society was held on Wednesday evening, November 7, in the Chemical Society's Rooms, Burlington House. The President (Mr. W. W. Fisher, M.A.), occupied the chair.

The minutes of the previous meeting were read and confirmed.

THE MARGARINE CLAUSE OF THE FOOD AND DRUGS ACT, 1899.

The PRESIDENT then read the following report, presented to the Council by the Committee which was appointed, at the suggestion of the Principal Chemist of the Government Laboratory, to confer with him on the subject of Section 8 of the Sale of Food and Drugs Act, 1899. The object of the conference was to arrive at some kind of agreement as to the manner of estimating the proportion of butter-fat in margarine (which by the section referred to was restricted to 10 per cent.), with a view to avoiding discrepancies which might arise through the employment of different methods by individual analysts. The investigations made in the Government Laboratory, and by the several members of the Committee, had been followed by recommendations as to the method of analysis and the calculation of results, which were fully set out in the report and appendix. The report had been agreed to by Dr. Thorpe and by the Committee as representing the Society of Public Analysts, and it had been incorporated in the recently published official report of the Principal Chemist of the Government Laboratory; so that, as far as the Government Laboratory was concerned, the method recommended stood as the official method for determining the percentage of butter-fat in margarine.

REPORT.

In view of prosecutions which may be raised under this clause, it is desirable that an agreement should be come to among analysts as to the method and the analytical criteria which should be employed to raise a presumption, until the contrary is proved, that the amount of butter-fat in margarine exceeds the statutory limit.

On the suggestion of the Principal Chemist of the Government Laboratory, a Committee of the Council of the Society of Public Analysts was appointed to confer with him on this subject.

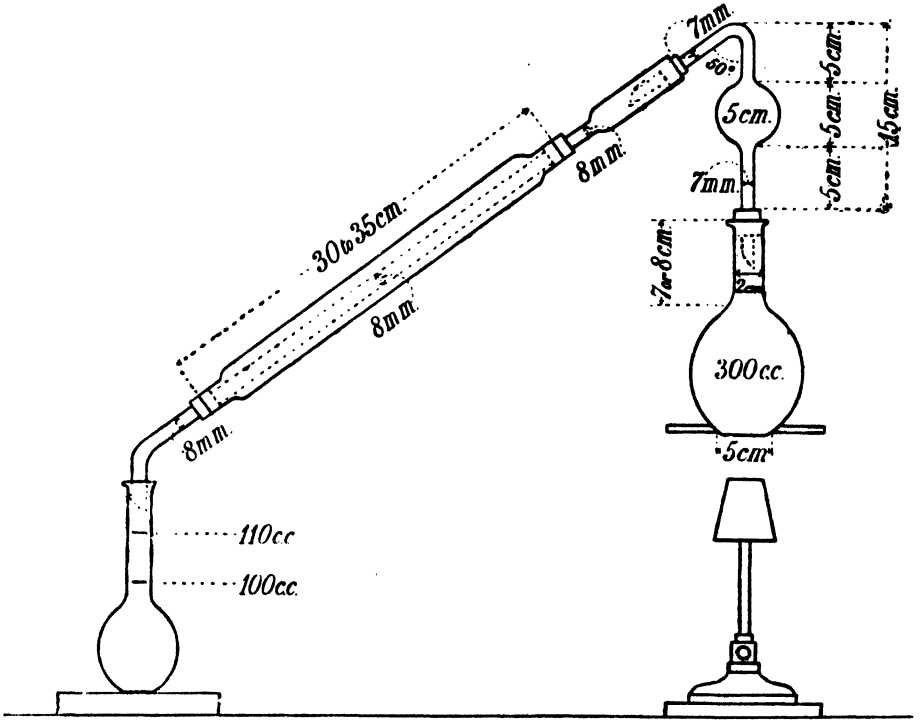
After a careful examination of methods of analysis and a series of determinations, made independently, of various samples of commercial margarine of known composition, and of mixtures prepared in the Government Laboratory of margarine with varying but known proportions of butter-fat of different Reichert-Wollny values, it has been agreed to recommend:

(1) That the proportion of butter-fat should be deduced from a determination of the amount of the "volatile acids," as ascertained by the Wollny modification of the Reichert-Meissl process, described below.

(2) That no presumption against the margarine in regard to its content of butter-fat should be raised unless the Reichert-Wollny number as ascertained by the method described exceeds 4.

(3) That the amount of butter-fat in margarine, when it exceeds the legal limit of 10 per cent., as determined by the method prescribed, shall be assumed to be as follows:

Reichert-Wollny Number of the Mixture.	Percentage of Butter-Fat present in the Mixture.
4·0	10
4·3	11
4·6	12
4·9	13
5·2	14
5·5	15
5·9	16
6·2	17
6·5	18
6·8	19
7·1	20



The foregoing table is to be regarded as applicable only to the determination of butter-fat in margarine.

(Signed)
T. E. THORPE,
W. W. FISHER,
A. H. ALLEN,
E. J. BEVAN,
O. HEHNER.

THE REICHERT-WOLLNY METHOD FOR DETERMINATION OF VOLATILE FATTY ACIDS IN MARGARINE AND BUTTER.

Five grammes of the liquid fat are introduced into a 300 c.c. flask, of the form seen in the figure (length of neck 7 to 8 centimetres, width of neck 2 centimetres). Two c.c. of a solution of caustic soda (98 per cent.) in an equal weight of water —preserved from the action of atmospheric carbonic acid—and 10 c.c. of alcohol (about 92 per cent.) are added, and the mixture is heated under a reflux condenser, connected with the flask by a T-piece, for fifteen minutes in a bath containing

boiling water. The alcohol is distilled off by heating the flask on the water-bath for about half an hour, or until the soap is dry. One hundred c.c. of hot water which have been kept boiling for at least ten minutes are added, and the flask heated until the soap is dissolved. Forty c.c. of normal sulphuric acid and three or four fragments of pumice or broken pipe-stems are added, and the flask is at once connected with a condenser by means of a glass tube 7 millimetres wide and 15 centimetres from the top of the cork to the bend. At a distance of 5 centimetres above the cork is a bulb 5 centimetres in diameter. The flask is supported on a circular piece of asbestos 12 centimetres in diameter, having a hole in the centre

5 centimetres in diameter, and is first heated by a very small flame, to fuse the insoluble fatty acids, but the heat must not be sufficient to cause the liquid to boil. The heat is increased, and when fusion is complete 110 c.c. are distilled off into a graduated flask, the distillation lasting about thirty minutes (say from twenty-eight to thirty-two minutes), the distillate is shaken, 100 c.c. filtered off, transferred to a beaker, 0·5 c.c. of phenolphthalein solution (1 gramme in 100 c.c. alcohol) added, and the filtrate titrated with decinormal soda or baryta solution. Precisely the same procedure (with the same reagents), omitting the fat, should be followed, and the amount of decinormal alkali required to neutralize the distillate ascertained. This should not exceed 0·3 c.c. The volume of decinormal solution of alkali used, less the figure obtained by blank experiment, is multiplied by 1·1. The number so obtained is the "Reichert-Wollny Number."

Notes on the Method.—The sample is melted and filtered from curd and water through a dry filter. From the filtrate the 5 grammes of fat for the process are taken. The soda solution is filtered clear from carbonate formed in its preparation, and kept in a special bottle. The Soxhlet spherical condenser is a convenient one for the reflux distillation. This is fixed near the water-bath in which the saponification is to take place, and is connected with the flask by means of a T-piece and indiarubber tubes inclined at an angle of 45°. During the saponification the free limb of the T-piece is directed upwards, and its end closed by a short piece of indiarubber and glass rod. At the end of fifteen minutes this limb is turned downward, and the piece of glass rod replaced by a tube carrying away the alcohol.

One hundred c.c. of hot distilled water are added, and the flask frequently shaken until the soap is dissolved. The Liebig is a convenient form of condenser. One containing a column of water 30 to 35 centimetres in length gives sufficient condensing surface. After shaking the distillate, about 5 c.c. are filtered through a dry paper into a 100 c.c. flask. This serves to wash out the flask. When the 100 c.c. are transferred to a beaker, the flask is not washed out, but the main quantity is neutralized with the standard solution of alkali and returned to the flask, then again transferred to the beaker and the titration completed.

The PRESIDENT then said that some explanation might be given of the adoption of a Reichert-Wollny number of 4 as representing 10 per cent. of butter-fat. Ten per cent. of butter-fat, if the butter had a Reichert-Wollny number of 30, would be represented by a Reichert-Wollny number of 3. The margarine itself, however, must always count for something, and the traces of volatile acids which it would probably contain might raise the number 3 to 3·5 or 3·7; so that, by way of margin to avoid disputes about very small proportions of butter-fat, which, after all, were immaterial, the number 4 was adopted, as being a whole number and more satisfactory than 3·85 or 3·9 would be, and giving the same practical results.

The appendix to the report contained a description of the method of analysis, with a diagram of the apparatus. The apparatus should be constructed in accordance with the measurements given, in order that the results might not be affected by minor differences of procedure.

Dr. RIDEAL said that this report was especially to be welcomed because it marked a new and satisfactory departure in the history of the Society and its relations with the Government Laboratory. The method described was practically the one which he had been in the habit of using for some years past. He would be quite prepared, and he hoped that every public analyst would be prepared, to adhere rigidly to all the details of the method as now laid down, because he believed that only by so doing could uniformity of results be secured; and from personal experience he was sure that its employment would lead to the avoidance of many disputes. He had much pleasure in moving that the Society formally adopt this method as an official method.

Major CASSAL seconded the motion. He agreed that the action which had been taken by the Society in this matter was one of considerable importance, and it was desirable that action of a similar kind should be taken in regard to other products.

The adoption of an official process was necessarily a matter of compromise under certain circumstances, and it would appear that the labours of the Committee had resulted in the adoption of a process which was satisfactory to both parties concerned. It was obviously important that in this, as in other matters, the Society should be in agreement with the Somerset House analysts, who had met the Society in a fair and proper spirit, which he had no doubt whatever would also be exhibited by them in the future in regard to any other questions that might arise.

Mr. EMBREY supported the motion, on the ground that it was quite as important that public analysts should agree amongst themselves as that they should agree with the Government chemists. There were, he thought, points in the method recommended which were open to criticism, but he nevertheless would be prepared to adhère to it, seeing that it had been agreed upon.

The motion, on being put to the meeting by the President, was carried unanimously.

A certificate of proposal for election to membership in favour of Mr. John Stewart Remington was read for the second time. Certificates in favour of Messrs. Percy Henry Carpenter, 46, Streathbourne Road, Upper Tooting, S.W., assistant to Mr. Alfred C. Chapman; and Samuel Russell Trotman, M.A., F.I.C., 1, Waverley Street, Nottingham, Public Analyst for the City of Nottingham, were read for the first time.

The following papers were read: "The Determination of the Available Brewing Extract of Malt," by Lawrence Briant; and "Notes on certain B. P. Tests," by C. G. Moor, M.A., and Martin Priest.

A NEW COLOUR REACTION FOR DISTINGUISHING BETWEEN CERTAIN ISOMERIC ALLYL AND PROPENYL PHENOLS.

BY ALFRED C. CHAPMAN, F.I.C.

(*Read at the Meeting, June* 6, 1900.)

MANY of the odoriferous constituents of essential oils are now known to consist of phenols or their simple derivatives, and some of these are of considerable technical importance, chiefly owing to the fact that they serve as the starting-points in the manufacture of certain well-known artificial perfumes.

Thus, eugenol and safrol serve respectively for the preparation of the important perfumes vanillin and heliotropin.

Many of these phenolic substances may be grouped in pairs, the one isomer containing the allyl grouping $CH_2 . CH : CH_2$, whilst the other has instead the propenyl group, $CH : CH . CH_3$, and the conversion of the former into the latter can, as a rule, be effected without difficulty.

In some cases, as, for instance, eugenol and safrol and their isomers, the general properties of the pair of compounds are so much alike that a simple colour reaction capable of distinguishing clearly and easily between them is of sufficient interest, I think, to warrant me in bringing it before the notice of the Society.

The reaction in question is brought about by simply dissolving 1 c.c. of the

phenol in 5 c.c. of acetic anhydride, and then adding (*a*) a fragment of fused zinc chloride or (*b*) 1 drop of concentrated sulphuric acid.

Experiments were made with the six substances, eugenol and iso-eugenol, safrol and iso-safrol, and estragol and anethol, and the colour changes recorded below were observed :

	Eugenol.	Iso-eugenol.
H_2SO_4.	Brown at first, becoming quickly purple, and finally wine-red.	A rose pink, quickly changing to a light brown.
$ZnCl_2$.	Pale yellow, the colour disappearing on standing.	Bright rose-pink coloration.
	Safrol.	**Iso-safrol.**
H_2SO_4.	A bright emerald-green colour, becoming brownish-green and finally brownish.	A faint transient pink, becoming reddish on standing.
$ZnCl_2$.	Pale blue, becoming less intense on standing, and finally light brown.	Pink, becoming brownish-pink and finally brown.
	Estragol.	**Anethol.**
H_2SO_4.	Purple, turning to indigo blue, and then to bluish purple.	No colour at first. After a short time a yellowish tinge.
$ZnCl_2$.	Blue-violet colour, which becomes deep mauve and finally brownish.	A pale yellow colour appearing slowly, which deepens on standing, and finally becomes brick-red.

Seeing that colour reactions are so largely influenced by the presence of impurity in the compounds to which they apply, I may add that no pains were spared to obtain the above substances in as pure a condition as possible.

Some of them (eugenol, iso-eugenol and iso-safrol) were prepared in my laboratory, whilst the remaining three were procured from Kahlbaum of Berlin, and purified by me.

In all cases the chief physical constants were carefully determined and compared with those given by the most reliable authorities, and when possible crystalline derivatives were prepared from them and identified.

There can, therefore, I think, be no reasonable doubt that all were in as high a degree of purity as it is possible to obtain them.

Discussion.

Dr. Lewkowitsch said that, in the case of the so-called colophony test, a more distinct reaction was obtained with sulphuric acid of specific gravity 1·53 than with an acid of greater strength ; and perhaps in the case of the test now described a somewhat weaker acid would give a more strongly developed coloration, as seemed to be shown by the zinc chloride.

Mr. A. Marshall inquired whether any other dehydrating agents had been tried.

Mr. Chapman said that the treatment of these hydroxy-compounds in the manner described was the ordinary method of preparing acetyl derivatives, and his attention had been quite accidentally directed to the reaction in that way. The investigation had not been carried any further, but he thought that the test as it stood would probably suffice for ordinary purposes.

DETECTION OF MAIZE IN WHEATEN FLOUR.

By G. Embrey.

(*Read at the Meeting, June* 6, 1900.)

During the past three or four years English millers have been seriously affected by the introduction of foreign wheaten flour, containing from 10 to 30 per cent. of maize flour; and yet very few prosecutions of dealers selling such have taken place.

Many fancy articles sold, as "Self-raising Flour" and "Pastry Flour," have also been found to contain from 10 to 20 per cent. of maize.

I have examined the published methods for detecting and estimating this substance, but find the results are not so constant as is desirable for proceedings under the Food and Drugs Act.

If we compare the flours separately as regards their chemical composition, we fail to discover variations sufficiently wide to enable us to estimate one in the presence of the other.

At one time I thought it possible to make use of the difference in the amount of fat found in the flours; but although the whole-grain of maize contains nearly 5 per cent. of fat, the samples of white maize flour on the market contain only 2·84 per cent. of fat, while wheat flour contains from 1·2 to 2 per cent. of fat.

There is some difference in the amount and in the character of the mineral matter. Thus, while maize contains 0·714 per cent. ash, nearly 60 per cent. of which is soluble in water, and which has 38·65 per cent. phosphates, calculated as tricalcium phosphate, wheat flour has usually only 0·42 per cent. of ash, 71 per cent. of which is soluble in water, 22·42 per cent. of the ash being phosphates; so the examination of the ash may be used to confirm the other methods of estimation.

I believe the usual method of detecting maize in presence of other flours is by means of the microscope; and the mode described by Allen, aided by the excellent drawing (facing page 411, "Commercial Organic Analysis," vol. i., third edition), is all that can be desired.

In a paper on "The Use of Maize as an Adulterant in Oatmeal," by J. White, F.I.C. (Analyst, vol. xx., p. 30), the author gives some excellent advice as to the microscopical examination of flours containing maize.

Still, I have been unable to obtain concordant results in quantitative estimations when using only the microscope and its appliances.

In vol. xxiv., p. 150, of the Analyst will be found an abstract from an article by K. Bauman concerning this subject, and a method both for detection and estimation of maize is given; but while his method of detecting it is simple and effective, that for its estimation does not work well in my hands. However, it is an extension of this method which I bring before the society to-night.

Bauman points out that a 1·8 per cent. solution of potassium hydroxide will under certain conditions gelatinize wheat starch, but leave maize starch unaffected. This I find to be the case, and taking advantage of this, have worked out the following modification and extension:

1. It is necessary to provide samples of pure wheaten and pure maize flours.

2. The following solutions are required:

(1)	Potassium hydroxide	18 grammes.
	(Make up to a litre with distilled water.)	
(2)	Iodine	0·25 gramme.
	Potassium iodide	1 gramme.
	Distilled water to	250 c.c.
(3)	Hydrochloric acid, specific gravity 1·16	50 c.c.
	Distilled water to	100 c.c.

Process.—Weigh out the following:

(*a*)	0·2	gramme of the sample under examination.								
(*b*)	0·18	gramme	wheat flour, and	0·02	gramme	maize flour	= 10	%	of	maize flour.
(*c*)	0·17	,,	,,	,,	0·03	,,	,,	= 15	,,	,,
(*d*)	0·16	,,	,,	,,	0·04	,,	,,	= 20	,,	,,
(*e*)	0·15	,,	,,	,,	0·05	,,	,,	= 25	,,	,,
(*f*)	0·14	,,	,,	,,	0·06	,,	,,	= 30	,,	,,

Place each of the above in test-tubes (15 centimetres × 2 centimetres) fitted with paraffined corks, then add to each 20 c.c. of the potassium hydroxide solution; shake uniformly for three minutes; add 12 drops of the hydrochloric acid; place in centrifugal machine revolving 600 times per minute; remove 1 c.c. of the liquid, avoiding carefully the residue at the bottom of the tube; make up to 50 c.c. in Nessler glass; add two drops of the hydrochloric acid, then 1 c.c. of the iodine solution; stir and compare tints; this will give the amount of maize flour present in the sample to within 5 per cent. only, which is not near enough for our purpose.

But if we take 10 c.c. of the clear liquid from each test-tube, add 1 c.c. of dilute sulphuric acid (1 : 7), and boil for two hours (thus entirely converting the starch into sugar), then neutralize, make up to 50 c.c., well mix, and place in a burette, and run into the following mixture, which is kept boiling:

Gerrard's solution*	10 c.c.
Fehling's solution	2 c.c.

until the colour is discharged, the made-up specimen, requiring the same amount to discharge the colour as the sample under examination, will give the percentage.

Discussion.

Mr. Bevan said that he had recently tried, with satisfactory results, a qualitative method for the detection of the presence of maize in wheaten flour which had been communicated to him by Mr. A. C. Wilson, of Stockton-on-Tees. In this the flour, or starchy compound, is mixed with clove oil, and examined under a $\frac{1}{4}$- or $\frac{1}{8}$-inch objective, when the hilum of maize appears as a black dot or star; the wheat or other starches are practically invisible.

* On p. 75 of Allen's "Chemistry of Urine," these directions are given for Gerrard's process:

"Ten c.c. of freshly-prepared Fehling's solution, or 5 c.c. of each of the constituent solutions, both accurately measured, should be placed in a porcelain dish, 40 c.c. of water then added, and the liquid heated to boiling. A solution of potassium cyanide, of about 5 per cent. strength, is gradually added from a burette or pipette until the deep blue colour of the liquid is nearly destroyed. The addition of the cyanide is continued very cautiously drop by drop, the liquid being kept constantly boiling and well stirred until the blue colour just disappears, or only a very slight tinge of blue remains. Excess of cyanide solution must be carefully avoided, so that it is safer to discontinue its addition when the blue colour is still faintly perceptible."

Mr. JOHN WHITE said that a qualitative test—which might also be made quantitative—for the detection, and, if necessary, the determination of maize in wheaten flour, was communicated to him some three or four years previously by Mr. E. W. T. Jones, and he had found it to answer all practical requirements. After the sample had been thoroughly mixed in a mortar, 1 gramme of it was placed in a test-tube, 10 c.c. of distilled water added, and the mixture well shaken; 15 c.c. of a 1 per cent. solution of sodium hydroxide was then added, and the whole again shaken. After standing for not less than three or four hours, nearly the whole of the wheat starch was gelatinized, as in the case of the treatment with caustic potash; and, if maize was present, a drop of the emulsion, examined under the microscope with a ¼-inch objective and an A or B eyepiece, showed the granules of maize very distinctly. Wheat of a certain special class appeared to resist the action of the alkali for a considerable time, but by polarized light this was easily distinguishable from the granules of maize. In the case of a sample examined jointly, the conclusions independently arrived at by Mr. Jones and himself had been in very close agreement.

ABSTRACTS OF PAPERS PUBLISHED IN OTHER JOURNALS.

FOODS AND DRUGS ANALYSIS.

Acidity of Milk. Vieth and Siegfold. (*Milch Zeit.*, 1900, xxix., 593; through *Chem. Zeit. Rep.*, 1900, 283.)—The authors publish two sets of observations, carried out at different times and places, to ascertain whether the acidity of milk, as produced under different conditions, is always approximately constant, and whether milk can be delivered to a dairy after a long journey in the hot season of the year perfectly sweet. The figures show that a high acidity is found not only when the milk is going sour, but also when an early souring can hardly be expected; so that the acidity must be considered natural. It is also evident that even in hot summer weather delivery of a mixed daily milk in good condition is quite possible, even if part of the bulk was undoubtedly sour. The natural acidity of milk is in no way constant in amount, but varies within sensible proportions. F. H. L.

Estimation of Fat in Condensed Milk. A. E. Leach. (*Journ. Amer. Chem. Soc.*, vol. xxii. [9], pp. 589-591.)—In the case of condensed milk containing added cane-sugar, the sample is well stirred to render it homogeneous, and 40 grammes are weighed out, washed into a 100 c.c. flask and made up to the mark with water. Twenty-five c.c. are placed in a test-bottle, which is then nearly filled with water and 4 c.c. of copper sulphate solution, of the strength of Fehling's copper solution, the whole being well shaken up and placed in a Babcock centrifuge, preferably driven by electricity, since heat cakes the precipitate and makes it harder to wash. When the separation is complete, the supernatant liquid is drawn off by a pipette, through a

filtering wisp of cotton, the precipitate is washed thoroughly in the machine; and, finally, enough water is added to amount approximately to the normal volume of 17·6 c.c. usually employed for the Babcock test, the subsequent stages of which are then carried out in the ordinary manner. C. S.

Detection of Coal-Tar Dyes in Fruit Products. A. L. Winton. (*Journ. Amer. Chem. Soc.*, vol. xxii. [9], pp. 582-588.)—The author recommends Arata's wool test, applied by boiling 100 c.c. of the liquid under examination for ten minutes with 10 c.c. of 10 per cent. potassium bisulphate solution, and a piece of white wool previously boiled in dilute sodium hydroxide and washed, since the natural colouring matters of fruit impart at most a pink or brown coloration which turns green in presence of ammonia, and is not restored on washing with water; whereas coal-tar dyes—the azo-group particularly—produce colorations either unaffected by ammonia or restorable by washing. Care should, however, be taken to ascertain whether the wool is really dyed, or merely coated with the colouring matter; chlorophyll, for example, and colouring preparations of vegetable origin, since they are merely deposited on the surface, are removed by friction or washing. It is better to apply the subsequent identification tests to the dyed wool rather than to the dye extracted therefrom. The amyl alcohol (alkaline or acid solution) confirmatory tests for fuchsine may be afterwards employed, as well as Gerard's mercuric acetate method and Cazeneuve's mercuric oxide test. The two last are, however, unsuitable for jellies, though useful for fruit juices and syrups. In reports it is considered better to avoid attempts at particularizing the dye-stuff present, beyond indicating the colour, *e.g.*, 'red' or 'orange coal-tar dye.' C. S.

Determination of Vanillin. J. Hanus. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 531-537.)—The experiments described were carried out with the object of devising a method for the determination of vanillin by the production of a hydrazone of suitable character by the addition of one of the hydrazines. Of those experimented with only the β-naphthylhydrazine hydrochloride and the *p*-bromphenylhydrazine were found to satisfy the requirements.

β-Naphthylhydrazine hydrochloride ($C_{10}H_7.NH.NH_2.HCl$).—The experiments were carried out as follows: The β-naphthylhydrazine solution was added to the vanillin solution in such proportion that 2 to 3 parts of hydrazine were present for every part of vanillin. The mixture was allowed to stand for five hours, after which it was filtered through a dried and weighed filter, and washed with hot water until the washings no longer exercised a reducing action upon silver nitrate. The precipitate was then dried at 90° C., and weighed.

To effect complete separation it is necessary that the mixture be allowed to stand for some time, though, on the other hand, standing too long may lead to an error in the opposite direction through the production of oxidation products of hydrazine, which cannot be removed by washing. Standing for five hours appears to give the best results.

p-Bromphenylhydrazine ($C_6H_4Br.NH.NH_2$).—Two to three parts of hydrazine

were used for each part of vanillin. The mixture was allowed to stand for four or five hours, after which it was filtered and washed as before. Finally the precipitate was dried at 100° C., and weighed. The results by both processes were satisfactory.

This method is applicable in all cases where an aqueous solution of the vanillin can be prepared, and it has the advantage over Welman's method (titration with alcoholic potash) of being unaffected by the presence of vanillic acid. H. H. B. S.

Researches on Cayenne Pepper. G. Gregor. (*Zeit. für Untersuch. der Nahr. und Genussmittel*, 1900, iii., 460-471.)

1. *On the Assimilability of Metallic Salts by the Cayenne Pepper Plant.*—In a paper contributed to the *Chem. Zeit.* (1899, xxiii., 433) Jonscher called attention to the fact that 0·91 per cent. of barium oxide in the form of readily soluble salt had been found in a sample of ground cayenne pepper. The publication of this paper, and its subsequent discussion in the columns of the journal, led the author to undertake the present investigation. The experiments were carried out as follows: Cayenne pepper plants were cultivated in wooden boxes filled with ordinary garden soil. In one case the soil was used alone; in two other cases barium sulphate and calcium sulphate respectively were mixed with it, whilst in the remainder the soil was watered respectively with solutions of barium chloride, calcium chloride, lead chloride, and copper sulphate. The experiments were commenced in July, and the ripe fruit was collected in October. After drying in the usual way, the percentage of ash in the fruit from each experiment was determined and examined for the particular metals experimented with. From the results obtained, the author concludes that neither barium nor lead is capable of being assimilated by the cayenne pepper plant, and that consequently the presence of these metals in the ash of the fruit must be taken as a proof of admixture.

2. *On the Percentage of Ash in different Sorts of Cayenne Pepper.*—The fruit grown by the author for the purpose of the preceding investigation was found to yield from 9·74 to 13·37 per cent. of ash, the latter result being obtained in the case of fruit grown upon soil containing calcium sulphate watered with solution of sodium chloride. These figures are not only much in excess of those obtained by other investigators, but are also above the maximum fixed by the German Union for establishing standard methods for the examination of food products, viz., 6·5 per cent., with 1 per cent. insoluble in hydrochloric acid, as well as above the maximum proposed by Swiss chemists, viz., 5 per cent., with 2·5 per cent. insoluble. In order, therefore, to further investigate the subject, the author collected local specimens of normally grown fruits for examination, and with these he found from 7·12 to 10·03 per cent. ash, and from 0·22 to 0·34 per cent. of this soluble in hydrochloric acid.

Further, the results of the examination of twenty-five commercial samples of ground cayenne pepper from various sources gave from 5·71 to 8·92 per cent. of ash, of which from 0·17 to 2·00 per cent. was soluble in hydrochloric acid.

The author remarks that the high percentage of ash insoluble in hydrochloric acid found in some of the samples examined must be due either to accidental

impurities, or to admixture with some foreign substance. Further examination of this part of the ash showed that the excess consisted in some cases of barium sulphate and in others of lead oxide. The proportion of barium sulphate was, in the author's opinion, too insignificant to admit of the supposition that it was purposely added to increase the weight. He considers it more probably due to the practice of artificially colouring the ground pepper. A colouring-matter sold for this purpose under the name of "chrome red" was found to consist of chrysaurein mixed with 60 per cent. of barium sulphate. H. H. B. S.

TOXICOLOGICAL ANALYSIS.

Detection of Sulphonal, Trional, and Tetronal in Cases of Poisoning. D. Vitali. (*Boll. Chim. Farm.*, 1900, xxxix., 461; through *Chem. Zeit. Rep.*, 1900, 243.)—The animal matters submitted for examination are warmed in a porcelain basin three times with twice their volume of 90 per cent. alcohol; after cooling, the extracts are filtered, and the solvent distilled off. The residual aqueous liquid is warmed, filtered, made alkaline with potassium hydroxide, and exhausted three times with an equal volume of ether. (Potash has no effect on sulphonal; it is only employed to prevent colouring matter passing into the ether.) The ether is driven off, leaving the sulphonal behind. It can then be identified by the reactions described by Wefers-Bettinck, Schwarz, Ritsert, and Vulpius, or by Vitali's own tests as follows: (1) When sulphonal is fused with three times its weight of potash, a garlic-like odour is evolved; the mass becomes yellow, then red, and scarlet when cold. If the melt is extracted with water, a turbid, bluish liquid is obtained, and in the filtrate polysulphides can be detected by means of sodium nitroprusside, thiosulphate by acidification. If the mixture of sulphonal with potash is heated to the melting-point of glass, the red colour changes to a blue, owing to the formation of a body analogous to ultramarine. (2) When sulphonal is warmed with a little metallic sodium, sodium sulphide is produced, as may be recognised by treatment with water and nitroprusside. (3) If sulphonal is heated with twice its weight of potassium periodate (only small quantities should be used), a slight explosion occurs, and potassium sulphate is produced. This test succeeds with 1 milligramme of substance.

Sulphonal resists putrefaction, and it can therefore be recovered without loss by the above process from animal remains in a state of decomposition. The same method of isolation, and the same tests, are available in the case of trional or tetronal. They can be distinguished one from another by their different melting-points and by the different appearance under the microscope of the crystals obtained by the spontaneous evaporation of their aqueous or ethereal solutions. Sulphonal and trional are only eliminated in their original condition through the urine in small quantities. They may be detected therein by concentrating the urine on a water-bath to the consistency of an "extract," treating the residue with boiling alcohol, filtering, distilling off the spirit, again filtering the aqueous liquid, boiling with potash to destroy urea, and finally shaking out with ether.

(*Cf.* ANALYST, 1899, xxxiv., 129.) F. H. L.

ORGANIC ANALYSIS.

The Carbohydrates of Irish Moss (Carrageen). J. Sebor. (*Oester. Chem. Zeit.*, 1900, iii., 441.)—The mucilage yielded on decoction of Irish moss contains a complex carbohydrate yielding on hydrolysis galactose, dextrose, and lævulose, also a small quantity of a pentosan, probably xylan. The sugars, however, are not present in the same proportion as in raffinose. Whether the moss contains a mixture of the three corresponding pentosans or a carbohydrate yielding the three sugars cannot be ascertained; but as the mucilage has an organic structure, is insoluble in water, easily yields colloidal solutions like starch paste, and is readily converted into dextrin-like substances, it would appear to be a vegetable reserve-stuff of great molecular complexity similar to starch. F. H. L.

Cedar-nut Oil. L. von Schmoelling. (*Chem. Zeit.*, 1900, xxiv., 815.)—This oil is obtained from the nuts of the Siberian cedar, or stone pine (*Pinus cembra*), a tree which forms vast forests in the southern districts of that country. It has a golden-yellow colour and a very pleasant, mild taste, though somewhat rancid. It is used in Siberia as a food. The oil is scarcely soluble in cold alcohol, carbon bisulphide or benzene; but in cold petroleum spirit, chloroform, acetone and amyl alcohol it is soluble in all proportions. The three first liquids dissolve it on warming. Mixed with an equal volume of fuming nitric acid, it gives a dark red colour, which is permanent for more than twenty-four hours. Ten drops of oil and 2 drops of strong sulphuric acid show a dark-brown ring with black streaks in the oil; with 1·53 sulphuric acid it exhibits a yellowish-brown colour. The constants of cedar-nut oil are as follows:

	Oil.	Fatty Acids.
Specific gravity	0·930	
Hehner number	91·97	
Saponification value	191·8	
Iodine value (Waller)	159·2	161·3
Acid value	3·25	193·0
Glycerin (esters × 0·0547)	10·31 per cent.	
Volatile fatty acids	3·77 ,,	
Free fatty acids	1·6 ,,	
Total fatty acids	95·74 ,,	
Mean molecular weight	280	290
Acetyl number (after six days' standing) ...	—	81·9
Liquid fatty acids (Muter and De Koningh)	—	87·0 per cent.
Unsaponifiable matter (Fahrion)	1·3 per cent.	
Solidifying point	—	11·3
Iodine value of liquid acids	—	184·0
Temperature reaction (Maumené-Archbutt)...	98°	

Kryloff examined a sample of this oil in 1898, and obtained: Hehner number, 93·33; saponification value, 191·8; iodine value, 149·5 to 150·5; acid value, 1·09; and volatile fatty acids, 2·0 per cent. Among the constituents of the oil palmitic acid

can be recognised, while the liquid acids consist mainly of linolic acid, with some oleic and very little linolenic acid.

On heating the oil with 5 per cent. of manganese borate for four hours to 140° or 150° a "varnish" is produced, which dries on glass in double the time taken by linseed varnish similarly prepared; the product is very viscid, and resembles a blown oil. This last characteristic, coupled with the high price of the original oil, would prevent it from being used in the manufacture of varnish. F. H. L.

Testing for Vegetable Oils by a Modified Welmann's Test. T. Geuther. (*Zeits. öffentl. Chem.*, 1900, vi., 328; through *Chem. Zeit. Rep.*, 1900, 283.)—Finding that the commercial 10 per cent. solution of phosphomolybdic acid is unsuited for analytical purposes, the author proceeds as follows: 5 grammes of pure sodium phosphomolybdate are mixed with 25 c.c. of water and 30 c.c. of pure 1·39 nitric acid, shaking till solution is complete. A test-tube is tared, and into it are weighed 5 grammes of the lard to be examined, after it has been melted, mixed together, and carefully filtered. Three grammes of the purest chloroform are next weighed into the tube, and finally 20 drops of the reagent are added from a pipette. After thorough agitation, the tube is set aside, and the colour which develops within two minutes is observed. In presence of only 5 per cent. of an unrefined and unbleached oil, a distinct dark green tint appears; while pure, fresh, filtered lard gives only a yellow colour. Any green colour that develops after the two minutes may be neglected.

F. H. L.

Action of Sodium Ethoxide on Fats—Volumetric Estimation of Water in Alcohol—Determination of Glycerol in Fats. H. Bull. (*Chem. Zeit.*, 1900, xxiv., 814, 845.)—The process which the author has already described (ANALYST, 1900, xxv., 126) for estimating the unsaturated fatty acids in train oil depends on the assumption that the neutral glycerol esters in those oils are saponified by sodium ethoxide. Such, however, is not the case unless the alcohol in which the original metallic sodium was dissolved contained at least 4 per cent. of water. This quantity of water not only causes complete saponification, but also raises the solubility in ether of the sodium salts of the train-oil unsaturated acids, while an increase in the amount of alcohol present behaves in a similar manner. Bull appends to his present article a table giving the unsaponifiable matter and the fatty acids with soluble sodium salts as redetermined after eighteen months' storage in half-filled bottles on the same oils previously examined (*loc. cit.*), the proportions of fatty acids being now considerably lower, owing, no doubt, to the action of air and light on the samples.

When sodium ethoxide is shaken with a fatty (*e.g.*, train) oil not containing any free acid, an emulsion is first produced, which quickly disappears, leaving a clear solution that deposits fine crystals of mono-sodium glyceroxide according to the equation (F being a fatty acid radicle):

$$C_3H_5.(OF)_3 + C_2H_5.ONa + 2C_2H_5.OH = C_3H_5.(OH)_2.ONa + 3C_2H_5.OF.$$

This reaction occurs almost instantaneously at ordinary temperatures, and

without the production of a sensible amount of heat; it proceeds between an equal number of molecules of fat and ethoxide, instead of between 1 molecule of fat and 3 of sodium hydroxide, as takes place during saponification.

Estimation of Water in Alcohol.—If, then, a neutral fat is boiled with a solution of sodium ethoxide in absolute alcohol, no saponification occurs; but in presence of water a certain quantity of ethoxide is decomposed into alcohol and hydroxide (which reacts with the fat), thus forming a means of calculating the moisture. Normal ethoxide is required, which is standardized by gently warming 10 c.c. with 5 c.c. of a fatty oil as free as possible from uncombined acids (medicinal cod-liver oil, for example) in a perfectly dry flask fitted with an upright condenser. The liquid is cautiously heated for thirty minutes, then allowed to boil for fifteen minutes; finally cooled, diluted with about 20 c.c. of neutral ether, and titrated with semi-normal hydrochloric acid and phenolphthalein. Repeating the process with an alcohol containing some moisture, less standard acid is used in the titration, and the difference calculated into H_2O. Various examples of the method are quoted which show satisfactory agreement among themselves, and which also indicate accurately the strength of the alcohol employed. It is clear that the same process is available for the valuation of other alcohols than ethylic. By altering the conditions the reaction may be utilized to prepare strictly absolute ethyl alcohol. In a sample dried over quicklime, the proportion of water still remaining is determined as above; the necessary amount of metallic sodium or sodium ethoxide and an excess of a neutral fat are added to the bulk, the whole is heated for a short time under an inverted condenser, and the alcohol is distilled off on the water-bath, using diminished pressure towards the end of the operation.

Estimation of Glycerol in Fats.—In a vessel graduated at the 50 c.c. point, and provided with a stopper, 3 grammes of fat and 3 c.c. of 2N sodium ethoxide are well shaken together and heated to 70° C. for thirty minutes on the water-bath. After cooling for half an hour in the air, 25 c.c. of dry ether are added, the whole is agitated, and diluted with more ether to the mark. In three hours' time the sodium glyceroxide, completely thrown out of solution by the ether, has settled to the bottom, and the supernatant liquid is perfectly clear. Twenty-five c.c. thereof are pipetted off, diluted with 10 c.c. of alcohol, and titrated with decinormal hydrochloric acid and phenolphthalein, overlooking the brown tint due to the presence of oxy-acids. The residual 25 c.c. in the tube are next titrated similarly, except that 5 c.c. of semi-normal HCl should be run in at once. From the difference between the volumes of decinormal acid absorbed, the amount of glycerol may be calculated by using the factor 0·0092. If the same pipette is always used, the results should be 0·06 per cent. too low, no allowance being made for the volume of the precipitated glyceroxide. The chief difficulty met with in the process is to ascertain the end-point of titration owing to the brown colour of the liquid; possibly some other indicator would be better than phenolphthalein. Four tests of a whale-oil (acid number, 3·6, saponification number, 188·3) gave 9·69, 9·54, 9·57, and 9·5 per cent. of glycerol; the first result being recognised as about 0·1 per cent. too high, due to adherence of the solution to the pipette.

The author has not succeeded in determining the amount of glycerol in com-

mercial glycerin by this process. Addition of ether causes a precipitation of sodium oxide as well as of the glyceroxide; in this respect benzene is a better precipitant to employ. The water in glycerin is capable of estimation as above; but the practical difficulties of the method render it of little interest. It should be noted that sodium glyceroxide behaves like the ethoxide: it saponifies only in presence of water, and quite slowly, as it is somewhat insoluble in spirit. This fact is important, since such conditions may arise when fats are being hydrolysed in alcoholic liquids of great strength. F. H. L.

Detection of Bile-Pigments. Triollet. (*Bull. Sciences Pharmacologiques*, July, 1900; through *Chem. Zeit. Rep.*, 1900, 284.)—This process is a further modification of that recommended by Gurdin and modified by Jolles. Fifty c.c. of urine are treated with an excess (40 or 50 grammes) of ammonium sulphate, and filtered through cotton-wool, which retains all the precipitated pigments. The wool is extracted with hot chloroform, which dissolves bilirubin and bilifuscin; the solution is evaporated to dryness. The wool is next extracted with hot alcohol, which dissolves biliverdin and biliprasin; the solution is also evaporated. The two residues are taken up in boiling water, yielding a faintly-coloured solution free from blood, albumin, pus, and urea. The liquid is then cautiously floated on to nitric acid containing nitrous acid. At the junction of the liquids two coloured zones appear—one bright red, the other yellow. In ten minutes a green ring appears between the two former, and five minutes later a fine blue colour will be seen between the violet-red and the green. Afterwards the tints become violet-red, blue, green, yellow, and grow in intensity to a maximum in half an hour. After two hours there is a blue ring between two yellow ones, and in five hours only a uniform yellow tint is left.
F. H. L.

Valuation of Glue. A. Heinemann. (*Chem. Zeit.*, 1900, xxiv., 871.)—The author doubts whether the processes hitherto suggested for the examination of glue are of much industrial use. Determination of the viscosity of a solution of known strength may indicate the value of the material if it be required to manufacture "compositions," "hectograph surfaces," etc.; but it does not appear to throw any light on the real adhesive power of the glue. Similarly estimation of water, fat, and ash may be important; but there is no evidence that the binding power is in proportion to the amount to true gelatin in the sample. Heinemann suggests a process which depends on ascertaining the minimum strength of a solution that exhibits adhesive power. Strips of strong, smooth paper $4 \times 3{\cdot}5$ inches are cut up; one of these is brushed over with a (say) 1 per cent. solution of the glue to be examined for a length of 2·5 inches, another dry strip is laid over it, and the whole is pressed together under a 5-pound weight for exactly 1 minute, or if the atmosphere be very damp, for 1½ or 2 minutes. The papers are then lifted, and it is noticed whether the joint will carry a weight. At or about the "critical" degree of dilution, the joint

will either support a fairly heavy weight, even 30 pounds, or nothing at all. By simultaneous comparison with a solution prepared from a standard sample of glue, altering the strength of the experimental solution as may be necessary, results can be obtained which should indicate the adhesive power and therefore the commercial value of the glue. F. H. L.

[Presumably the second strip is laid on the first so as to overlap only for just over the 2½ inches of painted surface, thus leaving at either end a length of 1½ inches of single paper whereby to clip the test piece. F. H. L.]

On Certain Peculiarities in the Urine of Vegetarians. J. H. Long. (*Journ. Amer. Chem. Soc.*, vol. xxii. [9], pp. 592-595.)—In the experiments detailed the reducing power of the urine was apparently about 20 per cent. above the average, but the difference was mainly due to higher concentration, the average daily excretion (874 c.c.) being below the normal. The proportion of creatinin was unusually low, the uric-acid creatinin ratio being 1 : 1·2 instead of 1 : 2, and is probably attributable to low food-consumption and metabolism.

The distribution of the reducing power (total, 6·888 grammes of cupric oxide per 1,000 c.c. of urine) is interesting, 2·373 grammes being allocated, on the basis of previous experience, to uric acid and creatinin, leaving 4·515 grammes of cupric oxide as the amount corresponding to the carbohydrates or similar bodies present. Hence it is considered that a purely vegetable diet, wherein fats and carbohydrates predominate, favours the increase of non-nitrogenous (probably carbohydrate) substances in the urine. C. S.

A Limiting Standard of Acidity for Moorland Waters. W. Ackroyd. (*Chem. News*, vol. lxxxii., pp. 162, 163.)—Plumbism, due to the solvent action of moorland water on lead piping, does not, in the author's experience, occur when the acidity of the water is lower than the equivalent of 0·5 part of sulphuric acid per 100,000 of water, and he therefore proposes this limit should be adopted as a tentative standard of acidity for such waters when the same is estimated by $\frac{1}{100}$ normal alkali in presence of phenolphthalein as indicator. It is stated that the range of acidity in nine samples of water, not above suspicion in respect of causing plumbism, was 0·53 to 0·91 (average 0·63), whilst in sixty-one samples from places where plumbism is unknown the acidity ranges from 0·20 to 0·41, the average being 0·27. C. S.

INORGANIC ANALYSIS.

Influence of Silica upon Silver Assay. L. Strauss. (*Proc. Amer. Inst. Mining Eng., Canadian Meeting*, 1900; through *Chem. Zeit. Rep.*, 1900, 275.)—When silver is assayed in presence of silica, some of the metal passes into the slag, causing loss; and experiments have shown that addition of ferrous sulphide to the

mixture renders the loss almost constant. In order to ascertain the precise action of the silica, Strauss has assayed various mixtures of silver (0·99 fine) and lead with pure ores, such as pyrites, zinc blende, lead glance, etc., sulphur and silica at temperatures of 900° to 1,000° C., keeping the amount of lead and silver so far as possible the same. From his results the author concludes that the effect of the sulphides is not uniform, but depends on the nature of the ore to an extent which demands further investigation. Nevertheless, in assaying pure silver and lead, increasing the proportion of silica increases the loss of silver. In presence of ferrous sulphide large quantities of silica carry silver into the slags; but if only a little silica is present, the iron sulphide reduces the loss. It is therefore impossible to insure obtaining the same yield of silver from different ore mixtures, even if the amount of metal in the assay is actually the same. F. H. L.

Estimation of Gold and Silver in Pyrites. W. Buddëus. (*Chem. Zeit.*, 1900, xxiv., 922.)—The ore is reduced till it will pass through a sieve of 300 or 400 meshes per square centimetre—extreme fineness is not essential—and 100 grammes are taken for analysis. If, however, it contains less than 50 grammes of gold per 1,000 kilos., 200 grammes should be employed, all the following figures being then doubled correspondingly. It is placed in a 70 c.c. biscuit crucible, lightly covered, and put into a bright red-hot muffle for thirty or forty-five minutes until the sulphur flame disappears. The crucible is then cooled, and the coherent mass is thrown out into a beaker or basin, wiping the crucible with a brush. Without breaking up the lump, it is covered with 250 c.c. of 1 : 1 hydrochloric acid, free from arsenic. After standing one hour in a warm place, a second 250 c.c. of acid are added, and the whole is boiled. The liquid is diluted to 1 litre, allowed to settle, filtered, and the precipitate, which contains all the gold, silver, silica, and alumina of the ore, is washed two or three times with water. The paper and contents are dried, introduced into a 150 c.c. Hessian crucible with 50 grammes of lead and 5 grammes of borax, and well mixed. If preferred, 50 grammes each of lead acetate and dry sodium carbonate may be used instead of the metallic lead. The whole is melted; the button is taken out, cupelled, and finally parted in the ordinary way. The preliminary removal of the iron sulphide prevents loss of gold and silver in the large mass of slag otherwise obtained, while it avoids the very high temperatures needed to convert the sulphide into a silicate, which tends to cause volatilization. For these and other apparent reasons the process is much cheaper to work; it gives considerably higher figures than the usual method—figures which agree much better among themselves, and it is therefore more accurate and trustworthy. F. H. L.

Estimation of Mercury in Urine. J. Malkes. (*Chem. Zeit.*, 1900, xxiv., 816.)—This process, devised by Stukawenkow, has been in use in Russia for several years, but appears to have been overlooked elsewhere. It depends on the precipitation of the mercury with albumin and the final production of mercuric iodide. Five hundred c.c. of urine in a 1-litre flask are mixed with 5 c.c. of egg albumin and

15 or 20 drops of acetic acid, then placed on a water-bath and heated for fifteen to twenty minutes. The whole is poured into a beaker, and allowed to settle for twenty minutes; the clear liquid is run away, and the deposit collected on a filter. The paper and its contents are laid on a porous tile for a few minutes. The precipitate is then removed from the paper, brought into a small cylinder, and covered with 50 c.c. of strong hydrochloric acid, a spiral of copper wire being immersed in the liquid. In about fourteen or sixteen hours all the mercury has amalgamated with the copper, and the acid has become dark in colour. The wire is washed with water, alcohol and ether, and dried between filter-paper. It is next dropped into a tube 5 millimetres in diameter with a crystal of iodine, and heated cautiously till the mercuric iodide forms a red sublimate on the walls of the tube. The amount of mercury in the original urine is estimated by comparing the size of this ring with that yielded by a urine to which a certain quantity of mercuric chloride has been added, it being convenient to prepare a series of such tubes to act as standards. The method is very exact, especially when only small amounts of mercury are present.

F. H. L.

Estimation of Tungsten in Ores. F. Bullnheimer. (*Chem. Zeit.*, 1900, xxiv., 870.)—Although the determination of tungsten in high grade or purified ores presents no particular difficulty, the presence of inferior material, and especially of phosphorus and arsenic compounds, complicates the process. One or two grammes of the finely-powdered mineral are best mixed with 4 grammes of sodium peroxide and 3 grammes of sodium hydroxide in a nickel crucible, and heated over a small flame till the mass softens. The temperature is then raised till the bottom of the crucible begins to glow and the mixture is thoroughly fluid, stirring continuously. After the melt has solidified, but while it is still hot, crucible and contents are thrown into water. If manganese causes the liquid to be green, it is decolorized with hydrogen peroxide, then cooled, diluted to 250 c.c. and filtered. To half the filtrate 20 grammes of ammonium nitrate are added, and after the tin and silica have settled, a sufficient quantity of magnesium nitrate solution is run in gradually and with agitation. After 6 or 12 hours the precipitate is filtered off and washed with ammonia and water; the filtrate is rendered slightly acid with nitric acid, cooled if necessary, and treated with 20 or 30 c.c. of a solution of mercurous nitrate (200 grammes warmed with 20 c.c. of strong nitric acid and some water, diluted to 1 litre and kept over mercury). After standing a few hours, ammonia is introduced till the liquid is only faintly acid, and the whole is allowed to rest until the supernatant solution is clear. The precipitate of mercurous tungstate is collected, washed with water containing mercurous nitrate, dried, and ignited first over a Bunsen and then over the blowpipe to constant weight in an uncovered crucible.

The sodium hydroxide in the fusion makes the melt more liquid and preserves the crucible. The nitrates of ammonium and magnesium must be employed, as their chlorides and sulphates would interfere with the mercurous reagent. It is very important not to add the magnesium nitrate till the ammonium nitrate has thrown down the tin and silica. If a considerable amount of molybdenum occurs in the sample, which is not often the case, much time is required to volatilize it completely

out of the final tungsten precipitate. The process may then be hastened by igniting shortly, adding ammonium chloride, and igniting again, first in the covered, afterwards in the uncovered crucible. F. H. L.

The Determination of Tungsten in Ores and Residues. H. Borntträger. (*Zeit. anal. Chem.*, 1900, xxxix., 361, 362.)—One gramme of the ore is fused with 10 grammes of sodium hydroxide for an hour, when the clear mass is extracted with hot water, the whole made up to 250 c.c., cooled and filtered. One hundred c.c. of the filtrate are added to a mixture of 15 c.c. of concentrated nitric acid, and 45 c.c. of concentrated hydrochloric acid, and evaporated to complete dryness in a porcelain dish. The residue is taken up with a solution containing 10 per cent. of ammonium chloride and 10 per cent. of concentrated hydrochloric acid, filtered, and the residue, which contains silica and tin oxide in addition to tungstic acid, dissolved in warm ammonium hydroxide, with which the filter is also washed. The solution is run into a mixture of 15 c.c. of nitric acid and 45 c.c. of hydrochloric acid, and the whole again evaporated to dryness. The tungstic acid, as thus obtained, is free from silica and tin oxide.

In the analysis of metallic tungsten, which also contains oxygen, carbon, antimony, iron, and silica, a preliminary ignition for thirty minutes is necessary, and in the fusion an addition of a little nitre to the sodium hydroxide is advisable.

Metallic tungsten, as met with in commerce, usually contains from 95 to 97·5 per cent. of tungsten.

The method of precipitation with mercuric nitrate is stated to give very uncertain results, owing to the readiness with which the finely divided mercuric tungstate passes through the filter. The method described above is now used in all the larger metallurgical works in Germany. C. A. M.

A Method for the Rapid Estimation of Lime. W. H. Hess. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 477.)—The lime is precipitated and separated as oxalate in the usual way. The filter-paper is burnt. Then the lime in the crucible is mixed with an equal bulk of ammonium nitrate and about twice as much ammonium sulphate. The crucible is then covered with a lid, and ignited cautiously until no more fumes are observed. Intense ignition is unnecessary, and is to be avoided. The lime is thus converted into sulphate, and is weighed as such. The results quoted are all 0·1 per cent. too low. A. M.

The Examination of Commercial Thorium Nitrate and Incandescence Mantles. W. Muthmann and E. Bauer. (*Berichte*, xxxiii., 2028-2031.)—It is well known that the thorium preparations obtained from monazite sand show enormous variations in their capacity for emitting light, so much so that the German factories have their mantles officially tested at Charlottenburg and Karlsruhe, and sell them with a guarantee as to their emission power.

This difference is altogether apart from the prejudicial influence of common impurities such as phosphoric acid, alkalies, and iron, chromium, and aluminium oxides.

The authors have examined different samples of commercial thorium nitrate by their cathode-luminescence method (*Berichte*, xxxiii., 1748 and 1760) and have found them to invariably contain impurities in the form of rare earths. In this method it was found best to convert the nitrates into anhydrous sulphates, and to subject these to the influence of cathode rays in an exhausted tube, the phosphorescent light emitted being decomposed by a prism, as used by Crookes. In all the preparations examined, the occurrence of lines of gadolinium and yttrium was proved, and it was established that the former greatly preponderated.

One sample of commercial nitrate (840 grammes) was dissolved in 5 litres of water and fractionally precipitated by means of a solution of potassium chromate, steam being introduced under a pressure of three atmospheres during the precipitation (ANALYST, xxv., 130).

The first six fractions consisted of thorium chromate yielding a pure white oxide (320 grammes). On further fractionation, a slight quantity of a dirty olive-green chromate was precipitated, and the residual solution, from which nothing more was precipitated by potassium chromate, yielded on the addition of potassium hydroxide precipitates of the hydroxides of gadolinium and yttrium. These gave about 0·5 gramme of the oxides, which, fromt heir luminescence spectrum, were found to consist mainly of Gd_2O_3. The mixed oxides from the olive-green chromate, which was the last chromium precipitate obtained, were found by spectrum analysis to consist principally of neodymium and praseodymium oxides.

Hence the authors concluded that the total amount of these impurities was at least 0·3 per cent.

The pure thorium nitrate thus obtained was mixed with the requisite amount of cerium ammonium nitrate, and photometric tests made with mantles prepared from the mixture. It was found that the addition of the above impurities has a marked injurious influence on the emission-capacity of the mantle, but that the ordinary impurities in the cerium oxide (neodymium and lanthanum salts, etc.) compose such a trifling proportion of the total earths in the mantle that they appear unlikely to have any appreciable effect upon the light. C. A. M.

The Estimation of Cerium in Cerous Salts. G. v. Knorre. (*Berichte*, 1900, xxxiii., 1924-1929.)—In order to use the author's volumetric method (ANALYST, xxiii., 191) with cerous salts it is necessary to convert these quantitatively into ceric salts. This may be readily effected by adding sulphuric acid to the solution, then ammonium persulphate in excess, and heating the liquid to the boiling-point. Even a very dilute solution becomes yellow in a few minutes when thus treated, so that the reaction appears to afford a sensitive test for cerium. An essential condition is that the sulphuric acid must not be added in too great an excess, since otherwise the hydrogen peroxide liberated would reduce ceric salts when formed.

The quantitative oxidation is carried out as follows: The solution of the cerous salt is acidified with the smallest possible quantity of sulphuric acid, and, after the addition of ammonium persulphate, boiled for one or two minutes. The beaker is cooled in water at about 40° to 60° C., a second portion of persulphate introduced,

and the liquid again heated to the boiling-point. After one more cooling, a third portion of persulphate is added, and the liquid now boiled for ten to fifteen minutes, after which it is advisable to add some more sulphuric acid to destroy the excess of persulphate as far as possible. From 0·2 to 0·3 gramme of cerium require for oxidation about 3 grammes of ammonium persulphate. This is dissolved in water, and about half added for the first boiling, and one-fourth for the second and third boilings.

When the oxidized solution is perfectly cold, the cerium is titrated with standardized hydrogen peroxide until colourless, and the excess of the latter titrated back with standard permanganate. C. A. M.

The Determination of Potassium in Potassium Salts. H. Neubauer. (*Zeit. anal. Chem.*, 1900, xxix., 481-502.)—For the estimation of potassium in various mixtures of sulphates and chlorides of potassium, sodium, calcium and magnesium, which are commonly known as "potash salts," the author recommends the following method, each stage of which is elucidated by experiments described in detail in the paper:

Twenty-five c.c. (=0·5 gramme of substance) of an aqueous solution of the salts are evaporated together with a few drops of hydrochloric acid and sufficient platinum chloride to leave a slight excess after the formation of the double chloride.

The evaporation is continued to dryness, but the heating must not be continued longer than is necessary.

After cooling the mass is moistened with about 1 c.c. of water, and carefully rubbed with the end of a flattened glass rod. It is next treated with at least 30 c.c. of commercial alcohol (93 to 96 per cent.) in successive portions of 10 c.c., and thoroughly rubbed with the glass rod after each addition. If much sodium or magnesium sulphate be present, the salt is first soft and pasty, but eventually becomes hard and crystalline.

The basin is now covered and allowed to stand for thirty minutes, the precipitate receiving an occasional rub during the time. It is then filtered into a Gooch crucible containing asbestos, after being washed with alcohol in the dish, as far as possible. On the filter it is washed with ether, and the latter removed by drawing a current of air through the filter.

The crucible is next gently heated while a current of hydrogen or coal-gas is introduced through a hole in the lid. The flame must be very small at first, in order to prevent decrepitation of the crystals. After five minutes it may be slightly increased, so that the bottom of the crucible is at a dull red heat in the middle. The reduction is continued for twenty minutes. The contents of the crucible are first moistened with cold water, and then washed with hot water, with the aid of the filter-pump, about fifteen times, and then with dilute nitric acid (5 per cent.) for about thirty minutes without the use of the pump, the acid in the crucible being added to as required. Finally, the acid is drawn off and the residual platinum washed with hot water, ignited and weighed.

The weight multiplied by 0·48108 gives the corresponding amount of potassium

oxide (K_2O). It is advisable to repeat the washing with nitric acid to insure the complete removal of the salts.

As there is a chance of error through the asbestos losing in weight during the washings, the author states that he has made successful experiments in the direction of using spongy platinum instead of asbestos in the Gooch crucible. C. A. M.

Diphenylcarbazide as a Reagent for Certain Metallic Compounds. A. Caseneuve. (*Journ. Pharm. Chim.*, 1900, xii., 150-156.)—The formation of the diphenylcarbazones of copper and mercury can be utilized for the detection of traces of those metals. Salts of silver, gold, and zinc (in concentrated solution) have also an action on the carbazide, but the faint rose colour produced cannot be confused with those of copper (violet) and mercury (blue). Certain oxidizing agents—*e.g.*, ferric salts and chromates—also produce characteristically coloured compounds.

Detection of Copper.—The diphenylcarbazide should be purified by crystallization from glacial acetic acid, and drying at 80° C. For the detection of copper in solutions containing 1 part or more in 1,000, a few drops of a recently prepared 1 per cent. alcoholic solution are added to the previously neutralized liquid, when an intense violet colour is immediately developed. In solutions of 1 : 10,000 or more, 5 c.c. of a cold solution of the reagent in benzene are shaken with 10 c.c. of the neutral solution under examination. Solutions of 1 : 100,000, which give no coloration with potassium ferrocyanide, show the author's reaction distinctly.

Detection of Mercury.—The test is made in the same way as for copper. A deep-blue tint, which is still visible in a dilution of 1 : 100,000, is obtained. It can be distinguished from the copper coloration by the fact that in a solution of a mercurial salt containing 1 : 10,000 it does not disappear on the addition of a drop of concentrated nitric acid.

Detection of Iron in Ferric Salts.—These give a red coloration with the benzene solution of the diphenylcarbazide, which is perceptible in solutions containing 1 : 100,000. On adding a drop of glacial acetic acid or of a 1 per cent. solution of potassium ferrocyanide the colour nearly disappears, the benzene only retaining a faint brown shade. The reaction is not so sensitive as those given by copper and mercury.

Detection of Chromates.—The solution of the chromate is rendered strongly acid with acetic or hydrochloric acid and a little powdered diphenylcarbazide introduced. An intense violet coloration is developed on shaking the liquid, and this reaction is sensitive for solutions containing only 1 part of bichromate in 1,000,000. The colour can be distinguished from that given by copper or iron by the fact that it is not extracted from its aqueous solution by benzene; moreover, iron and copper do not give a violet coloration in the presence of an excess of free hydrochloric acid. A chromate can thus be detected in the presence of a ferric salt. C. A. M.

The Use of Sodium Thiosulphate in Quantitative Analysis. F. Faktor (*Zeit. anal. Chem.*, 1900, xxxix., 345-354.)—The author has made numerous experiments on the behaviour of sodium thiosulphate with different metallic salts, with the

object of determining to what extent it could replace hydrogen sulphide in quantitative analysis.

Chromates.—On boiling together aqueous solution of potassium bichromate and sodium thiosulphate, a brown precipitate of hydrated chromic chromate is obtained, whilst part of the bichromate is converted into normal chromate. After continued boiling with thiosulphate in excess, the whole of the chromate is precipitated, and the precipitate can be ignited and weighed as chromic oxide.

Potassium chromate when treated in the same way does not yield a precipitate of chromic chromate, which, however, is obtained quantitatively on adding ammonium or magnesium chloride to the liquid before boiling. Sodium chloride, however, does not induce a precipitate.

Chromic salts are decomposed on continued boiling with sodium thiosulphate, yielding chromic hydroxide as in the equation:

$$Cr_2Cl_6 + 3Na_2S_2O_3 + 3H_2O = Cr_2O_6H_6 + 6NaCl + 3SO_2 + S_3.$$

As this method did not yield altogether satisfactory results, the precipitation was rendered more complete and rapid by adding to the solution of the chromic chloride a definite quantity of potassium chromate solution of known strength, together with some ammonium chloride, boiling, and deducting from the chromic oxide, obtained on igniting the precipitate, the amount due to the chromate added.

Lead Salts.—Good results are given by the following method: The hot solution of lead nitrate is mixed with ammonium chloride, and the resulting precipitate of lead chloride allowed to dissolve in the hot liquid. On now adding a hot concentrated solution of sodium thiosulphate, the lead is precipitated quantitatively as sulphide.

Mercuric Salts.—On treating a hot solution of mercuric chloride with sodium thiosulphate, the mercury is quantitatively precipitated as sulphide, and the precipitation is much more rapid than with hydrogen sulphide.

Silver Salts.—These react at the ordinary temperature with sodium thiosulphate, yielding a white precipitate ($Ag_2S_2O_3$), which on warming becomes yellow and finally black (Ag_2S). The tabulated results given by the author show that the method is suitable for the quantitative estimation of silver.

Nickel and Cobalt Salts.—Nickel salts give a black precipitate of nickel sulphide on being boiled with sodium thiosulphate, but too slowly and incompletely for a quantitative estimation, even after the addition of ammonium chloride. The same difficulty was experienced in the case of cobalt salts. C. A. M.

The Reduction of Nitrates by Lactic Acid. L. Vanino and O. Hauser. (*Zeit. anal. Chem.*, 1900, xxix., 506, 507.)—When bismuth nitrate is heated with lactic acid on the water-bath, it begins to decompose, and at a higher temperature (200° to 210° C.), metallic bismuth separates. In a quantitative experiment the authors obtained from 10 grammes of the salt about 4 grammes of black bismuth powder, or about 93 per cent. of the calculated quantity. Basic bismuth nitrate required a higher temperature for its reduction.

Mercuric nitrate is slowly decomposed above 100° C. with the deposition of mercury, and a similar reaction takes place in the case of mercurous nitrate, though more slowly.

Cadmium, silver, and lead nitrates all yield mirrors of their respective metals.

Cobalt nitrate heated with lactic acid at 360° to 370° C. yields a black magnetic powder, consisting of a mixture of carbon and metallic cobalt. The yield of the latter was 1·6 grammes as against 1·9 grammes calculated, and it constituted 52·6 per cent. of the powder. Nickel nitrate is similarly reduced. A strongly magnetic powder was obtained in the same way from ferric nitrate, but this was not proved to contain metallic iron.

With the chlorides and sulphates of these metals there was either no reduction or only a very slight one. C. A. M.

Estimation of Chlorides, Chlorates, and Perchlorates when mixed together. N. Blattner and J. Brasseur. (*Chem. Zeit.*, 1900, xxiv., 793.)—The author's process is based on the fact that sulphurous acid reduces chlorates to chlorides, but is without influence upon perchlorates. Twenty or 40 grammes of the sample are dissolved in 200 c.c. of water; in 50 c.c. of the solution the chlorine of the chlorides is determined by titration with silver. Another 50 c.c. are saturated with a current of pure sulphurous acid gas, or mixed with 50 c.c. of a saturated aqueous solution of the gas, then boiled gently, treated with precipitated chalk to destroy the free sulphuric acid, cooled, and titrated as before, giving the chlorine of the chlorides and chlorates together. The amount of perchlorate is deduced by carrying out the process already described by the authors (ANALYST, 1899, xxiv., 26). Examples are quoted showing that sulphurous acid has no effect upon perchlorates. The authors remark that they have analysed a large number of samples of "refined" Chili saltpetre, and have found between 0·15 and 1·0 per cent. of $KClO_4$, but they have never yet detected the presence of chlorates. F. H. L.

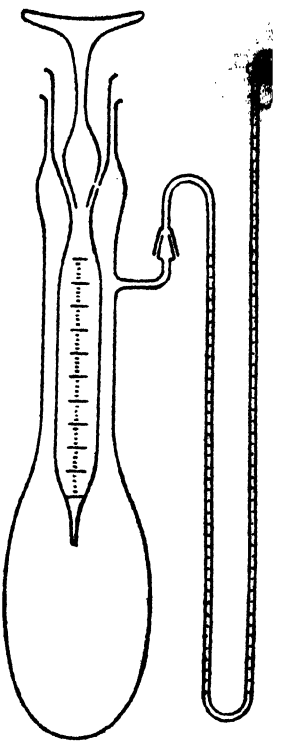
Erdmann's Reagent for Nitrites in Water. H. Mennicke. (*Zeits. angew. Chem.*, 1900, 711.)—This article describes further minute investigations into the value and delicacy of amido-naphthol-disulphonic acid as a test for nitrites, or as a means of estimating them in water. The results simply confirm the statements already made by Mennicke (this vol., p. 167) and by Erdmann (p. 81) as to the superiority of the new reagent over starch, Riegler's test, and all the various modifications of the Griess α-naphthylamine method. Erdmann now employs paramidobenzoic acid instead of the original aniline-*p*-sulphonic acid, a change which halves the time (now five minutes) required for diazotation, while, as before, the colour attains its maximum in one hour. Fluorescence is very much less noticeable than with any other of the tests; in fact, it can only be seen by examining the upper surface of the liquid with oblique light against a black background. In very extreme dilutions the red colour due to nitrites may be so faint as to be capable of confusion with the fluorescence colour; while by standing for a long time in an open tube the mixture of water and reagent may acquire a mauve or heliotrope tint. To eliminate the

former source of error, a stoppered tube charged with the reagent and doubly-distilled water (distilled over chalk and permanganate) should be kept for comparison; whereas the latter will be avoided by working always in closed tubes. With these precautions the utmost limit of delicacy becomes 1 part of $NaNO_2$ per 2,000,000,000. It is worth noticing that in sewage the Erdmann colour is more of a heliotrope than the wine or Bordeaux-red produced by pure solutions of a nitrite; but if a few drops of strong hydrochloric acid are added to the water the colour becomes normal. The colouring matter always remains in solution, and is therefore susceptible of measurement, even if the liquid contain as much as 0·025 gramme of $NaNO_2$ per litre. Various tables are given. F. H. L.

Simple and Accurate Method for estimating Dissolved Oxygen in Fresh Water, Sea Water, Sewage Effluents, etc. Letts and Blake. (*Chem. News*, vol. lxxxii., pp. 163, 164.)—The authors employ an ordinary separating funnel (332·5 c.c.), which is filled with the water under examination. Seven c.c. of the water are then drawn off and replaced by 5 c.c. of standard ferrous sulphate solution (48 grammes per litre), followed by 2 c.c. of strong ammonia. The stopper being inserted in the funnel, without introducing any air-bubbles, the contents are mixed by gentle agitation, and the resulting greenish-turbid mixture becomes darker in colour as the oxygen absorption progresses. After fifteen minutes the funnel is inverted and about 8 c.c. of dilute (50 per cent.) sulphuric acid are run in through the tube in order to dissolve the iron hydrates; the clear solution is then transferred to a porcelain dish and titrated with permanganate or bichromate (the latter giving better results with sea water and sewage effluent), preferably of such strength that 1 c.c. = 1 c.c. of dissolved oxygen at 0° C. and 760 mm. C. S.

The Quantitative Estimation of Ozone. O. Brunck. (*Berichte*, 1900, xxxiii., 1832-1842).—The method most commonly employed for the estimation of ozone consists in titrating the iodine liberated by the gas from a neutral or acid solution of potassium iodide. As many have failed to obtain reliable results by this method, the author has made experiments to determine the cause. He finds that when a neutral solution of potassium iodide is used, the quantities of ozone found are from 50 to 60 per cent. lower than with an acid solution.

By using an acid solution of potassium iodide the author states that reliable results are obtained, and that the only source of error is the decomposition of the hydriodic acid if the solution be concentrated; and this may be allowed for by a blank determination.



Either sulphuric or acetic acid may be used, but it is advisable to always employ the calculated quantity. In testing ozonizers, the most suitable method is to pass the current of gas through the acidified iodide solution for a given interval of time, or when frequent estimations are required, a proportional side current, as proposed by Rabe, may be employed.

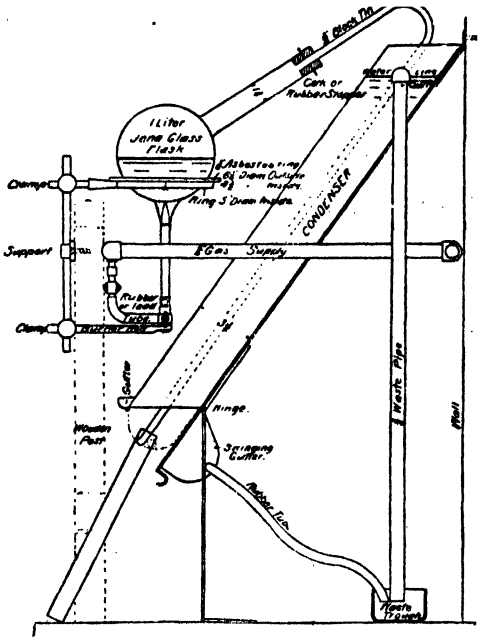
The most suitable strength in most cases for the iodide solution is one-fifth normal, and after the absorption an aliquot portion should be titrated with $\frac{1}{100}$ N. thiosulphate

solution. Nitrous acids are best removed by washing the gas with sulphuric acid, which, unlike the potassium hydroxide solution advocated by Cossa, does not attack the ozone. C. A. M.

APPARATUS.

An Apparatus for measuring Gas under Constant Volume. M. A. Job. (*Bull. Soc. Chim.*, 1900, xxiii., 288-291.)—The apparatus shown in the figure was devised with the object of measuring the increase of pressure in a closed vessel caused by the evolution of a gas in the course of a chemical reaction.

It consists of a glass vessel, the neck of which has a side tube attached to a mercury manometer of narrow gauge. A tube of special construction terminating in a graduated pipette is fitted into the neck of the flask, and this tube is closed by a stopper, which is in the form of a hollow key, with an opening in its side, which can be turned so as to coincide with a corresponding opening in the pipette. When the key is thus turned the liquid in the pipette runs out, being replaced by the air in the flask. The capacity of the apparatus is determined once for all by weighing it empty and filled with water.



In using the apparatus it should be immersed in a water-bath at the temperature of the room to insure that the initial and final temperatures are the same. The amount of the gas disengaged (reduced to 0° C. and 760 m.m.) is found by the formula $x = \frac{V}{760} \frac{h}{1+\alpha t}$, in which t is the temperature of the water-bath, h the excess of pressure measured, and the last part is to be found in gas-reduction tables. If the apparatus is constructed so as to hold 76 c.c., then $\frac{h}{1+\alpha t}$ expressed in millimetres will give x directly in cubic centimetres. The apparatus is recommended for the determination of carbonates, carbides, sulphides, ammonium salts, and urea.

C. A. M.

Platinum and Brass Electrodes for Analytical Purposes. H. Paweck. (*Chem. Zeit.*, 1900, xxiv., 855.)—This article consists partly of a claim for priority over Winkler in his advocacy of platinum gauze cathodes for electrolytic analysis (ANALYST, 1900, xxv., 55). Paweck, however, prefers a disc-shaped cathode made of wire 0·15 millimetre in diameter, 10 meshes per centimetre, about 30 square centimetres in total area, and with a 1·5 millimetre platinum wire fixed normally to it to serve as a handle and connecting piece. Such a cathode only weighs about 5·5 grammes,

and is therefore cheaper and more convenient than Winkler's gauze cylinder. As anode a perforated disc of platinum foil 6 centimetres in diameter may be employed.

Perfectly good results can be obtained in the deposition of copper, zinc, mercury, etc., by using a cathode of brass wire made exactly as above, a similar electrode constructed of platinum serving as anode. Ten grammes of copper may be deposited by working with a current of 1 to 1·5 ampères at 3 volts at a temperature of 30° C., allowing the action to proceed all night. Copper in white cast-iron can be conveniently determined by treating the original solution with sulphuretted hydrogen, dissolving the precipitate in a little nitric acid, diluting suitably, and electrolyzing with a current 0·2 ampère at 2·2 volts, electrodes 2 centimetres apart. F. H. L.

Apparatus for the Determiantion of Ammonia in Water and of Nitrogen by the Kjeldahl Method. R. S. Weston. (*Journ. Amer. Chem. Soc.*, 1900, xxii., 468.)—The apparatus is so arranged that the distilling-flask and the receiver can both be got at from in front. The condenser-tank is inclined so as to bring the lower end well forward, as shown in figure. Each distillation-flask is supported by a ring, which is clamped to a separate upright rod. A Bunsen burner is supported beneath each flask from the same rod. The upright rods are fixed to a horizontal support. At the bottom of the condenser-tank is a gutter to carry off moisture condensed from the atmosphere. There is also a swinging gutter to carry off the distillate whilst the apparatus is being boiled out ready for a determination. A. M.

An Asbestos Air Bath. O. Böttcher. (*Chem. Zeit.*, 1900, xxiv., 794.)—This piece of apparatus is suggested as a substitute for the water- or sand- bath used in evaporations; it is very simple and cheap, and is very economical in gas. It consists of a plate of asbestos 1·5 millimetre thick, its length and breadth being adjusted according to circumstances. Centrally on the plate is laid a ring of asbestos, 3 or 4 millimetres thick in its walls, 30 to 40 millimetres wide (*i.e.*, high), and of a diameter suitable to the flask or basin to be supported. The apparatus is heated with a Bunsen or an Argand burner, and if it be desirable to maintain the temperature of the bath at one particular point, a small hole may be punched in the ring, through which a thermometer is inserted.
